Adverse medical effects of anabolic-androgenic steroids have been well reviewed [46, 59]. Adverse medical effects may be short-term, relatively reversible, and limited to periods of use and acute withdrawal; or long-term, relatively irreversible, and persistent during periods of sustained abstinence. The short-term effects generate less disagreement among experts than do the

long-term effects, because good epidemiological studies of the latter are lacking. The major organ systems that are adversely affected by anabolic-androgenic steroids are endocrine, hepatic, and cardiovascular. Endocrine side effects result from having too high or too low concentrations of gonadotropins and sex steroids. In men, these effects include testicular atrophy, abnormal and reduced spermatogenesis, gynecomastia (due to metabolism via aromatization of some anabolic-androgenic steroids into estrogens), and premature male pattern baldness. Gynecomastia, particularly when painful, may require surgical correction. In women, these effects include clitoral hypertrophy, decreased breast size, hirsutism including abnormal facial hair (such as mustache and beard growth), menstrual irregularities, and deepened voice. Clitoral hypertrophy and deepened voice may be irreversible. If taken during pregnancy, anabolic-androgenic steroids can masculinize a female fetus. Hepatic effects include benign and malignant tumors, cholestatic jaundice, liver failure, and peliosis hepatis. Peliosis hepatic describes a condition characterized by blood-filled sacs or cysts in the liver that can be fatal upon rupture. Cardiovascular effects include hypertension, abnormal cholesterol levels, and cardiomyopathy as well as numerous case reports of myocardial infarction or stroke. Orally active C-17-alkylated anabolic-androgenic steroids are more toxic to the liver and cholesterol metabolism than injected anabolic-androgenic steroids including testosterone. Other adverse effects include acne, peripheral edema due to water retention, polycythemia, exacerbation of tic disorders, sleep disorders [100], and infections due to non-sterile injection practices. Taken by children, anabolic-androgenic steroids can cause premature closure of epiphyseal growth plates in long bones resulting in small stature.

Psychiatric Aspects and Effects

There is general consensus that anabolic-androgenic steroids are psychoactive drugs that can contribute to and cause psychiatric effects [4, 74, 80, 95, 97]. Many factors can influence the development of adverse psychiatric effects to drugs. Such factors include genetic vulnerability, social context, stress, personality characteristics, a past history of psychiatric problems, use of other substances, and expectancies. Case reports, retrospective studies, and psychiatric diagnostic studies of anabolic-androgenic steroids users provide some clues regarding the range of adverse psychiatric effects observed, however, it can be difficult to prove that anabolic-androgenic steroids, rather than co-existing factors (e.g., other drug use, predisposition, or environment) were responsible. Therefore, double-blind placebo-controlled trials that measure psychiatric effects of anabolic-androgenic steroids are more conclusive (see below).

The most frequently described adverse psychiatric effects of anabolic-androgenic steroids are extreme mood swings ranging from mania to depression, suicidal thoughts and behaviors, marked aggression including homicidal thoughts and behavior (“roid rage”), grandiose and paranoid delusions, and addiction [56, 74]. Mania or hypomania, violent aggression, and delusions typically begin during a course of anabolic-androgenic steroid use, whereas depressive episodes and suicide attempts are most likely to occur within three months of stopping anabolic-androgenic steroid use, i.e., during anabolic-androgenic steroid withdrawal [57]. Fortunately, most psychiatric effects such as mood swings are reversible with medically monitored cessation of anabolic-androgenic steroid use, but suicides and homicides are obviously irreversible.

The true rate of adverse psychiatric effects among anabolic-androgenic steroid users is unknown. Studies of illicit anabolic-androgenic steroid users typically include small numbers of subjects who may not be representative of all anabolic-androgenic steroid users; and the studies rely on self-report of past events which may not always be accurate [66, 70, 77]. One controlled study of 160 athletes reported that 23% of 88 anabolic-androgenic steroid users were diagnosed with major mood disorders (i.e., mania, hypomania, or depression) in association with

their anabolic-androgenic steroid use, including 11% diagnosed with major depression [77]. That study also suggested that psychiatric effects are dose-related: none of the anabolic-androgenic steroid users taking low doses had major depression whereas medium-dose and high-dose users had rates of 6 and 28%, respectively. Another study [57] found that rates of depression were higher during anabolic-androgenic steroid withdrawal than when actively taking anabolic-androgenic steroids (6.5% vs. 1.3%). That study also found that 3.9% of 77 illicit anabolic-androgenic steroid users had made suicide attempts during the withdrawal period [57]. Rates of completed suicides, however, are especially hard to estimate. In a series of 34 forensically evaluated deaths among male anabolic-androgenic steroid users, 11 users committed suicide, 9 were victims of homicide, 12 deaths were judged as accidental, and 2 were indeterminate [94].

Adverse psychiatric effects appear to be dose-related [68]. There are at least four double-blind, randomized placebo-controlled trials that employed relatively high doses of anabolic-androgenic steroids [78, 91, 98, 104]. Three of these studies indicate that some individuals will experience severe, adverse psychiatric effects after high doses of anabolic-androgenic steroids are administered [78, 91, 104], although one study found no evidence of psychiatric effects [98]. Averaging across studies, recent reviews have concluded that the incidence of prominent irritability or hypomania attributable to steroids during controlled trials is 5% [78, 82]. These gold standard studies, however, are likely to underestimate the incidence and severity of psychiatric effects, because ethical considerations limit the maximum doses of anabolic-androgenic steroids that can be administered to human subjects [78]. Illicit anabolic-androgenic steroid users typically consume 10–100 times the therapeutic doses prescribed legitimately by physicians to restore testosterone levels in patients who cannot make their own. By contrast, the maximum doses administered in the cited controlled trials were 5–6 times the therapeutic dose [78, 91, 98, 104].

Neurobiology

The following structures have been implicated in the psychoactive properties of anabolic-androgenic steroids: the midbrain [28, 41], nucleus accumbens [27], amygdala [20], hippocampus [29, 38, 54], and prefrontal cortex [28, 38]. Androgen receptors are prominent in the hippocampus, amygdala, and prefrontal cortex [39], structures involved in learning and/or aggression. Synaptic density in the hippocampus is androgen-dependent [54]. The size of the medial amygdala is also anabolic-androgenic steroid dependent [20].

Neurotransmitter systems altered by anabolic-androgenic steroids include gamma-aminobutyric acid [27, 33, 34], glutamate which correlated with aggressive behavior [25], dopamine [27, 51, 52, 83], opioids [41, 55, 71], norepinephrine [92], and serotonin [22, 53, 79, 92].

The mechanism of action of anabolic-androgenic steroids can vary depending on the availability (in different brain regions) of specific enzymes such as 5α-reductase or aromatase, and receptors such as androgen or estrogen. This is because many of the metabolites of testosterone are active [27, 29]. Thus, the actions of anabolic-androgenic steroids on the brain can be exceedingly complex.

Addiction

The term, addiction, is used here synonymously with substance dependence as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria. Abuse, which is conceptually defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition as either repeated use of a substance despite recurring adverse psychosocial consequences or as repeated use in hazardous situations, caused little debate among scientists when applied to anabolic-androgenic steroids. Accordingly, most articles on the topic include

the word *abuse* in their titles rather than *addiction* or *dependence*. Furthermore, the generally accepted abuse potential of anabolic-androgenic steroids led to their classification in 1991 by the Drug Enforcement Agency as Schedule III Controlled Substances. By contrast, addiction to anabolic-androgenic steroids has been historically controversial since it was originally proposed in a peer-reviewed journal [48], especially when anabolic-androgenic steroids are compared with traditional addictive drugs such as cocaine and opioids [24]. Some experts have been slow or reluctant to accept that the addiction-like aspects of long-term, heavy anabolic-androgenic steroid use could be dissociated from co-occurring compulsive behaviors such as repetitive, rigorous weight training activity [2]. Such activity might be reinforcing in itself, similar to "exercise dependence," or psychosocially (if not monetarily) rewarding in terms of winning competitions, or having athletic prowess or a fit-appearing body.

Animal studies have the advantage of eliminating the sociocultural influences of competitive athletics and bodybuilding. Although earlier animal studies failed to find self-administration of anabolic-androgenic steroids [26], it has now been shown that some animals will self-administer anabolic-androgenic steroids, particularly the anabolic-androgenic steroids that have relatively stronger androgenic than anabolic effects [102]. The evidence of addiction to anabolic-androgenic steroids from animal studies was a subject of comprehensive review [103]. One can hypothesize, therefore, that the anabolic effects of anabolic-androgenic steroids fuel their initial abuse by bodybuilders and athletes, whereas the androgenic properties endow anabolic-androgenic steroids with their psychoactive and reinforcing effects, including their potential for addiction.

When case reports and survey studies were reviewed in 2002, a total of at least 165 instances of anabolic-androgenic steroid dependence had been reported in the scientific literature among weightlifters and bodybuilders [10]. In 2005, 68 more instances were added [69] for a total of 233. Because all published reports of anabolic-androgenic steroid dependence involved convenience samples, the prevalence of anabolic-androgenic steroid dependence is not known. Across five studies involving a total of 426 anabolic-androgenic steroid users, rates of individual diagnostic criteria are listed in Table 2 [12, 21, 32, 64, 69]. Frequencies of withdrawal symptoms are shown in Table 3.

All reported instances of anabolic-androgenic steroid dependence have occurred in non-medical or illicit users who took anabolic-androgenic steroids for weightlifting and bodybuilding. Importantly, no cases of anabolic-androgenic steroid dependence have been reported in patients legitimately taking medically prescribed anabolic-androgenic steroids for clinical indications, which is primarily an issue of dose. Medical indications only require doses to restore normal physiologic function, whereas use for athletic performance or aesthetic appearance require supraphysiological doses of anabolic-androgenic steroids. In contrast to prescription opioid dependence, therefore, the development of addiction to anabolic-androgenic steroids does not appear to start with therapeutic doses that escalate over time as addiction emerges. Rather, dependence on anabolic-androgenic steroids seems to require deliberate self-administration of supratherapeutic doses from the beginning. The lack of anabolic-androgenic steroid dependence in individuals taking them for legitimate medical purposes has led to the erroneous conclusion that dependence does not develop without compulsive weightlifting activity, but this conclusion is confounded by the correlation between weightlifting and supratherapeutic doses.

Screening and Assessment

History

There is no one best way to screen or assess individuals for the use and consequences of consuming anabolic-androgenic steroids for

Table 2 Numbers of individuals meeting *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria for substance dependence

Study	Brower et al. [12]		Gridley and Hanrahan [32]		Midgley et al. [64]		Copeland et al. [21]		Perry et al. [69]		Total

non-medical purposes. What follows are sample questions that illustrate important areas to be covered.

Screening: Do you train or work out? How many times weekly? How many hours do you train on the days you do? How long have you been working out seriously? Do you train at a gym? Do you spend time there when not working out? Have you ever used substances such as nutritional supplements to increase your strength, body size, or athletic performance? Do you have any friends who use anabolic-androgenic steroids? Have you ever considered using them? Have you ever used anabolic steroids? If yes, what were you hoping to accomplish by taking them? If no, do you think you will take them in the future?

Assessment: Give me a list of all of the anabolic-androgenic steroids you have taken, which ones you take now, how much, how often, and for how long. Please indicate which anabolic-androgenic steroids you take by mouth and by injection. Do you cycle on and off? How long are your cycles? How much recovery time do you give yourself between cycles? What do you consider the benefits of using anabolic-androgenic steroids? Is there anything about using them that you do not like? Have they ever made you sick? "Messed" with your moods? Scared your friends or family? (If used by injection), have you ever shared needles with other users? What other drugs, if any, do you take to increase the effects of anabolic-androgenic steroids? To treat or prevent side effects, such as enlarged breast tissue? For fun or to get high? Do you use drugs to prevent detection by drug tests for anabolic-androgenic steroids? Where do you get your anabolic-androgenic steroids? Someone you know who sells them? (You don't need to tell me who it is.) A physician? The Internet? Travel to other countries?

Physical

Vital signs—hypertension. *Appearance*—muscle hypertrophy that is disproportionately larger in the upper torso than lower torso. *Skin*—acne, needle marks in large muscle

groups, especially the gluteals, male pattern baldness or alopecia in men and abnormal facial hair in women, jaundice if severe liver disease. *Eyes*—jaundice if severe liver disease. *Chest*—gynecomastia and tender breasts in men or decreased breast size in women. *Abdomen*—right upper quadrant tenderness, enlarged liver if diseased. *Urogenital system*—prostatic hypertrophy and testicular atrophy in men and clitoral hypertrophy in women. *Extremities*—edema/water retention.

Mental Status

Large clothes may be worn to hide physical build if there is a body image disorder. Deepened voice and other masculine features may be observed in women. In terms of psychomotor behavior, speech, mood and affect, thought content, thought processes, and perception, the mental status exam can be consistent with depression, hypomania, or mania, with or without psychotic features. Suicidal and/or homicidal ideation must be assessed due to well-documented increases in aggression and impulsivity. Paranoid ideation or delusions with or without hallucinations are also important to assess.

Labs

The most common laboratory test to detect the use of anabolic-androgenic steroids is an analysis of urine [81]. Although most clinical laboratories do not do these tests because they are specialized and expensive (most will eventually involve mass spectrometry/gas chromatography), clinicians should not hesitate to ask their local labs to send samples to where they can be analyzed. While waiting for the results, some common blood tests can be ordered as reviewed below.

Muscle enzymes can be elevated because of intensive weight training and intramuscular injections. Because alanine transaminase and aspartate transaminase overlap with liver enzymes, creatinine phosphokinase should also be ordered. Cases of rhabdomyolysis have been reported.

Liver enzymes can be elevated because many of the oral anabolic-androgenic steroids, especially the 17-alpha-alkylated ones, are metabolized there and can be toxic to the liver. Because alanine transaminase and aspartate transaminase overlap with muscle enzymes, bilirubin should also be ordered. Needle sharing, while not as common as among heroin addicts, can also infect the liver with hepatitis B or C.

A complete blood count may reveal elevations in hemoglobin, hematocrit, or red blood cell count, because anabolic-androgenic steroids can stimulate erythropoesis.

The hormones, luteinizing hormone and follicle-stimulating hormone, can be expected to be decreased, due to negative feedback of anabolic-androgenic steroids on the hypothalamus and pituitary gland. Testosterone and estradiol will be elevated with use of testosterone esters, but endogenous output of these hormones will be minimal.

A cholesterol profile will likely show elevated low-density lipoprotein cholesterol and decreased high-density lipoprotein cholesterol. Because this profile is generally associated with cardiac disease, it is important to bring it to the attention of the user. An electrocardiogram and echocardiogram may reveal cardiac disease more directly if present. Left ventricular hypertrophy is typical in anabolic-androgenic steroid users and sometimes other weightlifters, but diastolic dysfunction is more likely in anabolic-androgenic steroid users, and may also extend to the right ventricle [49].

A sperm analysis is not required but it will likely reveal either a decreased or zero sperm count, abnormal morphology, and reduced motility.

Treatment

Anabolic-androgenic steroid users are not commonly seen in addiction treatment settings, unless they are also dependent or abusing other substances like alcohol, opioids, or stimulants

[18]. They may present for psychiatric symptoms, but are most likely to be seen in primary care clinics or sports medicine clinics. It must be emphasized that no controlled studies of treating anabolic-androgenic steroid-related disorders exist [9, 74]. In the absence of a higher-level evidence base, the best we can do is borrow strategies shown to be effective for treating other substance-related disorders, while at the same time both respecting and targeting some unique features found among anabolic-androgenic steroid users. As with dependence on other substances, the goals of treatment are abstinence from all addictive drugs, restoration of physical and mental health, and improved coping and psychosocial functioning. Whether maintenance with testosterone agonist therapy is a reasonable goal will be discussed below. The remaining part of this section will be organized by specific anabolic-androgenic steroid-related disorders.

Anabolic-Androgenic Steroid Abuse

Anabolic-androgenic steroid abuse is defined as recurrent use that either causes adverse consequences or occurs in situations that are physically hazardous. It could be argued that elite athletes frequently compete in physically hazardous situations, making it rather easy to fulfill the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria for abuse. Usually treatment is aimed first at motivating anabolic-androgenic steroid users to stop their use via motivational interviewing and involvement of their social support network. The nature and severity of the adverse consequences require discussion in the context of the potential benefits of anabolic-androgenic steroids that users perceive for themselves.

Anabolic-Androgenic Steroid Withdrawal

Anabolic-androgenic steroid withdrawal does not ordinarily require medical detoxification. Anabolic-androgenic steroid users whose pattern of use included cycling and pyramid dosing, already know how to taper themselves from anabolic-androgenic steroids and should be encouraged to do so. Those who are motivated to stop using but have difficulty doing it will likely have the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition-defined dependence in addition to physiological withdrawal; and such users may benefit from medical detoxification. There are neither controlled studies nor agreement about how to do it. Suggested techniques include testosterone substitution therapy followed by a taper at a rate that is tolerable and safe [8]. Prior to such treatment, blood work for follicle-stimulating hormone, luteinizing hormone, testosterone, and estrogen should be obtained. There are several cases described of persisting human pituitary gonadotropin abnormalities weeks to months after tapering. Persisting human pituitary gonadotropin abnormalities may manifest clinically as sterility or depression, the latter of which should be treated as an anabolic-androgenic steroid-induced mood disorder (see below). Whether these cases may possibly benefit from long-term testosterone supplementation, analogous to agonist therapy for opioid dependence, is unknown and regarded as experimental. In addition, testosterone supplementation would not correct sterility. Instead, medications that stimulate the human pituitary gonadotropin axis such as human chorionic gonadotropin [63], luteinizing hormone, gonadotropin-releasing hormone [99], and estrogen blockers [85, 93] may be required. These latter hormones are also used illicitly [89]. Anabolic-androgenic steroid withdrawal shares characteristics with other endocrine withdrawal syndromes [36].

Anabolic-Androgenic Steroid Dependence

Treatment of anabolic-androgenic steroid dependence is subject to the same challenges as addiction therapy in general. Users often fail to appreciate the adverse consequences of their

use and/or overvalue the perceived benefits of their use. Thus, they lack motivation to stop using. Motivational interviewing and motivational enhancement therapy may be indicated for these cases. For individuals whose dependence is associated with intolerable withdrawal symptoms that lead to relapse, agonist therapy with testosterone may be considered with an endocrine consult. Agonist therapy has the advantages of replacing illicit drugs of unknown contents with pharmaceutical-grade medication that is injected by a nurse or doctor every 2–4 weeks during an office visit. Unfortunately, there are no controlled trials of any of these approaches.

In approaching the psychological aspects of treatment, several differences from other drugs of abuse are important to consider. One difference between anabolic-androgenic steroid-dependent individuals and many other addicts is that getting high is not the predominant goal of using anabolic-androgenic steroids (even though anabolic-androgenic steroid users may have used other substances to get high). Instead, the goals of using anabolic-androgenic steroids are very culturally congruent with American values: to be bigger, better, competitive, and a winner. Reaching such goals requires hard work, discipline, and delayed gratification whether or not one uses anabolic-androgenic steroids. Accordingly, anabolic-androgenic steroids are used to align with, not escape from, mainstream societal values.

Another difference is that anabolic-androgenic steroid users are more likely than other individuals with substance use disorders to be preoccupied with their bodies and physical attributes as a source of identity and self-esteem. Their goals, daily activities, and ways of coping with interpersonal conflicts will likely reflect their being a physical presence in the world. This is not to minimize anyone's intellectual abilities. Rather, it is to highlight that a reliance (or over-reliance) on physical attributes, and anything which interferes with that, may be expected to emerge as a therapeutic issue. The livelihood and self-esteem of professional athletes, bodybuilders, male models, etc., depend on it. While this is a crucial difference, it has some similarity to what is expected of other addicted individuals—that they let go of a substance and sometimes a lifestyle on which they have come to depend and value highly.

Physical attributes can refer to appearance or athleticism. For individuals focused on appearance, Pope et al. [76] and others [14, 35] have drawn deserved attention to the underlying body image distortion that can drive anabolic-androgenic steroid use. The struggle to get bigger, no matter how big one already is, has been referred to as "reverse anorexia nervosa". Later, the term, "body dysmorphic disorder", was coined by Pope and colleagues [76] and is a preferred descriptive, because distorted body image, not disordered eating, is at the core of the disorder (even though anabolic-androgenic steroid use has been linked to disordered eating [73]). While using anabolic-androgenic steroids for their myoactive effects is a crucial difference between anabolic-androgenic steroid users and other substance users, it bears a resemblance to addicted individuals who use substances to overcome and self-medicate social anxiety, depression, and chronic pain as a step toward functioning better, not worse, in our society. As with other individuals, the original goals are important to understand and manage in other ways, but this only works well when the addiction itself is treated.

Anabolic-Androgenic Steroid-Induced Mood Disorder

Anabolic-androgenic steroid-induced mood disorder may resemble mania during episodes of use and depression during episodes of withdrawal. The cycling of mood states can resemble bipolar disorder, and parallel the cycling on and off the anabolic-androgenic steroids. Acute mania is best treated with antipsychotic medication, but mood stabilizers are not necessary when individuals are willing to stop using anabolic-androgenic steroids unless an

independent mood disorder with bipolar features co-occurs. Whether a mood stabilizer would normalize bipolar-like symptoms for those who resist stopping anabolic-androgenic steroids is not known.

For individuals diagnosed with major depression who have no history of manic or hypomanic episodes (whether or not anabolic-androgenic steroid induced), antidepressant medication is indicated. For depressed individuals with a history of manic or hypomanic episodes that were only anabolic-androgenic steroid induced, then antidepressant therapy should be initiated cautiously and monitored closely. Whether anabolic-androgenic steroid-induced mania or hypomania predicts antidepressant-induced mania or hypomania is unknown. There is anecdotal case-report data that anabolic-androgenic steroid-induced depression can be treated successfully with selective serotonin reuptake inhibitors [58]. For individuals who do not respond to an adequate trial with selective serotonin reuptake inhibitors and who also have below-normal testosterone levels in the morning, consideration may be given to augmentation with testosterone gel [75]. Another approach involves short-term use of human growth hormone [31]. Suicides have been reported in anabolic-androgenic steroid users especially during withdrawal [72], and safety must be prioritized, including hospitalization when needed.

While medication can address the biological aspects of depression, anabolic-androgenic steroid users may also feel depressed in response to losing momentum with their training activities. Individuals cannot be expected to achieve or maintain the peak physical progress they made on anabolic-androgenic steroids with training and diet alone. Thus, they may feel smaller and weaker from losing muscle size and strength, which can contribute to depression. Individuals may need guidance in setting realistic expectations for themselves and in balancing their lives with other enjoyable activities that do not depend on muscle size and strength. This may entail a similar kind of lifestyle change that other individuals with addiction need to make in order to stay clean and sober. Alternative social supports and sources of gratification is a common theme in addiction treatment. In addition to selective serotonin reuptake inhibitors, cognitive behavioral therapy that challenges body image distortions may also help to alleviate depression in individuals with muscle dysphoria.

Anabolic-Androgenic Steroid-Induced Psychotic Disorders

Anabolic-androgenic steroid-induced psychotic disorder may require hospitalization for safety reasons and to insure abstinence. Treatment includes cessation of anabolic-androgenic steroid use and the temporary use of antipsychotic medication. With proper treatment, psychosis can be expected to remit within a few weeks.

Conclusions

Anabolic-androgenic steroids, which consist of testosterone, selected metabolites, and synthetic derivatives with cholesterol-like chemical structures, have both anabolic (muscle-building) and androgenic (masculizing) properties and legitimate medical uses. Their use is endemic among some groups of bodybuilders and male athletes, who take supratherapeutic doses (10–100 times therapeutic doses) primarily for their anabolic effects. By 1990, an estimated 1 million Americans had tried anabolic-androgenic steroids. Non-medical or illicit use is characterized by combining (“stacking”) multiple forms, including oral and intramuscularly injected preparations, as well as taking various other substances to augment their effects, ameliorate side effects, or escape detections. Use may occur in cycles, with drug-free intervals between cycles. A variety of adverse medical consequences are known, involving the endocrine, cardiovascular, hepatic, and central nervous systems. Psychiatric

effects result from the neurobiological actions of anabolic-androgenic steroids and include mood disorders, psychotic disorders, aggressive and impulsive behaviors with suicide and homicide as extreme outcomes, and addiction. Addiction treatment should account for both similarities and differences in taking anabolic-androgenic steroids when compared with classical addictive drugs such as stimulants, opioids, and alcohol, but controlled trials are lacking to guide clinical practice.

Caffeine

Jack E. James

Contents

Introduction

Of the numerous psychoactive compounds that humans ingest, none is more popular than caffeine. Indeed, caffeine is unusual amongst psychoactive compounds in being part of the daily diet of most people. With more than 80% of people worldwide consuming caffeine daily [95], current usage transcends almost every social barrier, including age, gender, geography, and culture. The popularity of caffeine exceeds that of any other psychoactive substance, whether it is nicotine, alcohol, or illicit drugs. Caffeine occurs naturally in a number of plant species, where it serves as a toxin to defend against herbivores. A common but erroneous belief, sometimes implied in advertisements for caffeine products, is that caffeine has always been widely present in the human diet. In fact, it was not until after European colonization in the seventeenth and eighteenth centuries that caffeine

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_26,

products, previously unavailable to most people, became widely accessible. That is, the ubiquitous presence of caffeine in the human diet is a phenomenon of fairly recent origin.

The aim of this chapter is to provide an overview of caffeine and its use, with particular attention being given to consequences for health and well-being. In that context, the emphasis throughout is on dietary use, taking account of both acute and chronic effects. Following relevant background, including mention of the main sources of caffeine and prevailing patterns of usage, attention is given to the pharmacology of caffeine, including the main mechanism of action and the key processes of physical dependence and tolerance. This is followed by a discussion of the psychopharmacology of caffeine, with particular attention being given to effects on psychomotor performance and mood, and the processes of withdrawal and withdrawal reversal. The remainder of the chapter deals mostly with the health consequences of dietary caffeine, beginning with mental health and well-being. That section is followed by two separate sections dealing with physical health, the first of which is concerned with cardiovascular disease, and the second with cancer, maternal use, and potential adverse interactions between caffeine and other drugs. Questions as to whether caffeine is addictive and whether there is a level of consumption that may be considered safe are examined, and processes for reducing and quitting caffeine consumption are reviewed. In the section thereafter, attention is given to emerging interests in potential health benefits of caffeine products, especially in relation to Type 2 diabetes mellitus and Parkinson's disease, and the growing interest in compounds other than caffeine in caffeine beverages. The section preceding the conclusions considers processes that threaten the integrity of caffeine science, a topic that to date has received far too little attention.

Main Sources of Caffeine and Patterns of Consumption

The main dietary sources of caffeine are tea and coffee beverages, and increasingly, soft drinks (e.g., colas) and energy drinks. The tea plant is indigenous to regions of China, South Asia, and India. Written accounts in China of tea leaves being used to brew a beverage date to as early as 350 A.D., and by about 600 A.D. tea had been introduced to Japan from China. It is unclear, however, to what extent tea was consumed by the general population of either country during these early periods. In the seventeenth century, the Dutch introduced tea to Europe and America, and today tea is cultivated commercially in about 30 countries. Coffee is indigenous to Ethiopia from where it was transported for cultivation to Arabia in the fifteenth century. By the early sixteenth century, the practice had been established in the Islamic world of extracting caffeine by infusing ground roasted beans. The Dutch brought coffee plants to Europe in the early seventeenth century, and established plantations in the Dutch East Indies. Subsequent colonization by other European powers led to new and extensive plantations being established in the West Indies, Latin America, Africa, and India.

By the late-eighteenth century, coffee replaced tea in popularity in the United States, and today coffee is the main source of caffeine globally. Tea continues to be consumed more widely, but qualifies as the second main source because its caffeine content is generally lower than that of coffee. Other common sources of caffeine include cocoa and chocolate (in both solid and beverage form), but the caffeine content of these is generally low and represents a negligible fraction of the total amount of caffeine consumed. In addition, although the daily intake of caffeine from sources specific to particular regions (e.g., maté in parts of South America) may be substantial for individual consumers, the overall intake from such sources is small relative to total global consumption of the drug. Similarly, some medications, both prescribed and over-the-counter, contain as much as 200 mg (approximately 2–4 cups of coffee or tea) per tablet or capsule, and could be an important (even the main) source of caffeine for some individuals. For the general population, however, caffeine-containing medications are typically taken intermittently, or not at all,

thereby contributing little to total population caffeine intake. Notwithstanding variations in per capita consumption between geographic regions, intake for the majority of consumers ranges from about 200 to 400 mg of caffeine per day (the approximate equivalent of 2–6 cups of coffee or tea per day).

Caffeine soft drinks are an increasingly important source of the drug, and often the main source for children. The more recently developed so-called "energy" drinks are also increasing in importance as a source of caffeine for young people. Whereas the caffeine in sodas and energy drinks sometimes partly derives from plant products involved in manufacture (e.g., cacao, cola nut, guarana), most of the caffeine content of such drinks is added in refined form. That is, these products, which are targeted primarily at children and adolescents, are explicitly designed to be psychoactive. The seeming inexorable growth in the consumption of caffeine by children has become a cause for concern in its own right (e.g., [72]) as well as giving rise to concerns that caffeine in the form of sodas and energy drinks may serve as a gateway to increased use of other drugs.

Although consumption patterns relating to the various main sources of caffeine may change during the lifespan (e.g., an individual may switch from drinking sodas during childhood to coffee in adulthood), exposure to caffeine is essentially lifelong for the majority of people. Indeed, the first exposure for most people precedes birth. Caffeine crosses the placenta [17, 236], and because most women consume caffeine while pregnant, the majority of newborns show pharmacologically active levels of plasma caffeine [36]. Exposure typically continues during childhood, with patterns of use tending to consolidate during adolescence and early adulthood. Thereafter, usage tends to stabilize, generally undergoing little change for the remainder of life [95]. The unparalleled prevalence of caffeine use introduces multipliers in relation to the possible impact of the drug. At the individual level, lifelong use could lead to effects accumulating over the lifespan. Furthermore, considering the near-universal use of caffeine, individual effects, even if small, could have a substantial cumulative impact when assessed across entire populations.

Pharmacology of Caffeine

Caffeine belongs to a family of purine derivative methylated xanthines often referred to as methylxanthines or merely xanthines. At room temperature, caffeine is a white odorless powder with a bitter taste [238]. Caffeine was first isolated from green coffee beans in 1820 by Ferdinand Runge in Germany, and later was found to be present in a variety of other species (e.g., tea, mate, cacao). Figure 1 shows the structure of caffeine (1, 3, 7-trimethylxanthine) and the three dimethylxanthine primary metabolic products of caffeine in humans. Following oral ingestion, caffeine is rapidly absorbed into the bloodstream from the gastrointestinal tract [7]. Approximately 90% of the caffeine contained in a cup of coffee is cleared from the stomach within 20 min [25], and peak plasma concentration is typically reached within about 40–60 min [177].

Once ingested, caffeine is readily distributed throughout the body, and the concentrations attained in blood are highly correlated with those found in the brain, saliva, breast milk, semen, amniotic fluid, and fetal tissue [95]. The drug has an elimination half-life of about 5 h in adults [171], and typical consumption patterns of 3–4 doses (e.g., cups) per day, result in plasma concentrations that remain at pharmacologically active levels for most of the waking hours. In adults, caffeine is virtually completely transformed by the liver, with less than 2% of the ingested compound being recoverable in urine [214]. Although the beverages and foods that contain caffeine may have other constituents (e.g., sugar, milk) that possess nutritional value, it should be noted that caffeine itself has no nutritional value.

Main Mechanism of Action

Caffeine exerts a variety of pharmacological actions at diverse sites, both centrally and

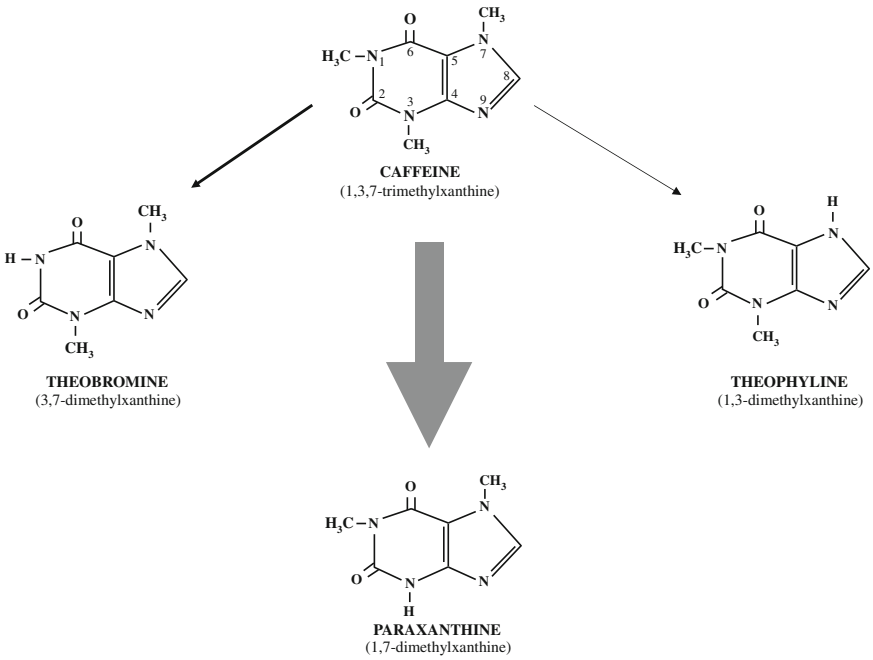

Fig. 1 Caffeine and its dimethylated metabolites in humans (*arrow widths* indicate approximate relative proportions of the metabolites in plasma)

peripherally, which are generally believed to be due mostly to competitive blockade of adenosine receptors [37]. Adenosine is a neuromodulator that acts on specific cell-surface receptors distributed throughout the body [19, 151, 197, 244]. Due to similarities in the molecular structure of caffeine and adenosine, caffeine occupies adenosine receptor sites, with A_1 and A_{2A} receptors appearing to be the primary targets. Table 1 summarizes some of adenosine's main actions, which are generally to inhibit physiological activity. At typical dietary levels of intake, caffeine blocks adenosine receptors, producing effects broadly opposite to those summarized in Table 1 [14, 20, 53, 135]. It appears, also, that A_1 and A_{2A} receptors may interact in functionally important ways with dopamine receptors [44, 59]. In particular, A_{2A} receptors may be involved in the control of the dopaminergic signaling system essential to motor control [31]. In addition, caffeine has been reported to stimulate neuroendocrine activity, especially the catecholamine stress hormones of epinephrine and norepinephrine (e.g., [129]). Increases in serum cortisol and/or urinary cortisol metabolites have also been reported [123, 142, 143, 173, 174]. However, findings have not been entirely consistent in that some investigators have found cortisol levels to be unresponsive to caffeine [121, 165]. It may be that the inconsistencies indicate that the typical challenge of about 250 mg (2–3 cups of coffee) represents a "borderline dose" to which some people may be unresponsive. For example, in one study, 250 mg of caffeine had no effect, whereas 500 mg increased plasma cortisol levels [216].

Table 1 Some acute biological effects of adenosine[a]

Biological system	Effect
Central nervous system	Decreased transmitter release, sedation
Cardiovascular	Dilated cerebral and coronary blood vessels
Renal	Antidiuresis
Respiratory	Bronchoconstriction
Gastrointestinal	Inhibition of acid secretion
Metabolic	Inhibition of lipolysis

[a]By blocking adenosine receptors, caffeine has effects broadly opposite to those summarized above

Physical Dependence

Repeated use of caffeine, such as occurs in the context of dietary use, generally leads to the development of physical dependence, evidenced by the appearance of behavioral, physiological, and subjective "withdrawal" effects provoked by abrupt cessation of use [111]. Although incompletely understood, the mechanism responsible for caffeine physical dependence is believed to involve adenosine. Repeated exposure to caffeine, including dietary use, is thought to result in an increased number of adenosine receptors and/or enhanced affinity, resulting in hypersensitivity during abstinence [14, 168, 242]. Sleepiness, lethargy, and headache are common symptoms of caffeine withdrawal in humans [40, 58, 80, 97, 122, 127, 172, 218, 220, 234], and cessation of as little as 100 mg (1 cup of coffee) per day, and possibly considerably less can produce symptoms (e.g., [140, 207]). These may be felt within about 12–16 h, with a peak at around 24–48 h, generally abating within 3–5 days, and only infrequently extending for up to 1 week [67, 81, 82]. Notably, studies show that decreases in psychomotor performance (not necessarily discernible to the individual) are detectable after as little as 6–8 h since caffeine was last ingested [73].

Tolerance

Drug tolerance refers to the progressive reduction in responsiveness which sometimes accompanies repeated exposure to a drug. It is evidenced by a decline in efficacy, whereby the same drug dose has less effect following repeated use or an increased dose is required to produce effects previously experienced. Although caffeine tolerance has been shown in relation to the locomotor stimulant effects of the drug in rats [46, 79], there have been relatively few empirical demonstrations of caffeine tolerance in humans. One focus of attention in relation to caffeine tolerance in humans has been the drug's cardiovascular effects [34, 90, 91], which it is widely believed undergo tolerance. The most often (and frequently, only) cited source for the claim of hemodynamic tolerance is a study by Robertson and colleagues [181], which is widely misquoted as having demonstrated complete hemodynamic tolerance to dietary caffeine. James [89] (pp. 111–113) has shown that the Robertson et al. [181] study did not demonstrate complete tolerance to caffeine, and that due to its many methodological shortcomings the study could not have demonstrated complete tolerance. On the contrary, as discussed in more detail below, empirical evidence from diverse sources converges to show that blood pressure remains reactive to the pressor effects of caffeine despite repeated exposure such as that which occurs when caffeine is part of the daily diet (e.g., James [90, 91, 99]).

Overall, it appears unlikely that complete tolerance occurs in relation to most effects arising from typical patterns of caffeine consumption. Importantly, the response magnitude to successive doses of the drug is generally inversely proportional to plasma caffeine level [211, 212]. Also, it is notable that overnight abstinence, which characterizes usual patterns of consumption, results in almost complete depletion of systemic caffeine by early morning [138, 171, 201]. Several lines of inquiry suggest that the pattern of diurnal depletion of systemic caffeine experienced by most consumers contributes to tolerance, if it occurs at all, typically being partial rather than complete. Indeed, the very fact that many hundreds of published experiments have reported significant caffeine-induced behavioral, physiological, and subjective effects provides strong evidence that usual patterns of consumption do *not* produce complete tolerance. Most participants in such experiments have been typical caffeine consumers who arrive at the experimental laboratory following a brief period of abstinence. Notwithstanding the brevity of the typical period of abstinence (e.g., overnight) employed in experimental studies of the acute effects of caffeine, participants are generally observed to be caffeine responsive. As is discussed in the following section, some

caffeine-induced responses (especially enhanced performance and mood) are attributable to withdrawal reversal. However, other responses, particularly increased blood pressure, are not attributable to withdrawal reversal. By definition, any observed caffeine-induced effects not attributable to withdrawal reversal provide proof positive that tolerance, if it has developed at all, cannot have been complete.

Psychopharmacology of Caffeine: The Critical Processes of Caffeine Withdrawal and Withdrawal Reversal

The earliest systematic examinations of the psychopharmacology of caffeine were conducted about a century ago [77, 78]. The strong consensus for most of the intervening period has been that caffeine is a stimulant capable of enhancing aspects of human psychomotor performance and mood. In recent years, however, that traditional view has been essentially disproved. Recent advances in knowledge about the dynamics of caffeine withdrawal and withdrawal reversal have radically transformed our understanding of caffeine psychopharmacology. In a typical study, behavioral and psychological outcomes are measured in healthy volunteers before and after double-blind administration of caffeine and placebo, and (compared with baseline and placebo) changes have often been reported in post-caffeine outcomes. This has been particularly evident in studies of performance and mood, wherein it has often been concluded that caffeine has enhancing properties. However, a critical appraisal of the typical study design shows that the findings yielded by such studies are, at best, ambiguous [92, 94, 105].

Paralleling the time-honored practice of placebo-controlled studies of medications, caffeine is typically withheld for a period prior to testing for effects, with the aim of ensuring all participants are equivalent in systemic drug levels at time of testing. Such efforts to achieve experimental control appear especially relevant to the assessment of caffeine effects, because the drug is used daily by most people. Typically, caffeine is consumed in separate portions throughout the day, with fewer portions consumed later in the day, followed by overnight abstinence [95]. With the half-life of caffeine in healthy adults being approximately 5 h [171], overnight abstinence usually leads to complete or near-complete elimination of systemic caffeine by early morning [138, 139]. Consequently, when employing the placebo-controlled paradigm, caffeine researchers have frequently made use of naturally occurring overnight abstinence by asking participants to forgo their usual morning caffeine beverage prior to laboratory testing.

What has not been fully appreciated until recently is that, having avoided caffeine since the evening before, study participants are generally entering the early stages of caffeine withdrawal by the time they are tested in the laboratory (typically, at least 12–14 h since caffeine was last ingested) (see [92] and [105]). As mentioned above, habitual use of caffeine produces physical dependence, evidenced by the appearance of readily measurable withdrawal symptoms following periods of abstinence (e.g., Juliano and Griffiths [111]). Thus, the crucial question is: To what extent do effects (e.g., enhanced performance and mood) generally attributed to caffeine represent genuine net effects of the drug or reversal of withdrawal effects induced by short periods of abstinence? [92]

Performance and Mood

The fact that caffeine is consumed daily by most people as part of a "normal" diet presents formidable methodological obstacles when trying to accurately isolate the net effects of the drug. Although the problem was largely ignored for decades, systematic attempts have begun to tackle key methodological challenges posed by caffeine withdrawal and withdrawal reversal. Approaches have varied, but generally fall into three broad categories, consisting of studies that compare consumers and low/non-consumers, pre-treatment and ad lib

consumption studies, and long-term withdrawal studies [95, 105]. The first two approaches (studies comparing consumers with low/non-consumers and pre-treatment/ad lib consumption studies) have been shown to involve substantial limitations (for a discussion see James [95] and James and Rogers [105]). In contrast, the third approach (long-term withdrawal) has proven successful. This has entailed taking the core features of the traditional drug-challenge paradigm, with its attendant strengths of double blinding and placebo control, and extending them to include alternating periods of daily caffeine use and non-use (abstinence).

Table 2 summarizes the core design features of an experimental paradigm employed successfully by James and colleagues (e.g., James [88, 90, 91, 97] and Keane et al. [117]) to elucidate caffeine's net effects using "long-term" withdrawal. During caffeine phases of that paradigm, participants ingest the approximate equivalent of 1 cup of coffee three times daily, thereby simulating the typical population pattern of caffeine consumption. The protocol employs six consecutive days of placebo/caffeine intake to achieve stability of responding before "challenging" participants on the 7th day of each alternating 1-week period. The 1-week time frame was chosen on the grounds that studies of caffeine tolerance in humans have generally found that effects plateau within 3–5 days of continuous use [34, 90, 91, 181]. In addition, there is a strong body of evidence showing that withdrawal effects generally abate within a similar time frame of 3–5 days (e.g., [66, 81]). The full research design, as shown in Table 2, offers the substantial benefit of being able to examine and compare the separate acute and chronic effects of caffeine in the one experiment. An abridged version of the design has also been used, consisting of the "PP" and "CC" conditions outlined in Table 2 without the "PC" and "CP" conditions (e.g., James and Gregg [100, 101] and James et al. [102]). While not elucidating the more detailed processes of withdrawal and tolerance, the abridged design allows key questions concerning caffeine's net effects to be addressed.

Long-term caffeine withdrawal studies have provided strong support for the withdrawal reversal hypothesis in relation to performance and mood [105]. That is, overnight caffeine abstinence has been found to be detrimental to performance and mood, with these adverse effects being removed when caffeine is re-ingested (restoration due to reversal of withdrawal effects). Importantly, recent studies have yielded consistent evidence of caffeine having little or no net beneficial effect on performance and mood under conditions of sustained caffeine use versus sustained abstinence [97, 101, 102]. Several other studies, which may not all strictly

Table 2 Summary of a double-blind placebo-controlled crossover protocol incorporating alternating periods of "long-term" caffeine exposure and abstinence[a]

Week	Run-in days (days 1–6)	"Challenge" (day 7)	Condition (abbreviation)	Effects revealed by challenge
1	Placebo	Placebo	PP	Sustained abstinence (i.e., caffeine "wash out"). Serves as a caffeine-free baseline.
2	Placebo	Caffeine	PC	Acute challenge. When compared with PP and CC, reveals the presence of tolerance.
3	Caffeine	Placebo	CP	Acute abstinence. When compared with PP and CC, reveals the presence of withdrawal.
4	Caffeine	Caffeine	CC	Habitual use. When compared with PP, reveals the net effects of habitual consumption.

PP Placebo ingested for 6 consecutive days followed by 1 day of placebo challenge, *PC* 6 days of placebo followed by 1 day of caffeine challenge, *CP* 6 days of caffeine followed by 1 day of placebo challenge, *CC* 6 days of caffeine followed by 1 day of caffeine challenge.

[a]Design originally described by James [90, 91, 97], versions of which have been employed in subsequent studies (e.g., James and Gregg [100, 101], James et al. [102], and Keane et al. [117])

qualify as "long-term" studies, have reported similar results in relation to performance and mood in adults [98, 110, 180, 184, 185] and children [72].

Sleep and Wakefulness

Former strong beliefs about caffeine being capable of enhancing psychomotor performance and mood are matched by equally strong beliefs that caffeine is effective in reversing negative effects of sleep loss [103]. Until very recently, however, studies of caffeine and sleep failed to take account of the processes of withdrawal and withdrawal reversal. Employing the abbreviated version of the experimental paradigm summarized in Table 2 (i.e., "PP" versus "CC" as defined in the table), James et al. [102] examined the effects of dietary caffeine in healthy volunteers who alternated weekly between placebo and caffeine and who were either rested or deprived of more than 50% of their usual nighttime sleep on the evening before testing. Confirming previous studies, caffeine was found to have no significant net enhancing effects for either performance or mood when participants were rested, while also having no net restorative effects when performance and mood were negatively affected by sleep restriction. Indeed, James and Gregg [101] found that caffeine exacerbated the marked adverse effects of sleep restriction on mood.

Similarly, after controlling for caffeine withdrawal effects, Rogers et al. [185] found that cognitive performance was unimproved by caffeine in participants who were sleep restricted. Acute (overnight) caffeine withdrawal was found to impair performance on tasks requiring sustained attention, and subsequent caffeine intake merely prevented further deterioration in performance (withdrawal reversal). In contrast, the significantly better levels of performance on the same tasks shown by long-term (3 weeks) withdrawn participants were not improved by caffeine. Additionally, acute caffeine withdrawal had a variety of negative effects on mood. More recently, Keane et al. [117] examined the effects of caffeine on patterns of electroencephalographic activity in a rare example of a study of electroencephalography in which caffeine withdrawal and withdrawal reversal were controlled. While again finding little evidence of positive stimulant effects, Keane et al. [117] found some similarities in effects on brain activity following caffeine ingestion (challenge) and acute caffeine withdrawal. As such, these findings are consistent with results from studies of performance and mood in which caffeine withdrawal and withdrawal reversal had been controlled. That is, rather than having positive stimulant effects, a change in drug state, whether in the form of acute caffeine challenge or acute caffeine withdrawal, may disrupt normal electrophysiological activity in the brain, which may in turn be the substrate for the observed negative effects on performance and mood.

The terms "sleep" and "wakeful" lack precise definition, and are sometimes used as if they were exact antonyms of one another. Possibly everyone, however, has had the experience of being both sleepy and wakeful (i.e., tired but unable to sleep, for example, during periods of acute worry). This should not be surprising, since it is unlikely that a single mechanism controls the processes of sleepiness and wakefulness. As such, caffeine may directly interfere with an aspect of sleep (e.g., block receptors in the adenosine mechanism) and thereby forestall sleep without necessarily or appreciably benefiting wakefulness. At the same time, sleepiness is a reliable effect of even brief periods of caffeine abstinence.

One source of confusion concerning caffeine's putative anti-soporific effects is the fact that withdrawal-induced sleepiness is reversible by ingesting caffeine, thereby creating the illusion that caffeine is effective in "stimulating" wakefulness and overcoming sleepiness. In reality, the overall effect of caffeine on the sleep cycle is likely to be disruptive, involving an increased risk of caffeine-induced sleep delay and withdrawal-induced periods of sleepiness. The former, caffeine-induced sleep delay, is possibly largely avoided by the majority of consumers who typically do not ingest caffeine after early evening. In contrast, although

sleepiness induced by caffeine withdrawal is possibly widely experienced, most people are probably unaware of it (i.e., unaware of caffeine withdrawal as a cause of daytime sleepiness). Indeed, there is a strong possibility, yet to be verified, that sleepiness induced by caffeine withdrawal is a common, though largely unrecognized, cause of fatigue-related traffic and industrial accidents.

Mental Health and Well-Being

Major systems of medical and psychiatric diagnosis give formal recognition to "disorders" of psychological function arising from caffeine misuse, noting that "misuse" in this context includes levels of use falling within the range seen in the general caffeine-consuming population. Since formal diagnoses can only be made after affected persons come to the attention of relevant professionals, it follows that a sizable proportion of the general public may be engaging in caffeine "misuse" even if a formal diagnosis has not been made. The 10th revision of the International Statistical Classification of Diseases and Related Health Problems [252] has a specific diagnostic classification of mental and behavioral disorders due to use of "other stimulants", including caffeine, which includes subcategories of acute intoxication, dependence syndrome, and withdrawal state. Similarly, under the label of caffeine-related disorders, under the broader rubric of substance-related disorders, the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision [5] has classifications for caffeine intoxication, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder.

Diagnostic and Statistical Manual of Mental Disorders, *4th Edition, Text Revision*

Considering the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision more specifically, the essential features of caffeine intoxication are shown in Table 3, which cites recent consumption of caffeine and five or more symptoms that develop during, or shortly after, caffeine use. As the name implies, the classification of caffeine-induced anxiety disorder refers to the occurrence of symptoms of anxiety (e.g., nervousness, worry, apprehension) associated with, and believed to be precipitated by, the consumption of caffeine. Caffeine-induced sleep disorder typically refers to insomnia (e.g., increased sleep latency, decreased sleep time, fragmented sleep) provoked by caffeine consumption. However, as explained above, periods of reduced caffeine intake or abstinence can also lead to bouts of sleepiness (hypersomnia). Thus, on the one hand, caffeine-induced sleep disorder refers to nighttime wakefulness, which many people may recognize as having experienced. On the other hand, caffeine-induced sleep disorder also refers to the occurrence of withdrawal-induced daytime sleepiness due to caffeine abstinence or reduced caffeine intake. Again, as suggested above, given that caffeine-induced nighttime insomnia is easily avoided by not consuming caffeine latter in

Table 3 Diagnostic criteria for caffeine intoxication

A. Recent consumption of caffeine, usually in excess of 250 mg (e.g., more than 2–3 cups of brewed coffee).
B. Five (or more) of the following signs, developing during, or shortly after, caffeine use:
(1) Restlessness
(2) Nervousness
(3) Excitement
(4) Insomnia
(5) Flushed face
(6) Diuresis
(7) Gastrointestinal disturbance
(8) Muscle twitching
(9) Rambling flow of thought and speech
(10) Tachycardia or cardiac arrhythmia
(11) Periods of inexhaustibility
(12) Psychomotor agitation
C. The symptoms in Criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder (e.g., an Anxiety Disorder).

Adapted from the American Psychiatric Association [5]

the day or evening, withdrawal-induced daytime sleepiness is possibly a more common occurrence, even if (or possibly because) it is less often recognized by consumers as a symptom of their caffeine use.

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision [5] also makes reference to a more general category of caffeine withdrawal, but refers to it as a syndrome under consideration and not yet a formal diagnosis. As pointed out by James (1997), this is an ironic position, because there is substantially more empirical evidence for the existence of caffeine withdrawal as a specific syndrome, than for any of the accepted caffeine diagnoses. Furthermore, the proposed diagnosis of caffeine withdrawal includes headache as a defining symptom. In reality, headache is a common, though not universal, symptom of caffeine withdrawal (e.g., [101]). By excluding cases of caffeine withdrawal headache not accompanied by other symptoms, and cases in which other withdrawal symptoms (e.g., lethargy, tiredness, irritability) are experienced without headache, the proposed diagnosis of caffeine withdrawal seems bound to lead to under-diagnosis.

The symptoms listed in Table 3 fall into two broad categories considered to be of lesser or greater seriousness. Less serious symptoms include restlessness, nervousness, excitement, insomnia, flushed face, diuresis, and gastrointestinal complaints, and may occur following daily use of as little as 100 mg of caffeine (about 1 cup of coffee). More serious symptoms include muscle twitching, rambling flow of thought and speech, tachycardia or cardiac arrhythmia, periods of inexhaustibility, and psychomotor agitation, said to occur at levels of intake of 1 gram or more per day. Although substantially above average dietary levels, consumption at this higher level of intake is not rare, possibly involving about 10% of the population. Indeed, Hughes et al. [83] interviewed 162 randomly selected caffeine users and concluded that 7% met the criteria for caffeine intoxication. Among those who had tried to stop caffeine permanently, 24% satisfied the criteria for caffeine withdrawal. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision [5] stipulates that reported symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. These stipulations, however, remain open to interpretation. Thus, of the many caffeine-induced dysphoric effects that are experienced in the population, the relative proportions that fall above and below the threshold of clinical significance remain unknown.

The Epidemiology of Caffeine Disorders

Given what appears to be a relatively low level of awareness of caffeine-induced dysfunction in the general as well as professional communities, there is a strong suspicion that caffeine "disorders" remain substantially undiagnosed despite the existence of formal diagnostic protocols. Moreover, in addition to clinical diagnosis, caffeine ingestion and withdrawal appear to have a variety of other commonplace psychological and behavioral outcomes that can be serious. For example, as well as the possibility that withdrawal-induced sleepiness contributes to fatigue-related accidents, caffeine-induced hand tremor has been found to undermine surgical precision. In a double-blind placebo-controlled crossover study, Urso-Baiarda et al. [229] found that moderate amounts of caffeine had a detrimental effect on microsurgical ability due to the adverse effect of the drug on hand steadiness. Also within a general surgical context, evidence indicates that patients commonly experience perioperative caffeine-withdrawal headache due to the requirement that they fast (and therefore do not receive their usual caffeine intake) prior to anesthesia [41, 57, 162]. Prophylactic administration of caffeine appears to provide a simple and effective remedy [69, 245]. Indeed, the reversal of headache under such circumstances is further evidence of the role of caffeine withdrawal in the development of headache. Findings such as these contribute to the impression that the population prevalence of

caffeine-induced disorders far exceeds that which would be implied by the frequency with which such problems are diagnosed in clinical settings.

Dietary Caffeine and Physical Health: Cardiovascular Disease

When considered in totality, the large and diverse body of relevant scientific literature is conclusive in pointing to adverse acute effects of caffeine on cardiovascular function, especially blood pressure. Though evidence of chronic effects is less conclusive (for reasons outlined below), the available evidence nevertheless provides strong grounds for concluding that dietary caffeine is a significant factor in the development of cardiovascular disease. The extent of the evidence is such as to suggest the need for primary prevention at a population-wide level, including appeals to consumers to avoid caffeine in the interests of cardiovascular health. Such action, however, has been largely absent and it is important to examine possible reasons. Accordingly, this section provides an overview of relevant experimental and epidemiologic findings, and considers reasons why the evidence may not have caught the attention of health authorities to the extent that it should. Two main reasons for this neglect, considered below, appear to be: confusion regarding the epidemiology of caffeine and cardiovascular disease due to exposure misclassification, confounders, and possible misunderstanding of putative threshold effects; and the belief that habitual caffeine use leads to the development of tolerance to the cardiovascular effects of the drug.

Concerns for cardiovascular health in the context of dietary caffeine have a firm foundation in demographics. Cardiovascular disease is the major cause of mortality and morbidity in the developed countries of the world accounting for approximately half of all deaths [233, 250, 251]. It is expected also that within the near future cardiovascular disease will be the major cause of death and disease throughout much of the developing world [169, 182, 183]. As well as being of high prevalence, cardiovascular diseases are generally of long latency, and have complex multifactorial causation involving lifestyle variables including diet. As mentioned above, the prevalence of dietary caffeine is extremely high and essentially lifelong. In that context, it is especially noteworthy that adenosine has an important role in the regulation of cardiovascular function as well as being the main mechanism of action for caffeine, thereby providing strong biological plausibility for a possible link between the two. Blood pressure level is of particular concern, because it is the single most important predictor of cardiovascular disease [156, 182], and compared with several other key indices of cardiovascular function blood pressure is particularly responsive to dietary caffeine.

Acute Effects of Caffeine on Blood Pressure

It has been shown conclusively that caffeine increases blood pressure acutely, with reports generally indicating increases in the range of 5–15 mg Hg systolic and 5–10 mg Hg diastolic. This acute pressor effect occurs across a wide age range, with effects lasting for up to several hours in healthy men and women (see James [95, 99] for a discussion). In addition, the pressor effect of caffeine is additive to that of cigarette smoking [54, 104, 210], is at least additive (e.g., France and Ditto [52], Greenberg and Shapiro [64], James [88, 90], and Lane and Williams [129]) and may be synergistic (e.g., [3, 128]) to the pressor effect of psychosocial stress, and is evident in persons with hypertension as well as normotensives (e.g., [71, 200]). Furthermore, studies show that caffeine produces acute increases in aortic stiffness and enhances wave reflection, both of which contribute to increased blood pressure as well as being independent risk factors for cardiovascular disease [116, 149, 239, 240]. Again, these effects have been observed in persons who are

normotensive as well as those being treated for hypertension, and appear to be synergistic to similar effects of smoking [241].

Epidemiology of Caffeine and Cardiovascular Disease

More than 100 large epidemiologic studies in more than a dozen countries have reported data on the relationship between dietary caffeine and cardiovascular function, morbidity and/or mortality. Taken as a whole, epidemiologic findings suggest that dietary caffeine is detrimental to cardiovascular health [99]. However, one feature of this large literature is the many inconsistencies in the reported findings. The response of some commentators and reviewers to this inconsistency has been to dismiss concerns about caffeine, a response that is neither logical nor consistent with overall findings. Dismissing concerns is particularly unjustified in light of the large and consistent body of evidence from experimental studies. By their nature, experimental studies afford a greater level of control than epidemiologic approaches. Indeed, by integrating experimental and epidemiologic findings, the former help to clarify inconsistencies in the latter.

Considered comprehensively, the experimental and epidemiologic findings raise concerns over the implications of dietary caffeine for population cardiovascular health. The assumption that clear consistency should have emerged in the epidemiologic findings, if caffeine were having substantive effects on blood pressure and other indices of cardiovascular function, fails to take account of the many methodological shortcomings in the epidemiologic studies published to date. In particular, there are grounds for concluding that the many "null" reports (i.e., non-significant associations) in the epidemiologic literature on caffeine and cardiovascular disease reflect a high rate of Type II error (i.e., failure to observe a real effect when one exists).

Misclassification

A major shortcoming of many studies is poor measurement of the key "exposure" variable, namely, caffeine consumption. Although this shortcoming has long been the subject of criticism (e.g., [61, 89, 198]), relatively little improvement or innovation has been undertaken by epidemiologists over the past three decades to try to overcome the problem. Although at least half of the relevant epidemiologic studies conducted to date collected blood samples (mostly for the purpose of measuring serum lipid levels), none took the obvious next step of measuring systemic levels of caffeine or its metabolites [99]. As such, use has not been made of the fact that good estimates of dietary caffeine levels can be obtained by analyzing plasma and saliva caffeine (or paraxanthine, the major metabolite in humans) using high-performance liquid chromatography (e.g., [1]) or enzymeimmunoassay techniques [100].

Furthermore, although dietary caffeine levels can be measured reliably using detailed self-report inventories [107], many studies have employed poor self-report protocols and have shown little regard for the reliability of the measurements employed. Since the inadequate methods frequently used are likely to have produced largely undifferentiated (i.e., random) measurement error, the effect in many epidemiologic studies will have been to underestimate the true association between caffeine and cardiovascular disease or to report "no association". Thus, while overall epidemiologic findings suggest that dietary caffeine has a modest detrimental effect on cardiovascular health, actual effects may be larger considering the often imprecise methods that have been employed [95, 96, 99].

Confounding in Epidemiologic Research

A frequent erroneous observation about the epidemiology of caffeine and cardiovascular health is that much of the research has ignored the influence of confounders. This "confounder myth" [95] asserts that reports of significant positive

correlations between caffeine consumption and cardiovascular disease are the result of failure to control confounders, especially cigarette smoking. As well as being a cardiovascular risk factor, smoking has been found to be positively correlated with caffeine use (e.g., [119, 167, 226]). The myth, however, arises from the fact that, for the past three decades, epidemiologic studies of caffeine have routinely controlled for cigarette smoking. Excepting one or two early studies, virtually all of the literature reporting a positive correlation between caffeine consumption and cardiovascular disease controlled for the influence of cigarette smoking.

In the context of population studies there is always a risk of unanticipated influence of an as yet unidentified confounder. The level of such risk is probably lower in epidemiologic studies of dietary caffeine and health than in many other areas, because the list of potential confounders controlled for in caffeine studies (including those that reported positive findings) is very long, including: age, gender, cigarette smoking, alcohol consumption, body mass index, dietary factors, serum cholesterol, blood pressure, medical history, use of oral contraceptives, family history of heart disease, physical activity, personality, region of residence, education level, and religion [89]. Indeed, rather than being inadequately controlled for confounder effects, there has probably been a tendency toward overadjustment for confounders in epidemiologic studies of caffeine (e.g., [120, 190]). In particular, findings have frequently been adjusted for blood pressure and cholesterol, which may be caffeine-related and coffee-related causal pathways in their own right. Thus, as with measurement error, the likely effect of overadjustment for confounder effects would be to increase the risk of Type II error; that is, to underestimate the actual strength of the association between caffeine consumption and cardiovascular disease.

Threshold Effects

It is common in epidemiologic studies of caffeine to stratify according to level of reported caffeine use. A proportion of studies adopting that approach have reported the existence of a "threshold", whereby a positive association is observed in consumers reporting higher levels of intake (e.g., "6 or more cups of coffee" per day) but not in consumers reporting lower levels of intake. Although such reports may be reassuring for "average" consumers, the notion of an actual threshold in this context is not persuasive. Experimental studies of caffeine have consistently found the acute hemodynamic effects of caffeine to be proportional to systemic caffeine level (e.g., [211, 212]). In the absence of other intervening variables, this dose-response effect would be expected to result in a relatively continuous relationship between caffeine and cardiovascular health outcomes rather than one marked by a threshold. Unreliability in the data, especially due to imprecise measurement of dietary exposure (as outlined above), is a more likely explanation of the threshold effects sometimes reported in epidemiologic studies of caffeine and population cardiovascular disease.

Epidemiology of Caffeine and Blood Pressure

As part of the much larger body of epidemiologic research on caffeine and cardiovascular disease, James [99] identified 18 population studies that were specifically concerned with caffeine and blood pressure. Of these, 5 reported no association between dietary caffeine and blood pressure, 6 reported a significant positive association for systolic and/or diastolic pressure, and 7 reported an inverse association for either systolic or diastolic pressure. The diverse findings are not explained by differences in the study populations, as these were similar in demographics and socioeconomics. Indeed, the level of inconsistency highlights the extent of the shortcomings that exist in the epidemiologic findings, which contrast the largely consistent pattern of pressor effects reported in experimental studies (discussed below). Of particular concern is

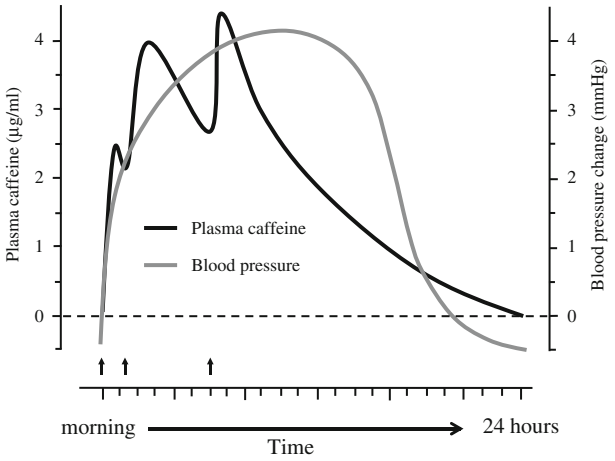

Fig. 2 Schematic representation of estimated 24-h plasma dietary caffeine concentration time course and associated change in blood pressure. Estimated plasma caffeine concentration assumes an elimination half-life of 5 h and ingestion of 1 cup of coffee after awakening and at two further time points (arrows) during the earlier part of the day (with evening and overnight abstinence). Associated blood pressure changes are relative to caffeine-free levels

the fact that epidemiologic studies have generally ignored issues related to the plasma caffeine concentration time course and associated pressor effects. The general pattern is shown in Fig. 2, which is a schematic representation of the estimated 24-h plasma caffeine concentration time course, assuming an elimination half-life of 5 h and ingestion of the approximate equivalent of 1 cup of coffee in the morning, mid-morning, and mid-afternoon.

Figure 2 helps to show that the strength, and even the sign, of the correlation between dietary caffeine and blood pressure level depends on the timing of blood pressure measurement relative to when caffeine was last ingested [99]. Using 24-h ambulatory monitoring, James [91] found that overnight abstinence produced transient modest decreases in blood pressure. Thus, taking a cross-section of the population, recent caffeine consumption is likely to have a pressor effect (positive association), whereas brief caffeine abstinence (10–12 h) may have no effect, and longer periods of abstinence (12–24 h) may decrease blood pressure modestly (inverse association due to withdrawal). In view of this analysis, a noteworthy feature of several of the studies in which dietary caffeine was said to have been protective (i.e., inverse association between intake and blood pressure) is that participants were asked to fast before being examined [99]. Specifically, participants in 5 of the 7 relevant studies were reported to have fasted, while one reported non-fasting and one omitted to report whether participants fasted or not. Thus, in the majority of the studies involved, caffeine consumers' blood pressure readings were likely to have been transiently lower (due to withdrawal) than "normal" for themselves and potentially lower also than their non-consuming counterparts.

Although interpretation of the findings of epidemiologic studies of caffeine and blood pressure depends crucially on knowing when blood pressure was measured relative to when participants ingested caffeine, with one exception [203], none of the relevant studies provides that level of detail. In the one exception, an overall analysis revealed no association between caffeine consumption and blood pressure level after adjustment for age, body mass, cigarette smoking, alcohol consumption, serum cholesterol, and family history of hypertension [203]. On closer examination, however, the authors reported that participants who had consumed

caffeine during the 3 h prior to measurement had significantly elevated blood pressure compared with participants consuming no caffeine for the same period. Importantly, because the increases in blood pressure associated with recent ingestion of caffeine were independent of average daily intake (a measure of habitual use), the results also confirm experimental findings that habitual caffeine consumption does not lead to complete tolerance to the pressor action of the drug.

Chronic Effects of Dietary Caffeine on Blood Pressure

Before the last decade, there had been little direct (experimental) examination of the chronic hemodynamic effects of dietary caffeine. Among the first studies to undertake such an examination, modest sustained decreases in blood pressure were reported when caffeine beverages were either removed from the diet [10] or replaced by decaffeinated alternatives [235]. Similar results were reported in a number of subsequent studies in which ambulatory monitoring was used to measure blood pressure level for extended time periods [63, 91, 109, 176, 221].

Moreover, it is known that blood pressure responses of similar magnitude may be accompanied by different patterns of change in cardiac output and total peripheral resistance, and these differences in hemodynamic profile may be implicated in cardiovascular pathology [65]. Speculation has existed as to whether caffeine-induced pressor effects are due to cardiac stimulation of contractility leading to increased cardiac output, or vasoconstriction leading to increased total peripheral resistance. Findings generally suggest that the blood pressure-elevating effect of caffeine is due primarily to increased vascular resistance [30, 56, 70, 100, 209]. Because greater risk has been attached to hemodynamic reactivity in which vascular, rather than myocardial, responses predominate [112], findings of caffeine-induced vascular resistance add to concerns regarding the possible implications of dietary caffeine for cardiovascular health.

Dietary Caffeine and Population Blood Pressure Levels

If, as this review indicates, dietary caffeine contributes to statistically significant elevations in blood pressure, it should be noted that such increases are modest in absolute terms, amounting to possibly 2–4 mm Hg for most waking hours of the day. The question, therefore, that needs to be considered is whether such increases are likely to have an appreciable effect on population cardiovascular mortality and morbidity. It is sometimes presumed that increases of such magnitude are not meaningful, on the grounds that blood pressure level is inherently variable. However, it should be remembered that the effects of caffeine are at least additive, and possibly synergistic, to blood pressure increases due to a variety of other factors (e.g., smoking, hypertension, stress). In this sense, caffeine represents a preventable additional burden on the cardiovascular system.

The clearest insight into the contribution of blood pressure increases to cardiovascular disease is provided by population statistics describing the relationship between blood pressure level and cardiovascular mortality and morbidity. Since the association between the population distribution of blood pressure and cardiovascular disease is primarily linear, any contribution by caffeine to population blood pressure level may be expected to contribute to the overall incidence of cardiovascular mortality and morbidity [147, 148, 175, 183, 233]. It is important to remember that exposure to caffeine is generally long (essentially lifelong for most consumers), the prevalence of exposure is high (more than 80% in most countries), and the incidence of cardiovascular disease is high throughout the world. While reduced blood pressure associated with reductions in dietary caffeine may be expected to be modest in absolute terms, even modest absolute changes in population levels of blood

pressure translate to significant changes in the population burden of cardiovascular death and disease.

For example, it has been estimated that a downward shift of 2–3 mm Hg in the population distribution of blood pressure would produce life-saving benefits equal to the cumulative benefits achieved by antihypertensive treatment [183, 188]. It has also been estimated that population-wide reductions of 2 mm Hg could avert 5% of deaths from coronary heart disease and 15% of stroke deaths [182, 183]. More specifically, James [87] estimated that if caffeine consumption had the effect of elevating average population blood pressure by 2–4 mm Hg (a reasonable inference considering the relevant experimental data (e.g., [96, 99, 109, 221]), extrapolation based on epidemiologic blood pressure data [147, 148] suggests that population-wide cessation of caffeine use could lead to a reduction of 9–14% of premature deaths from coronary heart disease and 17–24% of premature deaths from stroke. If caffeine were removed from the diet in populations where coffee specifically is widely consumed, additional benefits would be achieved due to the adverse impact of that beverage on serum cholesterol and homocysteine [99].

Dietary Caffeine and Physical Health: Non-Cardiovascular Disease

Cancer

Although numerous studies of cultured cells in vitro have demonstrated the mutagenic potential of caffeine, in vivo studies of intact nonhuman animals have suggested variously that caffeine: is not a carcinogen, is carcinogenic under some conditions, and is antitumoric under other conditions [95]. Moreover, the relevance of the in vitro and in vivo findings to lifelong dietary use of caffeine in humans remains unclear. Overall, there is a strong consensus that the experimental evidence as a whole suggests that the drug is not a significant carcinogen in humans. In addition, there has been extensive epidemiologic study of caffeine beverage consumption and cancer. Most of this research has been primarily concerned with coffee consumption, although over the past decade tea has also been a focus of attention. Because comparatively few studies have examined caffeine specifically, it is necessary to treat the findings for coffee and tea consumption as being only indirectly suggestive of the carcinogenic potential of caffeine.

All Cancers

Cancer is not a single disease, and therefore it is not surprising that most studies have been concerned with cancers located at one or a small number of specific sites rather than overall cancer rates. However, regarding overall rates, studies have tended to suggest no adverse impact of caffeine on cancer mortality (e.g., [137, 152]). On the other hand, studies of specific sites indicate more complex associations than that suggested by examination of the relationship between caffeine consumption and overall cancer incidence.

Lower Urinary Tract

Following an early report by Cole [29] of a significant association between coffee consumption and cancer of the lower urinary tract (renal pelvis, bladder, and urethra), there has been considerable epidemiologic interest in coffee as a possible cause of bladder cancer. The substantial body of literature that has accumulated tends to suggest a positive but weak association [84, 89]. However, although the association has been reported intermittently in different populations during the past two decades [26, 33, 158], widespread doubt exists as to whether the association is causal.

Pancreas

Early studies reported a relationship between caffeine beverages and pancreatic cancer [146,

219], one of the most rapidly fatal of human malignancies. Subsequent epidemiologic studies, however, yielded mixed results. In a review of relevant research conducted prior to 1990, the International Agency for Research on Cancer [84] concluded that the evidence was suggestive of a weak relationship between high levels of coffee consumption and the occurrence of pancreatic cancer, but cautioned that even this association could be due to bias or confounding. More recent studies have tended not to support the existence of even a modest positive correlation [55, 114, 202, 253, 255], although in one meta-analysis it was concluded that small amounts of coffee may be protective while high intake increases disease risk [163].

Breast

The epidemiology of caffeine and breast disease is somewhat mixed, especially among older studies, with some reporting a modest increased risk associated with caffeine consumption [131, 134, 150, 187] and others reporting no association [144, 189, 196]. More recent studies, however, have tended increasingly to report no association [47, 155, 208] and, more recently still, reports have appeared of an inverse association (i.e., "protective" effect) between caffeine consumption and breast cancer. Unfortunately, however, the pattern of findings has been inconsistent, with one study reporting an inverse association in premenopausal women and no association post-menopause [11], and another study reporting a weak inverse association in postmenopausal women but no association for the cohort overall [155].

Colon

Results of studies of caffeine consumption and cancer of the colon and/or rectum have also been highly varied. Some reported no association between coffee consumption and increased risk of disease [136, 164, 166], whereas others reported an increased risk [205, 213]. Still others, however, have reported a reduced risk [1, 12, 23, 86, 132, 133, 206, 223]. The frequency of reports of reduced risk (i.e., potential protective effect) has led to speculation about possible mechanisms of action, including rates of bile acid secretion and colonic motility [86, 223].

Other Sites

Results for other sites also tend to be mixed, with a pattern seeming to emerge of more recent studies reporting no association, or even a protective effect in some instances, thereby negating earlier findings of adverse effects. For example, Armstrong and Doll [6] reported a positive correlation between coffee consumption and cancer of the kidney, whereas later studies, with the exception of Asal et al. [8], have mostly failed to observe any relationship between coffee and/or tea consumption and kidney cancer. Similarly, whereas several earlier studies reported significantly increased risk of ovarian cancer in coffee consumers [130, 225, 249], more recent studies have tended to report no association [76, 215, 222].

Maternal Use of Caffeine

As mentioned above, caffeine readily crosses the placenta during pregnancy. Thus, throughout pregnancy, the developing fetus is exposed to concentrations of the drug equal to systemic levels in the mother. Naturally, questions arise regarding the implications of this exposure, especially considering the known pharmacological actions of caffeine. In 1980, responding to reasonable suspicions and early empirical findings, the United States Food and Drug Administration issued a warning advising pregnant women to restrict, or eliminate, coffee consumption. The focus of this warning was in relation to gross morphological (i.e., physical) abnormalities that had been observed in animal studies. However, animal studies usually

involved dosing levels higher than those typical of human dietary use, and the consensus today is that dietary levels are unlikely to result in morphological abnormalities [95].

Notwithstanding reassurance regarding gross defects, the question arises as to what represents an appropriate margin of safety for intrauterine exposure to caffeine in the human fetus. The usual safety standard employed by the Food and Drug Administration in relation to the human consumption of food additives is one-hundredth the maximum safe level of exposure in animals [227]. By that standard, virtually any pattern of regular caffeine consumption by a woman who is pregnant would put her unborn child at risk. That is, applying the Food and Drug Administration's usual standards, pregnant women should abstain from caffeine completely. Moreover, teratology (the scientific study of conditions caused by the interruption or alteration of normal development) includes not only the study of physical defects, but also the study of more subtle behavioral and emotional anomalies. Although a wide range of caffeine-induced developmental effects on behavior and neurochemistry have been demonstrated in animals, there have been very few reported studies in humans. The results that have been reported point to the need for further studies to examine caffeine as a potential behavioral teratogen [95].

Pregnancy Outcome

In addition to concerns about possible teratogenicity, there are concerns that maternal caffeine use could have adverse effects on pregnancy outcomes. Several studies have reported a positive association between maternal caffeine use and spontaneous abortion [28, 35, 60, 178, 247], whereas some others have found no association [43, 157]. It has been suggested that positive findings could be due to confounding from pregnancy-induced nausea, which is less frequent in pregnancies that miscarry than those that go to term. It is plausible that women who experience nausea might respond by reducing their caffeine intake. Consequently, it could be this "loss of taste" for caffeine rather than reduced caffeine per se that might be the basis for the observed positive correlation between higher caffeine use and spontaneous abortion. However, the nausea hypothesis has not been supported by studies that took account of nausea experienced during pregnancy [42, 60].

The mixed, sometimes contradictory nature of the findings for fetal loss is also characteristic of the findings for other major pregnancy outcomes. In particular, several studies have reported an inverse association between maternal caffeine use and fetal growth [159, 217, 237], while others have found no association [27, 68, 204]. Although the findings are far from consistent, it appears that the current weight of evidence is suggestive of an adverse effect of caffeine in that at least two meta-analyses have concluded that caffeine consumption is associated with a significant decrease in birth weight [45, 195]. Even then, it remains a possibility that the seemingly adverse effects of caffeine on particular pregnancy outcomes could have been due to the influence of confounders (e.g., recall bias). Overall, however, the available evidence points to maternal caffeine use being associated with increased risk of adverse pregnancy outcome, especially increased spontaneous abortion and lower birth weight.

Notwithstanding evidence of an association between caffeine consumption and adverse pregnancy outcomes, advice as to the need for caution regarding caffeine intake during pregnancy has tended to be heavily qualified. This appears to be partly due to the fact that several of the relevant studies have observed significant associations only for higher levels of intake, which has contributed to the belief that any causal involvement of caffeine is subject to a threshold. For example, in its most recent position statement on "nutrition and lifestyle for a healthy pregnancy outcome", the American Dietetic Association has specified a threshold of 300 mg/day, advising that pregnant women should avoid only higher levels of intake [113]. However, although there appears to be good agreement that caffeine can be harmful at higher levels of intake, there is no clear evidence-based reason that explains why immunity from harm is conferred at lower dietary levels. Moreover, as discussed above in

relation to cardiovascular disease, unreliability in the data due to imprecise measurement of dietary exposure to caffeine would appear to be a more likely explanation of any threshold of harm pertaining to maternal caffeine use. Indeed, with regard to the particular threshold advised in this context, 300 mg/day cannot reasonably be regarded as "high", since that level of intake can be readily reached and exceed by consuming as little as 2 cups of brewed coffee. All things considered, abstinence, as frequently recommended in relation to tobacco and alcohol, would appear also to be the most appropriate recommendation regarding caffeine use during pregnancy.

Adverse Interactions Between Caffeine and Other Drugs

Considering the near-universal use of caffeine, it is inevitable that the taking of other drugs will often coincide with that of caffeine. Regarding recreational drugs, it is commonplace to see smokers light up when drinking a caffeine beverage, and indeed cigarette smokers consume more caffeine on average than non-smokers. Similarly, alcohol is sometimes consumed in conjunction with caffeine, either as separate beverages or, as appears to be increasingly popular among younger-age groups, in a single beverage containing both alcohol and caffeine. Caffeine is also sometimes used to "cut" illicit drugs such as heroin, cocaine, and amphetamine, with the users of those drugs sometimes consuming substantial amounts of caffeine even when not intending to do so. Particular concerns, however, arise in relation to pharmaceuticals with which caffeine may interact adversely or whose therapeutic efficacy may be undermined by caffeine (e.g., benzodiazepines and some antibiotics) [89, 95].

Is Caffeine Addictive, and Is There a Safe Level of Consumption?

The evidence reviewed above indicates that dietary caffeine is a probable risk to cardiovascular health, poses a threat to fetal growth, interacts adversely with common therapeutic drugs, and produces dysphoric effects after brief abstinence. Therefore, taking account of its widespread and persistent use, should caffeine be considered a drug of addiction? Physical dependence is a common feature of drugs widely regarded as addictive. On this point, the evidence is conclusive; the occurrence of a characteristic syndrome of abstinence effects shows that repeated caffeine use leads to the development of physical dependence. Accordingly, it may reasonably be said that caffeine is a drug of addiction. On the other hand, the term "addiction" has wide currency, and carries a variety of emotive connotations (e.g., illegal importation, criminal syndicates, and violent crime) that have little relevance to dietary caffeine. Accordingly, it might be prudent not to be too strident in labeling caffeine an "addictive" substance. This stance, however, should not distract us from the evidence that dietary caffeine is harmful.

Considering the evidence of harm, it is appropriate to ask: Is there a safe level of consumption? As previously stated by this author, a balanced (if unpopular) answer to this question is that there is no daily level of intake that can be regarded safe [95]. The equivalent of as little as 1 cup of coffee produces modest increases in blood pressure lasting 2–3 h, which over the course of a lifetime is likely to contribute to increased cardiovascular disease; any exposure to caffeine during pregnancy exposes the fetus to a dose equivalent to that received by the mother; caffeine interacts negatively with therapeutic medications, and dietary use produces physical dependence.

Reducing and Quitting Caffeine Consumption

Despite strengthening evidence that dietary caffeine is harmful, few reports exist of systematic efforts for assisting habitual consumers to reduce or cease their use of the drug. Indeed, following a brief rise in interest about 2 decades ago, reports of systematic attempts to manage caffeine intake

appear to have all but disappeared from the literature. One early commentary on the subject more than a century ago advised that negative withdrawal effects could be avoided by a gradual reduction of caffeine [18]. That advice has stood well the test of time. Using a single-subject experimental design, Foxx and Rubinoff [51] reported favorable results for three participants who received a program of behavioral intervention based on nicotine and cigarette "fading" methods that the same research group had developed for smokers (e.g., [49, 50]. Treatment consisted of a combination of self-monitoring and a series of predetermined step-wise reductions in daily caffeine consumption in the direction of a specified terminal goal of reduced daily intake. Subsequently, Foxx [48] obtained follow-up data from the three original participants, reporting that the reduced intake of all three was substantially maintained 40 months following the termination of treatment. Bernard et al. [13] employed similar procedures with a single subject, and again reported favorable results.

These generally promising initial findings were confirmed in a larger study by James et al. [107] in which 27 chronic heavy caffeine consumers were monitored before and during a 4-week treatment program and at 6- and 18-week follow-up. However, because the results of this and previous caffeine-reduction studies were expressed solely in terms of participant self-reports, the reliability of the findings could be open to question. Accordingly, James et al. [107] reported plasma concentrations of caffeine and its primary demethylated metabolites (paraxanthine, theophylline, and theobromine) as well as self-reported caffeine intake during the course of a caffeine-fading regimen similar to that employed in the previous study by the same authors [106]. Overall, the 12 subjects, each with a history of heavy caffeine use, provided highly reliable self-reports of caffeine intake during the course of the 18-week program. However, unlike the earlier studies in which follow-up data had been obtained, participants in the James et al. [107] study showed signs of relapse at 12 weeks follow-up.

It has long been known that the accuracy of self-reports is enhanced when subjects are aware that their behavior may be independently checked (e.g., [141, 161]. Hence, the independent measurement of plasma caffeine levels in the James et al. [107] study may have encouraged subjects to be more accurate than participants in previous studies in reporting follow-up caffeine intake. If accurate and generalizable, the relapse reported by James et al. [107] is broadly consistent with reports of treatment outcomes for other dependence-producing substances. Although the reasons for the relapse observed by James et al. [107] remain unclear, relapse would not appear to have been due to the direct influence of withdrawal effects, since the resumption of higher levels of consumption did not occur until many weeks after the original treatment goal had been achieved. As such, firm statements cannot be made at this time regarding the long-term level of success of attempts to reduce caffeine intake. Nevertheless, it is clear from the available evidence that motivated individuals wishing to reduce or quit their use of caffeine can do so without experiencing pronounced (if any) negative withdrawal effects, provided that intake is reduced in a graduated (step-wise) fashion rather than abruptly (as when "going cold turkey").

Does Caffeine Have Health Benefits?

There has long been interest in caffeine beverages as possible sources of benefit, and much of that interest has centered on the putative benefits of caffeine for psychomotor performance and mood. However, as discussed above, there is now a firm body of evidence showing that caffeine has little or no net benefits for performance or mood. At the same time, at least partly fostered by industry-sponsored research, there has been substantial growth in interest in caffeine beverages as possible sources of benefit for physical health, especially in relation to diabetes and Parkinson's disease.

Type 2 Diabetes Mellitus

Several epidemiologic studies in the United States and Europe have reported significant dose-dependent reductions in the risk of developing Type 2 diabetes mellitus in association with caffeine and coffee consumption (e.g., [2, 191, 193, 231, 232]). While findings have prompted some authors to claim that caffeine and coffee protect against Type 2 diabetes, it is important to note that the studies in question were non-experimental and shared many of the same potential confounder effects that have generally undermined interpretation of epidemiologic studies of caffeine and health. More importantly, experimental studies have found the opposite pattern of results than would be expected from the population studies.

Double-blind placebo-controlled trials have consistently found that caffeine impairs glucose tolerance and decreases insulin sensitivity, and the findings have been reported for a wide range of participant groups including persons with diabetes and those without (e.g., [62, 118, 124–126, 140, 170, 232]). As such, it is difficult to reconcile how caffeine could offer protection against Type 2 diabetes when experimental studies have shown that it compromises glucose metabolism both before and after development of the disease. Thus, although caffeine appears distinctly unlikely to confer any protection against the development of diabetes, one issue is whether there may be a compound other than caffeine in coffee that offers such benefit. If such a compound exists, to be of benefit, it would need to be sufficiently potent not only to negate, but to exceed, the negative effects of caffeine.

Parkinson's Disease

There is a substantial body of recent epidemiologic evidence of an inverse association between caffeine consumption and the development of Parkinson's disease (e.g., [9, 74, 192]). This finding has been widely assumed to be causal, and has contributed to speculation about the "neuroprotective" action of caffeine. In particular, attention has focused on interactions between the dopaminergic and adenosinergic systems and caffeine's putative ability to forestall dopaminergic neuron degeneration through its action on the A_{2A} adenosine receptor (e.g., [21, 24, 115, 154, 199, 224]). An earlier population study by Jarvis [108] is sometimes cited as supportive of the idea that caffeine has neuroprotective properties. In a cross-section of the population, Jarvis reported that higher caffeine intake was positively related to better performance on certain psychomotor and cognitive tasks, and the effect was reported to have been larger in older participants. However, a more recent prospective study involving a larger population sample found little evidence of improved performance associated with caffeine consumption or of reduced age-related cognitive decline [230].

Moreover, Evans et al. [39] recently suggested that the inverse association between caffeine consumption and Parkinson's disease, as well as the similar relationship that exists with cigarette smoking (which has fostered the belief that nicotine is neuroprotective), may be "epiphenomena" rather than causal. Broadly, Evans et al. [39] argued that confounding due to individual differences in the personality disposition of impulsive sensation seeking may have led to misunderstanding of the findings. The authors cited evidence that sensation seeking is inversely associated with Parkinson's disease, with higher sensation seeking also being associated with higher caffeine consumption and smoking. Evans et al. [39] hypothesized that there are biological features characteristic of low-sensation-seeking individuals that also predispose to Parkinson's disease. Thus, rather than indicating any neuroprotective capability, higher caffeine and nicotine intake may simply be two behavioral manifestations of a generalized personality disposition, namely, impulsive sensation seeking, which itself is the expression of a biological substrate that confers a level of protection against the development of Parkinson's disease.

"Other" Active Compounds in Caffeine Beverages

Notwithstanding the strength of the evidence that dietary caffeine poses a number of significant risks to health, an important caveat arises when other compounds in caffeine beverages are considered. Whereas caffeine is generally accepted as being the main biologically active ingredient of those beverages, the presence of other compounds also having biological effects has become a focus of interest. Of course, the "other" active compounds could have either positive or negative implications for health. An example of the latter is the presence of a cholesterol-raising factor in unfiltered brewed coffee [194, 228, 243, 248]. However, influenced by industry-sponsored research over the past decade, interest has been strengthening in the search for beneficial effects from non-caffeine active compounds in coffee and tea (e.g., the relation between coffee and Type 2 diabetes mentioned above).

Accordingly, any assessment of the overall health implications of caffeine beverages must take account of the benefits, if any, of these other compounds. For example, it is claimed that polyphenols, especially chlorogenic acid, in coffee have potential cardiovascular benefits due to antioxidant properties (e.g., Bonita et al. [16]). Similarly, theanine, a non-proteinic amino acid, has been posited as having a blood pressure-lowering effect (e.g., [186]). At the same time, it must be emphasized that a notable feature of research into the benefits of caffeine beverages is the involvement of the caffeine industry at all levels of research, including basic and applied animal and human studies, and the production of published scientific articles including empirical studies and literature reviews. By any measure, industry involvement is extensive, even pervasive, and the conflicts of interest inherent in industry-sponsored research (including the dissemination of research findings) raise serious questions regarding the increasing frequency of "scientific" claims for the benefits of caffeine-containing beverages. In short, for some time, the integrity of caffeine science has been under threat.

Threats to the Integrity of Caffeine Science

Industry Influences on Research

The available experimental evidence, and to a lesser extent the epidemiologic evidence, supports the conclusion that caffeine use is a likely risk factor for health. Notwithstanding the importance of the implications of this conclusion for population health, there is little organized effort to inform and to advise the public on ways consistent with the magnitude of that threat. Indeed, it is evident from a close examination of the caffeine literature that this is a field of enquiry marred by a considerable amount of misinformation and misrepresentation. In particular, it is necessary to confront the reality that the academic pursuit of research on caffeine is extensively linked to the trade in caffeine products. Each of the main sources of caffeine, namely, coffee, tea, soft drinks, and energy drinks, is a multinational, multibillion dollar enterprise. By their own account, these industries have sought to lessen the impact of scientific findings that could threaten their commercial interests (see James [93, 98]).

Over the past quarter-century, various methods have been employed by industry to influence public opinion about caffeine and caffeine products. Such attempts include dissemination of selective information and funding for selected caffeine research [93]. During the 20 years from 1962 to 1982, the average number of cups of coffee consumed per day in the United States declined 39% [153], and it is evident from caffeine-industry publications that manufacturers attributed much of that decline to increased public awareness of scientific concern about possible caffeine-induced harmful effects [93]. Around 1990, there was an arrest in the downward trend, and thereafter a reversal evidenced by substantially increased sales of all categories

of caffeine beverages. Manufacturers of caffeine products appear to have been in no doubt about the reason for the improved commercial outlook for caffeine products. Industry representatives congratulated themselves on the success of their campaign to counter scientific findings that threatened their interests [75, 179]. In this regard, there appear to be parallels between actions by the caffeine industry to protect its commercial interests and similar activities by the tobacco and alcohol industries.

One influential industry body is the International Life Sciences Institute, which lists its Committee Members as including Coca-Cola, Kraft Foods, Mars, Nestlé, Procter & Gamble, Unilever, and others having commercial interests in caffeine products [85]. The International Life Sciences Institute actively pursues affiliations with the United Nations Food and Agriculture Organization and the World Health Organization, and is directly and extensively involved in publicly funded European Union research in areas of interest to its members [98]. The International Life Sciences Institute and the companies it represents commission scientific research into caffeine, and take an active role in sponsoring the production of scientific literature on caffeine [85]. Although affiliation with industry and material assistance from industry do not themselves constitute evidence of wrongdoing, such collaboration is worryingly commonplace in caffeine research (e.g., [15, 22, 85, 186]).

Despite being reported to have been extensively involved in assisting the tobacco industry to counter the World Health Organization's efforts to promote tobacco controls, especially in developing countries, the International Life Sciences Institute describes itself as having ongoing close involvement with the World Health Organization's activities [76]. A World Health Organization Committee of Experts on Tobacco Industry Documents reported that for many years tobacco companies operated with the "purpose of subverting the efforts of the World Health Organization to address tobacco issues [and that the] attempted subversion has been elaborate, well financed, sophisticated and usually invisible" [254] (p. 18). Subsequently, the Tobacco Free Initiative, a World Health Organization project, identified the International Life Sciences Institute as one such group [145, 160]. Moreover, the International Life Sciences Institute has been the subject of editorial criticism for its reticence in declaring a possible conflict of interest regarding its involvement in a publication concerned with health issues related to alcohol consumption [38]. The picture that has emerged is of an "institute" presenting itself as dispassionate and independent, while actually serving as a "third party" representative of commercial interests [98].

The research community needs to heed the dangers of industry influence on research. It is important that ways are found for ensuring exposure of possible conflicts of interest where they are not freely declared. Where possible conflicts do exist, ways must be found to safeguard against resulting threats to scientific integrity [98]. The importance and urgency of steps by the scientific community to counter such threats is highlighted by empirical evidence of bias attributable to pharmaceutical industry involvement in biomedical research. For example, in a study of the association between funding source and conclusions in randomized medication trials, Als-Nielsen et al. [4] found that after adjustment for study characteristics, industry-sponsored trials were 5 times more likely to yield conclusions favorable to industry's commercial interests than trials funded by nonprofit organizations.

Conflict of Interest and the Self-Serving Bias

A conflict of interest exists when an ethical or professional interest clashes with a pecuniary self-interest. Although a necessary prerequisite for openness, the mere declaration of a conflict of interest is unlikely to foil outcome bias in industry-sponsored research. For one thing, a simple declaration provides no basis for consumers of scientific research, including

scientists, policy makers, and the public, to judge the nature and extent of any consequential bias. Indeed, drawing on relevant experimental findings from social psychology, Dana and Loewenstein [32] have argued that declaring a conflict of interest can actually be counterproductive by exacerbating the declarer's bias. Dana and Loewenstein [32] explained that part of the difficulty in dealing with the problem is that it is usually assumed that bias founded on a conflict of interest is a matter of deliberate choice. This perspective contributes to the indignation that is sometimes expressed when the subject is raised. Unfortunately, however, the "deliberate choice" view of bias arising from conflicts of interest is inconsistent with empirical findings, which show that even when individuals try to be objective their judgments are subject to an unintentional self-serving bias [32]. In other words, self-serving bias is part of human nature. It is the role of the scientist to safeguard the integrity of research in the face of human limitations.

Indeed, unintentional self-serving bias might help to explain some apparent contradictions alluded to above. Weinstein [246] has shown that "behavioral performance tends to produce perceptions supportive of the behavior" (p. 2). If so, it is likely that caffeine consumers will be more readily accepting of conclusions consistent with their own extant caffeine-consuming behavior than findings that conflict with such behavior. Thus, it is possible that a subtle inherent self-serving bias inclines consumers of caffeine products to be more influenced by neutral or positive findings concerning caffeine than is engendered by more objective assessments. Furthermore, since most people consume caffeine daily, it is likely that the large majority of researchers, reviewers, and editors of scientific literature are caffeine consumers. As such, the resulting impact of an inherent self-serving bias on the way scientific findings are promulgated could be pervasive. For example, experimental findings are ordinarily accepted as providing stronger evidence of causal relationships than epidemiologic findings. Yet, the opposite view could be said to have been in operation in a number of important areas of caffeine research. In relation to cardiovascular disease and Type 2 diabetes mellitus, in particular, there appears to have been a tendency to ignore experimental findings of likely harm in favor of accepting epidemiologic findings of no harm. Unfortunately, however, there is relatively little published literature addressing the topic of self-serving bias in science, and as such little systematic knowledge has accumulated as to the extent of industry-based threats to scientific integrity.

Conclusions

Claims that dietary caffeine is of little importance to health are ill founded. Short-term withdrawal of caffeine has negative effects on psychomotor performance and mood, and these effects may reoccur chronically in habitual consumers. Caffeine produces modest increases in blood pressure that have long-term implications for cardiovascular health, caffeine interacts adversely with some medicines, and there is suggestive evidence of increased risk of spontaneous abortion and lower birth weight associated with caffeine use in pregnancy. Conversely, there is little or no satisfactory evidence of net benefits of dietary caffeine. Although further evidence is needed, it is unlikely that adverse effects are necessarily limited to groups characterized as "heavy" consumers. Notwithstanding the need for further research, the extensive involvement of industry bodies in that research effort raises questions concerning the integrity of caffeine science.

Serotonergic Hallucinogens

Mireille M. Meyerhoefer

Contents

Introduction

This chapter focuses on hallucinogens with psychoactive properties mediated through the serotonin system. Although commonly referred to as "hallucinogens", a lexigraphic disclaimer is warranted as the psychological experience elicited by these drugs centers on distortion of perception, not true hallucinations. The historical term "psychotomimetic" is also inaccurate as the state they produce has proven to be a poor model for schizophrenia. The most apt term is probably "psychedelic" from the Greek *psukhē*, meaning "mind" and *dēloun,* meaning "reveal" or "make visible". While the enlightenment sought by recreational users may be an artifact of the psychoactive experience, researchers study these compounds hoping to gain insight into how the brain produces the mind. Nonetheless, in conforming to common usage, in this chapter these drugs will be referred to as "hallucinogens".

History

Perceptions provide reassurance into our existence and the existence of the world around us. Thus it is not surprising that compounds capable of producing altered states of perception are regarded with mystical fascination and trepidation. The ritualistic consumption of plants, many of which derive there psychoactive properties through the serotonin system, has been an important part of religious and social ceremonies throughout human history.

Conceivably the oldest known ritualistic use of hallucinogens was in the Indus Valley during the second millennium B.C. A group of people known as Aryans worshiped a deity they named "Soma", which recent evidence suggests is the mushroom Amanita muscaria or Fly agaric [140]. This red and white spotted mushroom incidentally bears resemblance to the mushroom featured in the Mario Brothers video game worshipped by many adolescents in the second millennium A.D.

Spiritual use of hallucinogens has been a part of various cultures throughout the world. In the fourteenth century A.D., Aztecs and other Indians of Central America took psilocybin containing mushrooms to bestow powers of clairvoyance during religious ceremonies. Contemporary South American and Caribbean peoples snorted a narcotic powder (Cohoba) which, reminiscent of modern club drugs was used to promote friendliness during convulsive dance ceremonies. In Western cultures, hallucinogens may underlie mythos of witchcraft and sorcery. In his book *Hallucinogens and Shamanism* (1973), Michael Harner relates the symbol of a witch riding on a broomstick to the practice of medieval women achieving magical powers by anointing their mucous membranes with hallucinogenic substances. In a similarly clever fashion, Linnda Caporael hypothesized that that the affliction of the girls sparking the Salem witch trials resulted from ergot (the natural substance from which lysergic acid diethylamide is derived) poisoning caused by ingestion of rye grains contaminated with the fungus Claviceps purpurea [21]. More recently a study conducted by Griffiths et al. at the Johns Hopkins University found that when administered under supportive conditions psilocybin occasioned experiences similar to spontaneously occurring mystical experiences [50].

The modern synthetic drug era began in the late 1960s with the legendary synthesis of lysergic acid diethylamide by the Swiss chemist, Albert Hoffman. While working at Sandoz Laboratories, Hoffman synthesized lysergic acid diethylamide as part of an effort to develop ergot derivatives capable of reducing post-partum bleeding. Not useful in this regard, the compound was shelved. Five years later, according to psychedelic lore, Hoffman was haunted by a "peculiar presentment" and repeated its synthesis. After accidentally absorbing a small amount he experienced its psychoactive effects while bicycling home. Psychedelic enthusiasts refer to this fateful day, April 16th 1943, as "Bicycle Day".

In the 1960s and 1970s, Timothy Leary brought lysergic acid diethylamide and other psychedelics to the forefront of pop culture. His introduction of psychedelic drugs to academic and therapeutic settings led to the research responsible for most of what is currently known about these drugs. However, his temerarious promotion of these drugs for individual enlightenment and the ensuing underground abuse precipitated strict government regulation, which for several decades halted any legitimate research.

Prior to the Drug Abuse Control Amendments to the Harrison Narcotics Act in 1965 lysergic acid diethylamide was used as tool, albeit with debatable efficacy, in analytic therapy to uncover repressed memories and to elicit therapeutic abreactions [19, 115]. Attempts were also made to treat obsessive compulsive disorder, childhood schizophrenia, sociopathy, and alcoholism [4]. Perhaps thwarted by government restrictions, there have been no well designed studies confirming a clear therapeutic use for these drugs in treating somatic or mental illnesses. Today, restrictions on research have loosened and an organization known as the Multidisciplinary Association for Psychedelic Studies assists scientists in designing, obtaining approval and carrying out research on psychedelic drugs.

In the 1980s, attention to hallucinogen use reemerged with the trend of all night dance parties known to as raves. These large gatherings feature electronic dance music and laser light shows. Attendees often use psychedelic drugs to promote sociality and heighten the sensory stimuli of the music and lights. While 3,4-methylenedioxymethamphetamine (also known as Ecstacy) is the most notorious club drug, lysergic acid diethylamide and the traditional psychedelics make more than cameo appearances.

Epidemiology

Hallucinogen use has declined since the 1970s with the annual prevalence remaining below ten percent [66, 96, 99, 102]. The types of hallucinogens used have also changed. Lysergic acid diethylamide which was the most widely used

hallucinogen has been surpassed by psilocybin and newer synthetic club drugs. The National Survey on Drug Use and Health released a report describing patterns of hallucinogen use between 2004 and 2005 in persons over 12 years of age. Just over 1.5% of persons reported having used hallucinogens in the preceding year with use among males being twice that of females. On average, 943,000 persons tried hallucinogens for the first time each year and of these first time users 52.3% tried psilocybin mushrooms and 42.9% tried ecstasy. First time female users were more likely to have tried ecstasy (49.5% vs. 37.7%) while first time males were more likely to have tried psilocybin (61.1% vs. 41.1%). Highest rates of use are in persons between the ages of 18–25 [131], and there is a positive correlation between hallucinogen use and years of education [5].

Classification

Serotonergic hallucinogens can be divided by chemical structure (Fig. 1). Indolealkylamines, which have more than one carbon ring and are structurally similar to serotonin, include lysergic acid diethylamide, ibogaine, psilocin, psilocybin, and *N,N*-dimethyltryptamine. The phenethylamines because they have only one carbon ring more closely resemble amphetamine and the catecholamine neurotransmitters (dopamine, epinephrine, and norepinephrine). This class is comprised of mescaline, 3,4-methylenedioxymethamphetamine (or ecstasy), 3,4-methylenedioxyamphetamine, and dimethoxymethylamphetamine. The psychopharmacology of all of the serotonergic hallucinogens (except for Ecstacy) is similar.

Indolealkylamine			
Serotonin 	LSD (d–lysergic acid diethylamide)		Average dose: 30–300 µg Onset: 5 minutes Duration: 12 hours
	DMT (N,N–dimethyltryptamine)		Average dose: 60–100 mg smoked or intramuscular Onset: 3 minutes Duration: 30 minutes
	Ibogaine (12–methoxy–ibogamine)		Average dose: 2 to 5 grams Onset: 45 minutes Duration: up to 24 hours
	Psilocybin (O–phosphoryl–4–hydroxy–N,N–dimethyltryptamine)		Average dose 10–30 mg Onset: 10–40 minutes Duration: 2–6 hours
	Psilocin (4–hydroxy–N, N–dimethyltryptamine)		(The active metabolite of psilocybin)
Amphetamine 	Phenethylamine		
	Mescaline (3,4,5–trimethoxyphenethylamine)		Average dose: 300–500 mg Onset: 30 minutes Duration: 10–12 hours
	Ecstasy (MDMA; 3,4–methylenedioxymethamphetamine)		Average dose: 80 to 160 milligrams Onset: 30–45 minutes Duration: 6 hours
	DOM (2,5–dimethoxy–4–methylamphetamine)		Average dose: 3–10 mg Onset: 30 minutes to 1 hour Duration: 14–20 hours
	MDA (3,4–methylene-dioxyamphetamine)		Average dose: 80 to 160 mg Onset: 1 to 1.5 hours Duration 6 to 10 hours

Fig. 1 Chemical structures of indolealkylamine and phenethylamine hallucinogens

In order to avoid redundancy, this chapter begins with a general discussion of mechanism of action and then concentrates on representative idolealkylamines (lysergic acid diethylamide and psilocybin) and phenethylamines (mescaline and 3,4-methylenedioxymethamphetamine) with lysergic acid diethylamide serving as a prototype for comparison. Of note, although 3,4-methylenedioxymethamphetamine is technically a phenethylamine its pharmacology and psychoactive properties are different enough to warrant a separate discussion.

Mechanism of Action

After nearly a half a century of research, it is currently understood that the psychoactive effects of both indolealkylamine and phenethylamine hallucinogens are mediated primarily through agonist activity at the 2A subtype of serotonergic receptors (serotonin-2A receptors). The structural resemblance of indolealkylamines to the serotonin neurotransmitter led researchers to suspect their psychoactive effects were serotonergically mediated. Furthermore, the reported similarity of psychic experiences elicited by the phenethylamines and the indolealkylamines [57] as well as cross-tolerance between the two classes [13, 143, 145] suggested a shared mechanism of action. With advancements in molecular biology, 14 distinct serotonergic receptors comprising seven families (serotonin-1–7) [15] were discovered. Determining which receptors mediate the psychoactive effects, however, presented a challenge. Ethical and legal restrictions precluded the use of human subjects leaving researchers to rely on animal models. Recognizing that perceptions, being subjective experiences, are impossible to unequivocally assess without verbal communication the astute reader may wonder how one could to tell if a rat is hallucinating. The reader should refer to a review article by Winter outlining the role of drug-induced stimulus control in uncovering the mechanism of action of serotonergic hallucinogens [144].

Serotonin Receptor

The monoamine family of neurotransmitters is comprised of serotonin, epinephrine, norepinephrine and dopamine. The serotonin receptor system is the most complicated. Fourteen distinct receptors belonging to seven families have been discovered so far. The system is made more complex by posttranslational receptor modifications, multiple G-proteins, phenotypic switching and crosstalk within and probably between receptor families [61]. All but one of the serotonin receptors are coupled to G-proteins. The serotonin-2A and serotonin-2C receptors are similar and often referred to as the serotonin-2A/2C receptor. There is a paucity of ligands with selectivity between these two subtypes making it difficult to rule out an ancillary role of serotonin-2C receptors in the psychoactive effects of hallucinogens [39].

The serotonin-2A receptor is located on chromosome 13q14-q21 and is comprised of 471 amino acids. It is coupled to $G_{q/11}$ and agonist activity stimulates hydrolysis of inositol phosphates which increases levels of cytosolic $[Ca^{2+}]$. Serotonin-2A receptors are widely distributed. Peripherally, they mediate vascular smooth muscle contraction, platelet aggregation, capillary permeability and they regulate hormone secretion. Centrally, they are located in the cortex, claustrum and basal ganglia.

Indolealkylamine Hallucinogens

Lysergic Acid Diethylamide

Street Information

Today, the majority of lysergic acid diethylamide is synthetic. However, it can be derived from two naturally occurring substances; the embryo of morning glory seeds (Rivea corymbosa) and Claviceps purpurea (the parasitic fungus mentioned above). Sunlight and chlorine—even at tap water concentrations—will inactivate

Fig. 2 Photographs of lysergic acid diethylamide taken from the United States Drug Enforcement Administration Website

lysergic acid diethylamide but it can be stored as a solid salt or dissolved in pure water as long as it is kept at low temperatures and protected from light and air [123]. Synthetic lysergic acid diethylamide is crystalline. It is crushed into a white odorless, tasteless powder that is dissolved and administered orally, sublingually, intramuscular or intravenous. Sublingual mediums include postage stamps, chewing gum or sugar cubes often decorated with new age symbols (Fig. 2).

Street names for lysergic acid diethylamide, as for all of the serotonergic hallucinogens, are creative and include, but are not limited to, "Acid", "Loony Tunes", "Elvis", "Window pane", "Dots", and "Mellow yellow". Lysergic acid diethylamide is extremely potent and can even be absorbed subcutaneously. Doses of 20–30 μg produce psychoactive effects in humans [49], and Hoffman estimated it to be five to ten thousand times more potent than mescaline [58]. Surprisingly, lysergic acid diethylamide has a large safety window with no reported human deaths. The only mortality associated with lysergic acid diethylamide has been an elephant that received 300 mg via dart rifle as part of an unusual experiment. He was also administered chlorpromazine and barbiturates; therefore, it is unclear whether lysergic acid diethylamide was in fact the cause of death [142].

Lysergic acid diethylamide is easily produced in great quantity. For example, 25 kg of ergotamine tartrate (a substrate for lysergic acid diethylamide) yields 5 kg of lysergic acid diethylamide or 100 million doses. The returns are lucrative as one dose of lysergic acid diethylamide costs less than one cent to make and sells for about 10 dollars [94]. Today, an average dose ranges from 100 to 300 μg, considerably lower than in the 1970s [24].

Physiological and Psychological Effects

Lysergic acid diethylamide is hepatically metabolized and has no active metabolites. It has a half-life of 3–5 h [8, 105, 112]. Psychoactive effects peak at 2–4 h and can last for up to 12 h depending on dose, tolerance, body weight, and age [123, 135]. Users of lysergic acid diethylamide typically experience autonomic symptoms within several minutes and psychoactive effects approximately 10 min later. The autonomic symptoms are mainly sympathomimetic, e.g., elevated blood pressure and pulse, diaphoresis, piloerection, nausea, uterine contractions, hyperreflexia, and tremor. Anisocoria (unequal pupils) and hippus (rhythmically dilating pupils) are not uncommon [117].

Not only does mood become amplified, but it can shift rapidly and some users have reported experiencing multiple moods simultaneously. Sensory perceptions become enhanced and distorted [68, 78, 97]. Typical descriptions include vivid colorful geometric shapes, trails of actual objects and seeing body parts separate from themselves. Dramatic complex disturbances may occur such as animation of inanimate objects or Satan's face appearing on someone's body [121]. Auditory distortions are less common. At higher doses, synesthesia may occur (perceiving a sensation in different modality such as hearing colors). Distortions in the sense of time include time halting, stretching, repeating, and ceasing to exist.

When the overall experience is perceived as enlightening or emotionally stimulating, it is referred to as a "good trip". Other times the experience might be nightmarish, with fears of insanity or losing control. Such negative experiences are referred to "bad trips". The cause of good

trips versus bad trips is not known. A "guide" is often enlisted to assist the user through the experience. Having a good trip does not predict subsequent good trips, and the reverse appears to be true as well. The psychic experience generally lasts 8–12 h and is often followed by a pleasant "psychic numbness".

Abuse and Dependence Potential

Tolerance to the psychological effects of lysergic acid diethylamide, but not the physiological effects, develops quickly [17]. In contrast to highly addictive drugs such as cocaine and heroin there does not appear to be a withdrawal syndrome and users usually do not develop cravings or seek higher and higher doses. Although humans self-administer lysergic acid diethylamide, it does not serve as reinforcement in animal models. In concordance with these observations, the United States Drug Enforcement Administration does not consider it to be an addictive drug [95].

Adverse Effects

Although lysergic acid diethylamide is considered relatively safe when compared with other drugs of abuse, there are case reports of respiratory failure, hyperthermia, and coagulopathies associated with massive doses [70]. Early on a relationship between lysergic acid diethylamide and chromosomal damage was suspected but this has been consistently refuted and lysergic acid diethylamide does not appear to be teratogenic [23]. Lysergic acid diethylamide, however, does induce uterine contractions which could disrupt pregnancy. In general, there are three main reasons why people who use lysergic acid diethylamide come to clinical attention: "the bad trip", "flashbacks", and persistent psychosis.

The Bad Trip

Bad trips occur in about one in ten lysergic acid diethylamide uses [33] and may lead to an emergency room visit. It is usually easy to figure out that the patient has taken lysergic acid diethylamide. In addition to the psychological and physiological symptoms described earlier, patients usually have a clear sensorium without memory impairment and are able to provide a complete history. Furthermore, they often are accompanied by someone who was with them when they took the drug and who can confirm the suspected diagnosis.

In some cases a "bad trip" from lysergic acid diethylamide may be suspected but a confirmative history cannot be attained. For example, the individual may have unintentionally been exposed, may have been poisoned or may simply be too agitated to provide a coherent history. Toxicology panels in most acute care settings do not routinely screen for lysergic acid diethylamide. In these cases, several additional etiologies should be considered such as intoxication with another hallucinogen, psychiatric illness, and delirium.

Differentiating lysergic acid diethylamide from other phenethylamine and indolealkylamine hallucinogens, for the most part, is academic as they are treated similarly. It is, however, important to differentiate lysergic acid diethylamide from phencyclidine intoxication as the pharmacological management differs. Lysergic acid diethylamide is never smoked; therefore, if an individual reports having smoked the hallucinogen, phencyclidine should be considered. In addition, individuals intoxicated on phencyclidine are often brought in by authorities because of extremely disorganized, inappropriate, or combative behavior.

Acute lysergic acid diethylamide intoxication and the "bad trip" may superficially resemble psychiatric illnesses such as panic disorder, schizophrenia, or the mania of bipolar disorder. Sympathomimetic symptoms, ocular abnormalities (hippos and anisocoria) and visual perceptual disturbances suggest lysergic acid diethylamide intoxication but are not pathognomonic. Time is the best way to differentiate lysergic acid diethylamide psychosis from schizophrenia or mania. After several hours without pharmacologic treatment, lysergic acid diethylamide

intoxication wears off. Mania and schizophrenia do not. While feeling overwhelmed, scared and afraid of losing control occurs in panic attacks, lysergic acid diethylamide intoxication is further characterized by dramatic and persistent perceptual distortions. As with any altered mental state, the clinician should have a low threshold for suspecting delirium. Unlike delirium, there is generally no fluctuation level consciousness with lysergic acid diethylamide intoxication.

The "bad trip" generally does not require inpatient hospitalization because of its time limited course and quick recovery. The patient should be placed in a quiet, non-stimulating environment and provided continuous reassurance that his or her state of mind is drug induced and will not result in permanent brain damage [129]. Given that most emergency rooms are chaotic and understaffed, this may not be a realistic option. Furthermore, the patient may be too disorganized or combative to be "talked down". When medications are needed, benzodiazepines are probably the best choice, as long as delirium has been ruled out. The use of neuroleptics should be reserved for instances where none of the aforementioned efforts have succeeded. High-potency (less anticholinergic) neuroleptics should be used because anticholinergic neuroleptics have been associated with paradoxical reactions [119], hypotension, and anticholinergic crises [79, 125, 126].

Flashbacks

Flashbacks are referred to as hallucinogen persisting perception disorder by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition when they cause significant distress. They are defined as "the transient recurrence of disturbances in perception that are reminiscent of those experienced during one or more earlier Hallucinogen Intoxications" [32]. The most common phenomena are visual distortions such as color confusion, geometric hallucinations and trailing, but the content of the flashback may involve any of the senses [60, 116]. It is not known what causes flashbacks. Theories include persisting damage to visual processing systems [1, 7], death of inhibitory cortical interneurons [3, 42], reverse tolerance [127], and that they are an atypical dissociative state [86].

Flashbacks may occur several days to several years after the antecedent use of lysergic acid diethylamide and have been reported with mescaline, phencyclidine and marijuana [69, 86]. Some users find these episodes pleasant and even refer to them as "free trips". For others, they are terrifying and recur frequently (hallucinogen persisting perception disorder). Obviously, they can be dangerous if they occur at an importune time such as while swimming or driving. An antecedent good trip does not predict a good flashback.

It is unclear what determines who will experience flashbacks and whether or not the experience will be pleasant. Flashbacks have reportedly been induced by a myriad of situations including stress, exercise, pregnancy, sexual intercourse, dark environments, flashing lights, monotony, and use of other psychoactive drugs [2, 9, 24, 74, 121]. It is estimated that anywhere from 15 to 60% of lysergic acid diethylamide users experience flashbacks [121, 141].

People experiencing flashbacks may seek treatment with their general physician, ophthalmologists, neurologists or psychiatrists with concerns about their vision, that they have a neurological disorder, or that they are loosing their mind. The best treatment, as with "the bad trip," seems to be reassurance [134]. There is no established pharmacological treatment, but case reports suggest that such individuals may respond to typical antipsychotics [11, 75, 87, 93], clonidine [73], benzodiazepines [4, 24, 134], naltrexone [76], or phenytoin [133]. The atypical antipsychotic risperidone may exacerbate hallucinogen persisting perception disorder [6, 10, 90]. In addition, there have been reports of both exacerbation [82] and reduction [147] of hallucinogen persisting perception disorder following treatment with selective serotonin reuptake inhibitors. Despite their efficacy and minimal side effects, benzodiazepines may not be the first-line treatment for many individuals with

flashbacks because of abuse potential. Given that the flashback experience is often precipitated by psychiatric illnesses as well as other illicit drug use, it is possible that the success of the medications listed above is related to treatment of concurrent illness. Regardless of treatment, the frequency of flashbacks tends to decrease with time.

Persistent Psychosis and Relationship to Mental Illness

Occasionally, lysergic acid diethylamide appears to precipitate a "persistent psychosis" characterized by visual hallucinations, mania, grandiosity, and religiosity [4]. It is estimated to occur in 0.08% [81] to 4.6% [38] of people who have used lysergic acid diethylamide. This syndrome has led to innumerable studies attempting to establish a relationship between lysergic acid diethylamide use and psychiatric illness. In general, these studies suffer from a multitude of weaknesses. It is beyond the scope of this chapter and not particularly fruitful to present all of the case reports and studies regarding lysergic acid diethylamide-related psychosis. For a comprehensive overview, the reader is referred to Abraham et al. [4].

Speculation that lysergic acid diethylamide could cause schizophrenia was based on [1] a perceived similarity between lysergic acid diethylamide-associated psychoses and schizophrenia and on [2] the observation that lysergic acid diethylamide is a serotonin-2A agonist and the atypical antipsychotics block serotonin-2A receptors. Although the two states are characterized by perceptual disturbances, they are otherwise dissimilar. Auditory hallucinations, delusions and negative symptoms, core features of schizophrenia, are not typical of lysergic acid diethylamide-related psychoses. The frequently reported symptoms of persistent psychosis (grandiosity, religiosity, visual distortions) are not characteristic of schizophrenia. In regard to the serotonin-2A receptor link, it is now clear that the serotonin-2A antagonistic properties of atypical antipsychotics do not lend superior efficacy in treating schizophrenia.

Psilocybin

Psilocybin, like lysergic acid diethylamide, is an indolealkylamine hallucinogen. Psilocybin can be derived from several genera of mushrooms—thus the street name "magic mushrooms." Psilocybe cubensis is the most common source of psilocybin. This mushroom grows on cow and horse manure in South America, Mexico, and most non-arid areas of the United States [128]. As with lysergic acid diethylamide, it was Albert Hoffman who isolated and then synthesized psilocybin. It was marketed by Sandoz laboratories under the trade name Indocybin® as a potential tool for psychotherapy in the 1960s.

Psilocybin and its active metabolite psilocin are both schedule I drugs. The spore prints, however, remain legal (except in California), presumably to provide mycologists the ability to grow pure psilocybin. Not surprisingly, several drug-oriented magazines advertise home cultivation kits that include live mycelia. The mushrooms can be eaten fresh, dried, or brewed. They are usually ingested orally but there is a case report of intravenous injection [28]. Psilocybin is metabolized into psilocin which responsible for the psychoactive effects [77]. Typical doses of psilocybin range from 4–20 mg (40 μg/kg) corresponding to 1–2 g of dried mushrooms [128]. Sympathomimetic symptoms occur at lower doses (3–5 mg), and psychological effects are elicited by doses above 8 mg [108]. Psychological effects begin within 30 min of ingestion, peak at 2–3 h, and dissipate by 12 h [33].

Physiological changes are less pronounced than with lysergic acid diethylamide and are composed mainly of mydriasis and slight elevation in blood pressure and heart rate [33]. The psychological experience is similar to the other indolealkylamine and phenethylamine hallucinogens and cross-tolerance develops rapidly

[64, 113]. Some users report a more spiritual experience with psilocybin, but this may stem from its well-known use historically in spiritual ceremonies. Griffiths et al. conducted a double-blind controlled study in which hallucinogen naïve subjects were given either psilocybin or amphetamine under conditions that would foster a spiritual experience. In this study, psilocybin occasioned sustained experiences similar to spontaneously occurring mystical experiences [50].

As with lysergic acid diethylamide, use of psilocybin from a physical standpoint, is relatively safe and the adverse reactions, albeit uncommon, are managed similarly. Only one third of "magic mushrooms" bought on the street actually contain psilocybin (many are simply store-bought mushrooms laced with phencyclidine) and there are many wild poisonous mushrooms. Adulteration and misidentification are the most common cause of serious adverse outcomes. As with the other serotonergic hallucinogens, tolerance develops quickly but physical dependence does not occur.

Phenethylamine Hallucinogens

Mescaline

Mescaline (3,4,5-trimethoxyphenylethylamine), commonly referred to as Peyote, is a phenethylamine hallucinogen found in several species of North and South American cacti. These cacti have been dubbed the "Divine Cacti" in reference to their several thousand year history of spiritual use by natives of Northern Mexico and the Southwestern United States. The North American peyote cactus, Lophophora williamsii, is a small, spineless cactus that grows in the Rio Grande and in parts of the Mexican plateau.

Mescaline was first isolated from peyote cacti in 1896 and was synthesized approximately 20 years later. It is extracted from the head (top) of the cactus which must be carefully cut at ground level to allow re-growth. Improper harvesting will kill the plant [80]. Because of improper harvesting in Southern Texas Peyote is now listed as an endangered species. Peyote, like the other serotonergic hallucinogens is a Schedule I compound. However, many states allow "bona fide religious" use by members of the Native American Church.

Natural peyote has a bitter taste. It is dried and chewed, soaked in water and drank or injected. Mescaline is typically sold as disk shaped "buttons" composed of either crushed peyote or synthetic mescaline. Genuine peyote is rare outside of the southwestern United States with less than 17% of street samples actually containing mescaline [120]. The hallucinogenic dose is approximately 5 mg/kg (0.3–0.5 g). Each button contains about 50–100 mg of mescaline [120], and users typically ingest 3–8 buttons [71].

Mescaline is markedly less tolerable than the other serotonergic hallucinogens. Within the first 30 min, before the onset of psychological symptoms, users experience nausea, vomiting, restlessness, and headaches [33, 59]. By 1–2 h, however, these unpleasant physiologic symptoms dissipate and the psychic phase characterized by euphoria, sensory distortions, and feelings of confidence begins. The entire experience lasts up to 14 h [33, 59]. As is the case with lysergic acid diethylamide and the other serotonergic hallucinogens, tolerance develops rapidly and physical dependence does not occur [67, 80]. Treatment of acute intoxication and adverse consequences as with lysergic acid diethylamide and psilocybin involves reassurance and use of benzodiazepines if necessary.

3,4-Methylenedioxymethamphetamine, also Known as "Ecstasy"

3,4-Methylenedioxymethamphetamine (ecstasy) is a synthetic drug, primarily smuggled into the United States from clandestine laboratories in Canada, Belgium, and the Netherlands

[34]. It differs from traditional indolealkylamine and phenethylamine serotonergic hallucinogens in structure, pharmacology and psychoactive properties, falling somewhere between amphetamine and mescaline. 3,4-Methylenedioxymethamphetamine was first synthesized in 1912. It was patented as a precursor for a psychotherapeutic agent in 1914, as a cough suppressant in 1956, as a tranquilizer in 1960, and as an appetite suppressant in 1961, but it was never marketed [22]. Rumors abound that the military tested its use as an interrogation tool hoping to capitalize on its ability to instill feelings of openness and intimacy [92]. In the early 1980s, 3,4-methylenedioxymethamphetamine was used in psychotherapy and was purported to improve self-esteem and therapeutic communications [47]. As with lysergic acid diethylamide, there are no data to support its efficacy, and in 1985 the United States Drug Enforcement Administration classified 3,4-methylenedioxymethamphetamine as a schedule I drug.

Pharmacology

While 3,4-methylenedioxymethamphetamine promotes the release and inhibits the breakdown of all monoamine neurotransmitters (serotonin, dopamine and norepinephrine), its most potent and probably most psychologically important interactions are with the serotonin system [41, 72]. In addition to releasing serotonin and inhibiting its breakdown by monoamine oxidase, 3,4-methylenedioxymethamphetamine blocks serotonin reuptake by the serotonin transporter. In total, these actions lead to an acute increase of monoamines in the synaptic cleft followed by neuronal completion within 4–6 hours [18, 31, 47, 92]. This depletion is exacerbated by its acute inhibition of tryptophan hydroxylase, the rate limiting enzyme in the synthesis of serotonin [16]. The rank order of potency for stimulating monoamine release is norepinephrine = serotonin > dopamine [107]. It is hypothesized that the psychological effects result from 3,4-methylenedioxymethamphetamine's effects on the serotonin system, while its physiological effects are adrenergically mediated [136].

In addition to these amphetamine-like effects, 3,4-methylenedioxymethamphetamine has affinity for serotonin-2, M1-muscarinic, H1-histaminergic, and α2-adrenergic receptors, but the clinical significance of this receptor binding profile is unclear. 3,4-Methylenedioxymethamphetamine also indirectly raises blood levels of adrenocorticotropin-releasing hormone, antidiuretic hormone, cortisol, dehydroepiandrosterone, oxytocin, and prolactin [31, 132]. Oxytocin and prolactin are naturally released following orgasm and childbirth and are thought to facilitate bonding. It has been hypothesized that 3,4-methylenedioxymethamphetamine-mediated release of these hormones results in the sense of intimacy central to the 3,4-methylenedioxymethamphetamine experience [106, 132].

3,4-Methylenedioxymethamphetamine is hepatically metabolized via the cytochrome P450 system [47]. It has saturable kinetics meaning that at higher doses metabolism is slower and toxicity is disproportionably more likely [29, 30, 47]. So far, identified metabolites include 3,4-methylenedioxyamphetamine, 4-hydroxy-3-methoxy-methamphetamine, 4-hydroxy-3-methoxyamphetamine, 3,4-dihydroxyamphetamine (also called alpha-methyldopamine), 3,4-methylenedioxyphenylacetone, and N-hydroxy-3,4-methylenedioxyamphetamine. The contribution of these metabolites to the psychoactive and toxic effects of 3,4-methylenedioxymethamphetamine is an area of active research [138].

3,4-Methylenedioxyamphetamine is known to be psychoactive and like 3,4-methylenedioxymethamphetamine it causes release of serotonin and produces an empathogenic experience [65, 118]. It also resembles the traditional serotonergic hallucinogens in that it has higher affinity for the serotonin-2A receptor and produces more profound sensory disturbances. Much of the toxicity associated with 3,4-methylenedioxymethamphetamine has been attributed to this metabolite [25]. In addition to being a metabolite of 3,4-methylenedioxy-

methamphetamine, 3,4-methylenedioxyamphetamine has been synthesized and is used recreationally under the name "Mellow Drug of America".

Street Information

3,4-methylenedioxymethamphetamine is universally referred to as Ecstasy but its street names includes "XTC", "X", "E", "M", "Rolls", "Beans", "Disco Biscuit", "Adam", "Clarity", "Lovers speed", and "Hug Drug". The practices of combining 3,4-methylenedioxymethamphetamine with lysergic acid diethylamide or psilocybin to produce a more powerful psychological experience are referred to as "Candy Flipping" and "Hippie Flipping" respectively. Mentholated products such as cigarettes or vapor rub are often used to heighten the drug's effects.

Ecstasy is distributed as small single-dose tablets of various colors often decorated with icons or phrases (Fig. 3). These tablets usually contain 15–150 mg of 3,4-methylenedioxymethamphetamine. The tablet form lends a pharmaceutical appearance and a false impression that the contents are safe and uncontaminated. However, pure ecstasy, as described below, is considerably less safe than perceived by most users and often the contents are contaminated with acetaminophen, stimulants or other hallucinogens [40, 46, 122, 146, 148]. Although ecstasy is usually ingested orally, the tablets can be either crushed and snorted or dissolved and injected [89, 113].

Ecstasy is classified with other synthetic drugs such as gamma-hydroxy-butyrate, ketamine, and flunitrazepam as a club drug

Fig. 3 Photographs of 3,4-methylenedioxymethamphetamine taken from the United States Drug Enforcement Administration Website

because of its popularity at dance parties, raves, and night clubs. In fact, it has been estimated that 3,4-methylenedioxymethamphetamine is present at seventy percent of raves making it the most prevalent club drug [98]. It follows marijuana as the second most commonly used control substance in Europe [26], and in 2004 the United Nations World Drug Report estimated that more than 8.3 million people worldwide had taken ecstasy. In 2007, according to the Monitoring the Future study, 6.5% of 12th graders reported having used ecstasy.

Physiological and Psychological Effects

3,4-Methylenedioxymethamphetamine is structurally similar to both amphetamine and mescaline however it is less stimulating and addictive then amphetamine and produces less profound sensory distortions than mescaline and the other serotonergic hallucinogens [20].

Physiological effects include sympathomimetic symptoms such as tachycardia, mydriasis, diaphoresis, tremor and hypertension [103]. Urinary retention, esophoria (eyes turning inward), trismus, and bruxisms are also common [63]. 3,4-Methylenedioxymethamphetamine users attempt to avoid the latter by sucking pacifiers or lollipops [124]. Interestingly, with repeated administration these adverse effects become more pronounced and the sought after psychological experiences diminish [48].

The psychological experience begins 30–60 min following oral ingestion, peaks at 60–90 min, and last from 4 to 8 h [47, 122]. Users initially feel agitated, have decreased thirst and hunger and experience a distorted sense of time. This is followed by increased energy with euphoria, enhanced sense of intimacy and social tolerance [36, 51, 91]. Its effects on sociality have earned it the vernacular name "the luv drug" and the proposed pharmacological classification as an "entactogen" or "empathogens" [100, 137]. Several days after ingestion of 3,4-methylenedioxymethamphetamine, users tend to experience depressive symptoms, referred to as "the midweek blues" [27, 48, 100, 137, 139].

There is no evidence at this time to suggest that 3,4-methylenedioxymethamphetamine is addictive. As is the case with lysergic acid diethylamide, dependence is unlikely because tolerance develops rapidly [48, 109].

Adverse Consequences

Compared with lysergic acid diethylamide, untoward psychological experiences are less common and less severe. They include over-arousal, sensory illusions, depersonalization, anxiety and occasionally panic attacks [109, 139, 148]. As is the case with the bad trip, benzodiazepines may be helpful [85, 104].

There is much speculation but no definitive evidence of permanent brain damage in humans. The speculation stems from findings in animal studies of an association between 3,4-methylenedioxymethamphetamine and sustained depletion of serotonin and 5-hydroxyindoleacetic acid, inhibition of tryptophan hydroxylase, loss of serotonin receptors and transporters, and loss of fine axons in various brain areas [47]. This evidence for brain damage in non-human species precludes ethical prospective studies in humans. Thus, as with lysergic acid diethylamide, the majority of studies attempting to clarify a relationship between 3,4-methylenedioxymethamphetamine use and long-term sequelae are retrospective and unable to control for poly-drug use or to pre-existing susceptibility to mental illness. Whereas repeated use of straight amphetamine is clearly associated with long-term brain damage, there is no clear evidence for a similar response to 3,4-methylenedioxymethamphetamine; however, only time will tell as the current cohort of club-drug users' age.

Unlike lysergic acid diethylamide, Ecstasy use has been associated with severe life-threatening adverse consequences [111]. The risk of death for first-time users is estimated to be between 1 in 2000 and 1 in 50,000 [45]. 3,4-Methylenedioxymethamphetamine has received much of its notoriety for causing severe hyperpyrexia leading to rhabdomyolysis, disseminated intravascular coagulopathy and multi-organ failure [56]. 3,4-Methylenedioxymethamphetamine, via its affects on serotonin and dopamine, resets the body's internal thermostat. This is compounded by the hot, aerobically intensive dance party venues where it is often used [55] and by the frequent augmentation with diuretics such as alcohol and caffeine.

3,4-Methylenedioxymethamphetamine users are also susceptible to developing another hyperthermic condition, serotonin syndrome, particularly if they have ingested other serotonergic drugs. This is not unlikely given the multitude of drugs with effects on serotonin. Recreational drugs such as amphetamines or cocaine may intentionally be combined with ecstasy. Inadvertent use of prescribed antidepressants as well as purposeful use of these drugs to boost the psychological effects of 3,4-methylenedioxymethamphetamine is also common. Unusual serotonin reuptake inhibitors such as phenylpiperidine opioids (methadone, meperidine, tramadol, propoxyphene) and monoamine oxidase inhibitors such as linezolid and isoniazide and ritonavir in combination with lysergic acid diethylamide might also precipitate a serotonin syndrome [43, 101]. Serotonin syndrome is characterized by muscle rigidity, shivering, tremor and increased deep tendon reflexes. The excessive muscle contraction leads to hyperthermia [43]. The associated mortality rate is 10–15% [51].

3,4-Methylenedioxymethamphetamine is associated with a host of other life-threatening consequences. It directly increases antidiuretic hormone release [54]. This combined with over hydration in response to the well publicized concern of hyperthermia may induce dilutional hyponatremia and subsequent cerebral edema [53, 83]. Symptoms include headache, delirium, irritability, nystagmus, and fatal cerebral herniation [41]. Perhaps because of its sympathomimetic properties, there have been numerous case reports of an association with intracranial hemorrhage, venous sinus thrombosis [44, 52, 62, 114] and sudden death due to cardiac arrhythmias [51, 56, 88, 130]. Interestingly, there also appears to be an

association, for unclear reasons, with pneumothoraces and pneumomediastinaum [11, 14, 84, 110]. Unrelated to hyperthermia-induced multi-organ failure, 3,4-methylenedioxymethamphetamine can cause liver failure that likely is mediated by a hypersensitivity reaction [12, 35, 37]. In individuals under 25 years old, Ecstasy is a common cause of hepatic injury and should be suspected in any young person presenting with liver damage [12].

Management of Acute Toxicity

Activated charcoal may be used in the acute management of 3,4-methylenedioxymethamphetamine toxicity in the unlikely scenario that the individual presents within 1 h of ingestion. Otherwise, management involves fluid replacement in dehydrated patients with hypotension and tachycardia and use of labetalol for tachycardia and hypertension. Antihypertensive medications blocking both α and β adrenergic receptors are preferable. Unopposed β receptor blockade may worsen hypertension due to loss of β adrenergic-mediated vasodilation. Treatment of severe hyperthermia, whether due directly to 3,4-methylenedioxymethamphetamine or 3,4-meth ylenedioxymethamphetamine-induced serotonin syndrome, involves rapid cooling and supportive measures provided in an intensive care setting. Severe cases require sedation, intubation and paralysis to decrease heat production from muscle contraction [51]. It is unclear at this point whether dantrolene is helpful [51].

Conclusions

In conclusion, many serotonergic hallucinogens are naturally occurring compounds that have been used for thousands of years to induce perception altering experiences. They have been an important part of spirituality in many cultures throughout history, likely reflecting the profundity of the experience they elicit. Fascination with these mind altering drugs continues as clandestine chemists persist in synthesizing more varieties. Surprisingly, despite their potent psychological effects, these drugs are considerably safer and less addictive than many other drugs of abuse such as heroin or cocaine. Ecstasy, the most popular of the synthetic compounds, differs considerably from the traditional serotonergic hallucinogens in pharmacology and psychoactive experience. Its empathogenic effects are attractive to young people and lend a false impression of safety as it already appears to be a more dangerous drug than the traditional serotonergic hallucinogens. The long-term effects have yet to be determined as the current 18–25 year olds are the first generation to use it in significant numbers.

Introduction

Ketamine and phencyclidine are chemically related to each other and have psychotropic effects similar to other prototypical hallucinogens such as lysergic acid diethylamide. Phencyclidine was developed first as a dissociative anesthetic for animals and humans, but seizures, recreational abuse and unpredictable effects have prevented its therapeutic use. Ketamine was developed after phencyclidine and has similar properties, although it is still used therapeutically as an anesthetic and analgesic in humans and animals. Most ketamine used illicitly is diverted from veterinary supplies. Both drugs have been abused since the 1970s and have become popular again in the 2000s, especially among young adults who are active in the club scene.

Pharmacology

Mechanism of Action

Ketamine and phencyclidine are arylcyclohexylamines, which are dissociative anesthetics that produce perceptual distortions similar to hallucinogens, as well as other effects, so they are often classified as hallucinogens. Ketamine is a derivative of phencyclidine that is less potent and shorter-acting, and is still used therapeutically in medical settings as an anesthetic and analgesic in humans [7]. Ketamine and phencyclidine selectively reduce the excitatory actions of glutamate on central nervous system neurons mediated by the *N*-methyl-*D*-aspartate receptor complex [3]. These receptors mediate ion flux through

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_28,

channels permeable to sodium, potassium, and calcium, and are involved in synaptic transmission, long-term potentiation, and neuron plasticity. Pharmaco-magnetic resonance imaging has confirmed that the subjective effects of ketamine are mediated by enhanced glutamate release [12]. In addition, phencyclidine affects mu opioid receptors [15], blocks dopamine uptake [4], and inhibits serotonin uptake [43]. Phencyclidine binds to specific receptors in the liver, kidney, lung, heart, and brain [48]. However, the exact mechanism of the effects of ketamine and phencyclidine has not been determined. Metabolism of ketamine and phencyclidine occurs in the liver by oxidation, hydroxylation, and then conjugation with glucuronic acid [49].

Routes of Administration

Ketamine and phencyclidine can be taken orally, inhaled intranasally, smoked, or injected intramuscularly, subcutaneously, or intravenously. Ketamine is obtained primarily in powder form and taken by intranasal insufflation ("snorting") of lines [22], which has a more rapid onset but a shorter duration of effects than when taken orally. Ketamine injection involves particular paraphernalia and high-risk practices [25]. Intramuscular injection is perceived as easier and less threatening than intravenous injection [26].

Phencyclidine is taken as a tablet ("PeaCe Pill," or "PCP"), powder ("angel dust"), or liquid ("whack"). It is smoked alone or when added to tobacco cigarettes or marijuana joints, a combination known as "fry" [35]. The onset of effects when smoked is almost immediate, similar to intravenous administration [30], and is much more rapid than when taken orally (onset takes more than an hour).

Epidemiology

Ketamine

Ketamine was developed in the 1960s as a surgical anesthetic [9]. Recreational use began in the 1970s on the U.S. West coast [36], but it was not registered as a scheduled drug in the U.S. until 1997 or until 2006 in the U.K. The prevalence of ketamine use appears to be stabilizing in the U.S. [23] but is rising in Europe and Asia [22]. There are many different street names for ketamine (Table 1). Nearly all ketamine users are polysubstance users, with 98% using drugs from three or more drug classes, such as inhalants and heroin [50].

Table 1 Street names

Ketamine	Phencyclidine
Cat Valium	Angel dust
K	Animal tranquilizer
Ket	Embalming fluid
Kit Kat	Fry
Special K	Hog
Super K	PCP
Vitamin K	Peace Pill
	Purple Haze
	Whack

The National Institute on Drug Abuse has identified six drugs as club drugs, including ketamine. Club drugs are licit and illicit drugs from different classes that are used primarily by young adults in bars, clubs, concerts, and dance parties or "raves". These substances are used illicitly in those settings due to the perception that they enhance the sensory experience at dance parties where strobe lights, glow sticks, and "techno" music (wordless music with a driving beat) are part of the overall event [46]. Over 40% of those who use club drugs have tried ketamine [28]. Regular ketamine users are older (in 20s as opposed to teens), employed, and better educated compared with most other club drug users [13]. Although ketamine use is very common among club goers—up to 66%—there is a very low prevalence of ketamine use among young people in the general population [50].

Separate from clubs and raves, ketamine is also frequently used in other settings, such as at home or a friend's house. In addition to club goers, it is used by young injection drug users [25], health care workers [32], and men who have sex with men [8].

Phencyclidine

Phencyclidine was first synthesized in the 1950s as a dissociative anesthetic for therapeutic use and originally described as a drug of abuse in the 1960s. Phencyclidine at various times has achieved popularity as a street drug with many different street names (Table 1), and is frequently sold in mixtures with other drugs [41]. Its use waxes and wanes because of its unpredictable effects. Its use increased in the 1970s and peaked in the 1980s but has experienced a resurgence in popularity since the late 1990s [5]. Although not classified as a club drug by the National Institute on Drug Abuse, phencyclidine is used by young adults in settings similar to other club drugs [5].

Trends in the popularity of specific drugs of abuse tend to be cyclic. Relatively large numbers of new users will experiment with a given drug or develop a pattern of recurrent use, often in combination with other substances. With more users, information about undesirable effects spreads among users, or public health concern prompts a response with dissemination of information about abuse and problems. Then the prevalence of abuse may subside for a while. Phencyclidine has gone through previous cycles of popularity because it is relatively easy to manufacture in clandestine laboratories. However, unpleasant effects of repeated use (including propensity to violence and psychotic symptoms, as well as a high frequency of "bad trips") result in a drop in popularity. Phencyclidine use is on the rise again, along with the use of ketamine as part of the club drug scene.

Abuse and Dependence

Diagnostic and Statistical Manual of Mental Disorders Criteria

The criteria in the text revision of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition [2] for abuse and dependence for ketamine and phencyclidine do not differ significantly from the general criteria for substance abuse and dependence (Table 2). Ketamine dependence falls under the heading of phencyclidine-like substances in the text revision of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition and does not have a separate diagnosis or criteria set. A specific withdrawal syndrome has not been identified for

Table 2 Abuse and dependence criteria

Abuse	Dependence
Maladaptive pattern of use leading to clinically significant impairment or distress, manifested by 1 or more of the following within a 12-month period:	Maladaptive pattern of use leading to clinically significant impairment or distress, manifested by 3 or more of the following within a 12-month period:
1. Recurrent use resulting in failure to fulfill major role obligations at work, school, or home	1. Tolerance, as defined by either: a. Need for markedly increased amounts to achieve the desired effect b. Markedly diminished effect with continued use of the same amount
2. Recurrent use in situations in which it is physically hazardous	2. Often taken in larger amounts or over a longer period than intended
3. Recurrent substance-related legal problems	3. Persistent desire or unsuccessful efforts to cut down or control use
4. Continued use despite recurrent social or interpersonal problems caused or exacerbated by the effects of the substance	4. Great deal of time spent in activities necessary to obtain, use, or recover from the effects of use
	5. Important social, occupational, or recreational activities are given up or reduced because of use
	6. Use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by use

these drugs, which is also the case for other hallucinogens. Therefore, criteria specific to withdrawal are not utilized to determine a diagnosis of dependence for either ketamine or phencyclidine. There are no other unique criteria for abuse or dependence on ketamine or phencyclidine in the text revision of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition.

Tolerance and Withdrawal

Tolerance develops rapidly to the desired effects [24], resulting in reduced length of the subjective experience and requiring an increase in dose to maintain the expected effects. Users escalate the amount used to achieve the full hallucinogenic experience, up to seven times the original amount [31]. Use of higher recreational doses can result in more adverse effects, especially physiological side effects. Use of very high doses can result in onset of full anesthetic effects, which may result in an overdose situation for a recreational user. Continued use of ketamine or phencyclidine despite experiencing these consequences constitutes addiction.

A definitive physiological withdrawal syndrome does not appear to develop after stopping use of ketamine or phencyclidine. Phencyclidine users who smoked at least weekly and acknowledge psychological dependence reported no withdrawal symptoms upon stopping [17].

Intoxication

Ketamine

Psychological Effects

Initial use of ketamine is primarily based on desire for experimentation and openness to new experiences, and secondarily for pleasure [31]. Appealing effects described by users include visual hallucinations and out-of-body experiences; undesirable effects include memory loss and decreased sociability [31]. General central nervous system depressant effects include poor concentration and poor recollection similar to alcohol intoxication, which is not unexpected for an anesthetic drug [37].

Ketamine effects include profound changes in consciousness and psychotomimetic effects such as changes in body image (feeling that the body is made of wood, plastic, or rubber) and possible feelings of spiritual separation from the body, including out-of-body experiences. At low doses, users describe mild dissociative effects, distortion of time and space, and hallucinations [31]. However, laboratory administration of ketamine to healthy volunteers resulted in no reported hallucinations [37]. At large doses, users experience severe dissociation with intense detachment such that their perceptions seem to be located deep within their consciousness and reality is far off in the distance; this is called the "K-hole" [31].

The analgesic and dissociative effects may result in injury or even death in users [31]. Emergency department visits associated with ketamine use increased 200 times from 1995 to 2002 [11]. Cognitive impairments can occur even when a user is drug-free, and frequent users have greater impairment than infrequent users when drug-free [10].

Physiological Effects

At low doses, ketamine causes stimulant effects with a temporary increase in blood pressure and heart rate, as well as diplopia and nystagmus [19]. Tachycardia and hypertension are the most common physical findings after illicit use [47]. Other findings of intoxication include pupil dilation and muscle rigidity. Rhabdomyolysis may result from muscle rigidity combined with exertion in severe agitation. Very large doses result in deep anesthesia with coma and respiratory depression [39]. Other physiologic effects of ketamine include severe gastric pain known as "K-cramps", but the etiology of this is unknown [31].

Management

Management of ketamine intoxication is primarily supportive, and adverse effects typically resolve over several hours for mild to moderate intoxication. A thorough history and physical examination, along with toxicological screening for the presence of ketamine, establish the diagnosis. A quiet environment without bright light can help reduce the agitation and psychotic behaviors that are due to overstimulation.

Additional supportive care may be required for severe intoxication or overdose. Benzodiazepines such as lorazepam are helpful for more severe agitation, anxiety, and/or muscle rigidity.

Phencyclidine

Psychological Effects

A reason for initial use of phencyclidine has been described as a desire for enhancement to the user's everyday life [14]. Reasons for continuation of use include feelings of strength, power, and invulnerability, as well as psychic numbing to self-medicate anger and dysphoric symptoms [17]. The phencyclidine experience is regarded as pleasant only half the time and aversive the other half, but some users report that this unpredictability of effects is an attractive feature [6].

Phencyclidine produces brief dissociative psychotic reactions, similar to schizophrenic psychoses. These reactions are characterized by changes in body image similar to those of ketamine as described above. Moderate phencyclidine intake may lead to a catatonic-like picture, with the individual staring blankly and not responding to stimuli; the eyes remain open, even when the individual is in a comatose state. At higher doses, users have great difficulty differentiating between themselves and their surroundings. Some users have religious experiences while intoxicated, such as feelings of meeting God or knowledge of their own impending death [16].

A dissociative phenomenon occurs occasionally, with phencyclidine abusers exhibiting dangerous or violent behaviors [27]. The individual also may appear psychotic. Previous psychiatric history is associated with a higher likelihood for assaultive behavior from phencyclidine use [29]. Levels of consciousness may fluctuate rapidly while the individual is recovering from the intoxication. The effects of phencyclidine can last for several days since it is one of the longest-acting drugs of abuse.

Physiological Effects

In low-dose intoxication, the individual presents with nystagmus, confusion, ataxia, and sensory impairment. This is the only drug of abuse that causes a characteristic vertical nystagmus (it can also cause horizontal or rotatory nystagmus), which helps to identify it as the cause when an individual presents with intoxication by an unknown drug. The text revision of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition provides a specific criteria set for phencyclidine intoxication [2] based primarily on physiological signs and behavioral changes (Table 3). Three stages of phencyclidine intoxication have been described [38], and individuals may fluctuate between the first two stages for several hours; the third stage occurs when individuals take high doses (Table 4).

In high doses, the drug produces seizures and severe hypertension. The hypertension should be treated vigorously since it may cause hypertensive encephalopathy or intracerebral bleeding. Phencyclidine can also cause life-threatening hyperthermia with temperatures over 106°F, which may occur many hours after use.

Management

The most effective treatment of phencyclidine intoxication is increasing its urinary excretion

Table 3 *Diagnostic and Statistical Manual of Mental Disorders* criteria for phencyclidine intoxication

A. Recent use of phencyclidine (or a related substance)
B. Clinically significant maladaptive behavioral changes that developed during or shortly after phencyclidine use. For example: Belligerence Assaultiveness Impulsiveness Unpredictability Psychomotor agitation Impaired judgment Impaired social or occupational functioning
C. Within an hour (less when smoked, "snorted", or used intravenously), 2 (or more) of the following signs: 1. vertical or horizontal nystagmus 2. hypertension or tachycardia 3. numbness or diminished responsiveness to pain 4. ataxia 5. dysarthria 6. muscle rigidity 7. seizures or coma 8. hyperacusis
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

by acidifying the urine with ammonium chloride or ascorbic acid [45]. Urine acidification should only be performed after it is determined that the individual does not have myoglobinuria (indicating rhabdomyolysis) to prevent the development of acute renal failure. Some practitioners feel that the benefits of urine acidification are outweighed by the risks, especially in individuals with hepatic or renal impairment. If the individual is at low risk for hepatic or renal disease, acidification can be initiated. The urine pH should be monitored and kept around 5.5, after which a diuretic can be administered to enhance excretion. The urine should be checked for the presence of phencyclidine to ensure that it is being excreted. Phencyclidine can be deposited in adipose tissue and released over time, which may result in a prolonged state of confusion that can last for weeks; urine acidification may be helpful to deplete the reserve drug.

In an individual who is hypertensive due to phencyclidine, intravenous antihypertensive medications should be administered to reduce blood pressure. Psychotic behavior can be treated with haloperidol. If the individual is severely agitated and poses a potential threat to self or others, haloperidol or lorazepam is effective to control agitation; barbiturates may be even more efficacious [34].

Phencyclidine Intoxication Delirium

Clinical Presentation

The most common psychiatric syndrome that brings phencyclidine users to medical attention is acute delirium. The duration and severity are dose-related, but the acute episode usually lasts 3–8 h. Phencyclidine intoxication delirium is characterized by clouded consciousness that waxes and wanes (Table 5); this fluctuation may be due to periodic gastric secretion with intestinal reabsorption [20]. The individual's mental status fluctuates through paranoia, mania, rapid thought and speech, grandiosity, and emotional lability. All individuals initially experience distortion of body image (loss of body boundaries) and depersonalization (sense of unreality), followed by feelings of estrangement and loneliness; some individuals become catatonic and have dreamlike experiences. Clinically, individuals display insomnia, restlessness, hyperactivity, purposeless or bizarre behavior, perseveration, agitation, and aggression. Phencyclidine intoxication can be differentiated clinically from phencyclidine delirium because phencyclidine intoxication is accompanied by horizontal or vertical nystagmus, ataxia, or slurred speech, and occurs with a clear sensorium (similar to intoxication with other hallucinogens).

Phencyclidine delirium may persist much longer than the acute intoxication episode. There are three phases of phencyclidine delirium: agitated phase, mixed phase, and resolution phase. Each phase lasts around 5 days. The duration is influenced by degree of exposure to phencyclidine, individual susceptibility, dosage of

Table 4 Stages of phencyclidine intoxication

	Stage 1: Behavioral toxicity	Stage 2: Stupor	Stage 3: Coma
Duration	1–2 h	1–2 h	1–4 days
Vital signs			
Blood pressure and heart rate	Mild elevation	Moderate elevation	Significant elevation
Body temperature	98–101°F	101–103°F	103–108°F (malignant hyperthermia)
Respiratory rate	Mild elevation	Moderate elevation	Periodic respirations, apnea
Visual			
Nystagmus	Horizontal, then vertical	Horizontal, vertical, rotary	Horizontal, vertical, rotary
Pupil response	Variable, often miotic	Reactive	Dilated
Gaze	Blank stare	Fixed stare or roving eyes	Disconjugate
Mental status	Poor concentration, repetitive movements, agitation	Catatonic (with eyes open)	Coma
Reflexes			
Deep tendon reflexes	Clonus	Crossed limb reflexes	Absent
Gag reflex	Increased	Repetitive swallowing	Absent
Corneal reflex	Normal	Absent	Absent
Response to pain	Reduced pinprick sensation	Response only to deep pain	No response to deep pain
Drooling	Mild	Moderate	Severe
Nausea	Mild	Moderate	Severe
Spasticity	Rigidity, spasms, ataxia, dysarthria, grimacing, bruxism	Rigidity, twitching, myoclonus, spasticity	Myoclonus, opisthotonos

Table 5 *Diagnostic and Statistical Manual of Mental Disorders* criteria for phencyclidine intoxication delirium

(A) Disturbance of consciousness (reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.

(B) A change in cognition (memory deficit, disorientation, language disturbance) or development of a perceptual disturbance that is not better accounted for by a pre-existing, established, or evolving dementia.

(C) The disturbance develops over a short period of time (hours to days) and tends to fluctuate during the course of the day.

(D) Evidence from history, physical examination, or laboratory findings of either:
(1) The symptoms in Criteria A and B developed during phencyclidine intoxication, or
(2) Phencyclidine use is etiologically related to the disturbance

This diagnosis is made instead of a diagnosis of phencyclidine intoxication only when the cognitive symptoms are in excess of those usually associated with phencyclidine intoxication and when the symptoms are sufficiently severe to warrant independent clinical attention.

antipsychotic medication given, and whether urine acidification is undertaken.

Management

The hyperactivity, agitation, and aggression displayed by individuals with this condition result in intense physical exertion. Individuals with phencyclidine delirium are usually hospitalized in a closed psychiatric unit, but it is worthwhile to avoid use of physical restraints and to assure adequate hydration. Benzodiazepines and haloperidol may be helpful for phencyclidine delirium. Urine acidification facilitates excretion of phencyclidine and helps to ameliorate more rapidly the psychosis of this disorder. Urine

acidification should continue for at least 3 days after the acute delirium has resolved, and individuals typically require 3–10 days of urine acidification. Electroconvulsive therapy is useful if individuals fail to respond to antipsychotic treatment after a week of inpatient treatment [18, 40].

Phencyclidine Organic Mental Disorder

Phencyclidine organic mental disorder is a mental impairment that may result from chronic phencyclidine use [45]. Characteristics include memory deficits, confusion or reduced intellectual function, assaultiveness, visual disturbances, and speech difficulty. The most common speech difficulty is blocking, which is the inability to retrieve the proper words. The course is variable, but the confusional state may last 4–6 weeks. Urine acidification may shorten the course, although symptoms gradually improve with time if phencyclidine use does not recur.

Management involves protection from injury and helping to deal with disorientation. Excessive stimulation may result in agitation and violent behavior, so stimulation and sensory input should be minimized. A simple, structured, supportive approach works best in a nonthreatening environment with a nonjudgmental staff.

Chronic Use

It can be difficult to differentiate whether specific long-term effects of chronic use of ketamine or phencyclidine are due solely to the ketamine or phencyclidine. Most users of ketamine or phencyclidine are polysubstance users, so attribution of chronic effects is complicated by use of multiple other substances that may produce their own adverse effects. The current generation of ketamine users is the first to have used it long-term. The chronic health effects of ketamine are not known. More research with studies of the effects of chronic use of ketamine and phencyclidine on physical and mental health is necessary. This will help direct future prevention efforts.

Repeated use of ketamine or phencyclidine may result in long-term psychiatric consequences, such as anxiety, depression, or psychosis. The risk of a prolonged psychiatric reaction depends upon the user's underlying predisposition to develop psychopathology, the amount of prior drug use, and the use of other drugs, as well as the dose and purity of the drug taken [44]. Individuals may present with apathy, hypomania, paranoia, delusions, hallucinations, formal thought disorder, or dissociative states. Treatment of prolonged anxiety, depression, or psychosis is the same as when these conditions are not associated with drug use.

Long-term adverse effects of the chronic use of ketamine include psychological problems such as dysphoria, apathy, or agitation, and impairment of short-term memory [21]. Chronic ketamine use results in impairment in semantic memory [33], with greater impairment correlated with more frequent use; this improves with reduction in ketamine use. Impairment in episodic memory, attention deficit, and some schizotypal symptoms (dissociation, blunted affect, and cognitive disorganization) persist after 3 years despite cessation of ketamine use [33]. Long-term adverse effects of the chronic use of phencyclidine include intoxication delirium and organic mental disorder as described above.

The long-term consequence most commonly associated with the use of drugs such as ketamine and phencyclidine is flashbacks. A flashback is an episode in which certain aspects of a previous psychedelic experience are unexpectedly re-experienced. Triggers include stress, exercise, use of other drugs (especially marijuana), or entering a situation similar to the original drug experience; they may also occur spontaneously [46]. The content varies widely and may include emotional or somatic components, but the perceptual distortions are most commonly re-experienced. This may consist of

afterimages, trails behind moving objects, flashes of color, or lights in the peripheral visual fields. These episodes last several seconds to several minutes and are self-limited. The unpredictability of flashbacks often provokes anxiety when they occur. Flashbacks are fairly rare and tend over time to decrease in frequency, duration, and intensity, as long as no additional drug is taken [44]. Flashbacks are unlikely to occur more than 1 year after the original drug experience. Treatment of flashbacks consists of supportive care, including reassurance that the episode will be brief; benzodiazepines help to reduce anxiety. Although much has been written about flashbacks, the phenomenon is poorly understood and there is not universal support for its existence.

Chronic use of phencyclidine or ketamine may result in different physical health problems. Some health effects are related to the route of administration. Intranasal insufflation results in nasal problems according to studies of regular users [31]. Injection (whether subcutaneous, intramuscular, or intravenous) may result in exposure to blood-borne pathogens such as human immunodeficiency virus or hepatitis C virus, subcutaneous abscesses, or bacterial endocarditis. The most common reason for ketamine users to seek medical attention due to ketamine use is from severe gastrointestinal cramping known as "k-cramps". Up to a third of frequent ketamine users experience this [31], but the cause is unknown and no treatment exists currently. A fifth of users have reported bladder problems due to ulcerative cystitis [42]. Another effect of long-term ketamine use is headaches.

Addiction Treatment

The pattern of use of ketamine and phencyclidine is usually intermittent in social settings, so it may be perceived as less of a problem. This may limit willingness to consider addiction treatment by those who abuse these drugs. Adolescents and young adults are the primary users, so family members should be part of the treatment program. Treatment of abuse and dependence is often difficult due to the young age of most users and concurrent polysubstance abuse. Treatment involves similar components to that of other types of substance abuse, including individual counseling, support groups, and 12-step self-help group attendance. There is no pharmacologic treatment available for phencyclidine or ketamine abuse [1]. Treatment settings focus on behavioral components such as individual and group counseling.

Individuals who chronically abuse phencyclidine display characteristics such as impulsiveness and poor interpersonal relationships [45]. This may make successful treatment more challenging, but a treatment environment with a supportive structure can be helpful. Due to the dissociative effects of ketamine and phencyclidine, those who abuse these drugs may have a sense of loss of contact with their bodies. Progressive relaxation techniques, yoga, and regular exercise may help individuals in treatment to focus and improve their concentration [45]. Chronic use of ketamine and phencyclidine may result in cognitive impairments, so a long-term treatment program must take this into consideration to be successful in maintaining abstinence. The treatment environment should provide a supportive structure [45], recognition that initial engagement may be minimal, and utilization of routine and repetition. Treatment staff can improve the chances for a successful outcome by displaying patience and persistence with individuals.

The Biology and Treatment of Pathological Gambling

Iris M. Balodis and Marc N. Potenza

Contents

Introduction

Gambling has become increasingly accessible and socially acceptable over the past two decades, with an increasing number of venues and opportunities through casinos, video lottery terminals, sports betting venues, and online poker and other gambling sites. Although most people participate in gambling activities recreationally, some experience gambling problems, including the most severe form, pathological gambling [107]. Pathological gambling has been associated with significant financial debt, family tension, divorce, and criminal activity such as fraud and embezzlement [77, 87]. Extreme cases have involved staged kidnappings and serious child neglect leading to death, murder, and suicide [77].

Pathological gambling is defined as persistent and recurrent maladaptive gambling behavior that jeopardizes personal, occupational, or social functioning [1]. In the text-revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, pathological gambling is classified as an "impulse control disorder not elsewhere classified", a category that also includes disorders such as kleptomania and pyromania. The core feature of these disorders is the failure to refrain from committing a specific act: individuals generally experience a sense of tension or arousal that is relieved by committing the act, typically resulting in pleasure or gratification (e.g., gambling, stealing, or setting fires) [1].

The Psychiatric Nosology of Pathological Gambling

Pathological gambling has been conceptualized as a disorder falling within an

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_29,

obsessive-compulsive spectrum and as a "behavioral addiction" [9, 97]. Studies of impulse control disorders describe clinical elements including an urge to engage in a typically enjoyable yet, in the long term, counterproductive or harmful behavior, a mounting tension until the behavior is completed, a temporary abatement of tension following completion of the behavior, and a return of tension or appetitive urge following varying amounts of time [67]. Impulse control disorders have been described as having elements of impulsivity and compulsivity. Although the underlying motive of pathological gambling is initially pleasure, with increasing frequency individuals may feel "out of control" and their urges may become unpleasant or ego-dystonic [67, 73]. Although some compulsive aspects to gambling are evident, the co-occurrence of obsessive compulsive disorder and pathological gambling is not that common, while comorbidity with substance dependence occurs frequently [22, 55, 88]. The diagnostic criteria of pathological gambling, listed in the text-revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, share similarities with those for substance dependence. Individuals with pathological gambling can demonstrate tolerance and withdrawal symptoms as they gamble with increasing amounts of money in order to achieve the same hedonic experience, and they may become irritable or restless when attempting to cut down on or quit their gambling [1]. Like individuals with drug addictions, those with pathological gambling demonstrate impaired control over their behavior and may hide the extent of their involvement from loved ones or commit forgery or fraud to sustain their gambling [1]. The term problem gambling has been at times used to describe less severe patterns of gambling than exhibited in pathological gambling. This category is conceptually similar to that of substance abuse, although no formal criteria exist for problem gambling [118]. In addition, the term has been used at times inclusive and at other times exclusive of pathological gambling. The most commonly used screening instrument for pathological gambling is the South Oaks Gambling Screen, and this screen queries the types and frequencies of gambling behaviors as well as gambling-related impact on life functioning, particularly with respect to borrowing money for gambling [65]. The South Oaks Gambling Screen is valid and reliable, and a score ≥ 5 signifies probable pathological gambling [65].

Cognitive Distortions

A frequently acknowledged criterion of pathological gambling is the "chasing" of losses, whereby gamblers attempt to regain accumulated losses by returning to a gambling venue shortly following sustaining gambling losses. Nearly winning (e.g., receiving identical symbols on 2 of the 3 reels on an electronic gambling machine) has been suggested to contribute to gambling behaviors [20]. Individuals with pathological gambling, as well as recreational gamblers, may report other cognitive distortions, such as overestimating their chances of winning and their sense of control: "I know what it takes to win this game". In dice gambling and certain other forms, individuals may keep track of previous numbers in order to inform their subsequent bets with the thought that certain numbers will either appear more frequently because they have been observed previously ("hot numbers") or not ("numbers that are due"). Such a "Gambler's Fallacy" ignores laws of probability: that each role of the dice functions independently of the last. Superstitious behaviours ("I only play at nights"), and attributional biases ("That dealer always makes me lose") are also expressed in pathological gambling as well as in recreational gambling groups [120]. Cognitive distortions may represent relevant considerations in the maintenance of pathological gambling, although their frequent occurrence in non-pathological gambling samples questions their centrality to the disorder [74].

Prevalence Estimates and Characteristics

Precise pathological gambling prevalence estimates may be related to assessment measures and other factors. However, most studies report lifetime prevalence estimates ranging from 0.4 to 3% in the general population, representing approximately two to three million adults in the United States [88, 115, 126]. All types of gambling are also not equally represented in pathological gambling populations; one study suggests that pull-tabs, casino gambling, bingo, cards, lottery and sports betting, in descending order, are most strongly associated with pathological gambling [129], and another study found the highest proportion of pathological gamblers at off-track compared with other venues [77]. Pathological gamblers may engage in multiple types of gambling [129]. Factors associated with pathological gambling include male sex, adolescent and young adult age, and presence of other psychiatric disorder(s) [107]. Minorities and those with a lower socio-economic status also appear more likely to gamble and may be at particular risk for pathological gambling [129]. Some studies have found that men and women with pathological gambling show similarities in demographic and clinical features, including time spent gambling, percentage of income lost through gambling and gambling urge severity [40]. Other studies have identified gender differences in manifestations of gambling behaviors that may have significant implications for prevention and treatment strategies. While men constitute about two-thirds of the pathological gambling population and often show a longer duration of onset and begin gambling early in life (childhood/adolescence), women appear more likely to develop pathological gambling later in life and demonstrate a more rapid progression between onset and problematic engagement, a phenomenon observed in substance use behaviors and described as "telescoping" [40, 117, 130]. Gender differences also exist in the types of gambling behavior and in gambling "triggers". Women may report engaging in fewer forms of gambling, mostly bingo and slot machines, and often cite feeling prompted by negative mood states [40]. In contrast, men are more likely to gamble on cards or sporting events and report a greater saliency of sensory cues, such as sounds or advertisement, in their triggers for gambling [40]. Additionally, women, as compared with men with gambling problems, may experience greater psychiatric comorbidity, particularly with mood and anxiety disorders [26, 27, 88].

Pathological gambling frequently co-occurs with other psychiatric disorders [98]. Some studies estimate that up to three-quarters of individuals with pathological gambling report an alcohol use disorder, over 60% are daily tobacco smokers or nicotine dependent, and up to 40% report other drug abuse [56, 88]. About half of individuals diagnosed with pathological gambling also experience a mood disorder, with a particularly high odds ratio of 8.6 for mania, and roughly 40% are also diagnosed with anxiety disorders [88].

Comorbidity is not limited to the Axis I disorders. Estimates of personality disorders range from 29 to 93% in the pathological gambling population, with one study reporting an average of 4.6 personality disorders per person with pathological gambling [11, 81, 88]. While borderline, histrionic, and antisocial personality disorders are most often cited, these may represent a component of an externalizing syndrome [88]. Personality and temperamental factors may play a role in the maintenance of pathological gambling, as pathological gamblers may show high levels of impulsiveness, novelty-seeking, rigidness, extravagance, and harm avoidance combined with low levels of self-directedness [32, 58, 81]. In particular, impulsivity has been investigated as a key underlying construct, and accordingly, in pathological gambling, severity of gambling behavior and psychological disturbances appear related to this measure [112]. Identification of co-occurring disorders is important as the disorders may guide treatment strategies and influence treatment outcome [13].

The Biochemistry of Pathological Gambling

Serotonin

Pathological gambling shares similar biochemical features with substance dependence and other disorders characterized by impulsive features [13]. Low central levels of serotonin metabolites are observed in the cerebral spinal fluid samples of individuals with impaired impulse control including those with pathological gambling [66, 79, 80, 122, 123]. However, the precise nature of central serotonin function in pathological gambling is complicated by findings suggesting increased levels in pathological gambling [80]. Low endogenous levels of serotonin in pathological gambling are suggested by blunted prolactin responses following a pharmacological challenge [75]. Pharmacological challenges using the partial agonist metachlorophenylpiperazine produce a euphoric high in pathological gamblers, a response also observed in individuals with other impulsive disorders [5, 25, 113]. Together, these findings suggest a role for serotonin in pathological gambling, although the precise nature of its involvement requires further investigation.

Dopamine

Given a role for the mesocorticolimbic dopamine system in mediating the reinforcing properties of drugs [60], dopamine has been hypothesized to be involved in gambling behaviors. The maturation of the mesocorticolimbic dopamine and other systems during adolescence may in part explain the high estimates of gambling problems evidenced during this period [16]. Some data suggest that dopamine levels may increase during gambling behaviors [108]. However, ligand-based imaging studies involving pathological gamblers have yet to be published in peer-reviewed journals. Like with serotonin, studies examining dopamine metabolites in pathological gambling populations have generated inconsistent findings. While one study reported alterations in dopamine metabolites suggesting increased dopamine turnover in pathological gambling, this finding was largely mitigated when controlling for cerebrospinal fluid flow rates [6, 79].

During gambling activity, dopamine levels increase after longer playtimes in both recreational and pathological gamblers [72, 108]. Consistent with the idea that gambling and stimulants generate similar effects, priming individuals with the pro-dopaminergic (and pro-noradrenergic) drug amphetamine was associated with an increase in the desire to gamble and reduction in the confidence to resist gambling in pathological gamblers, and pleasurable and motivational responses were positively associated with problem gambling severity [131]. However, the dopamine D2-like receptor antagonist haloperidol was also found to promote gambling thoughts and behaviors [132]. Hence, a precise role for dopamine in pathological gambling requires further investigation.

Individuals with Parkinson's disease, a disorder characterized by dopamine system degeneration, have experienced gambling problems [28, 125, 127]. Dopamine agonists, such as pramipexole, ropinirole, and pergolide, have been associated with impulse control disorders such as pathological gambling in Parkinson's disease [99, 124, 127, 128]. Other factors, including levodopa dosage, age at Parkinson's disease onset, marital status, family history of gambling problems, family or personal history of alcoholism, high levels of impulsivity, and presence of an impulse control disorder prior to Parkinson's disease onset have also been associated with impulse control disorders such as pathological gambling in Parkinson's disease in systematic, cross-sectional studies [99, 128]. As such, the extent to which pathological gambling in Parkinson's disease reflects the pathophysiology of Parkinson's disease, its treatment, a combination thereof, or other factors requires additional research.

Norepinephrine

Norepinephrine, implicated in sensation-seeking and arousal, has also been investigated in the neurobiology of pathological gambling. Although healthy individuals demonstrate increased levels of norepinephrine prior to, as well as during, gambling sessions, pathological gamblers show particularly high levels of this neurochemical [72, 108]. The desire to start or continue gambling positively correlated with norepinephrine levels in one study of pathological gamblers [72]. The report of altered catecholaminergic response patterns in pathological gambling subjects suggests that gambling may represent a compensatory behavior to heightened arousal levels [72].

The Genetics of Pathological Gambling

An elevated frequency of pathological gambling in first-degree relatives of those with the disorder suggests a genetic component to the disorder [8]. Individuals who report gambling problems in their parents are themselves more likely to have higher scores on the South Oaks Gambling Screen; additionally, if their grandparents are also perceived as having gambling problems, these individuals may have a 12-fold higher odds of meeting criteria for pathological gambling [33]. The heritability estimate of a pathological gambling diagnosis from the Vietnam Era Twin registry is 46%, and lifetime prevalence estimates of pathological gambling in identical twins and fraternal twins are 22.6 and 9.8%, respectively [29]. A further analysis of this sample revealed that both identical and fraternal twins with subclinical pathological gambling symptoms were more likely to have a twin with full pathological gambling [109]. These results support a continuity model of pathological gambling, where subclinical gambling and clinical pathological gambling are differentiated by the number rather than the type of contributing factors [110]. Genetic studies provide support for a familial co-aggregation of pathological gambling and other disorders, such as alcohol dependence, antisocial behaviors, and depression, with significant contributions stemming from shared genetic factors [96, 109, 110].

Molecular genetics have inconsistently implicated allelic variants. In one early study of dopamine-related genes, a D2 dopamine receptor gene variant associated with substance dependence [78] was found in 51% of pathological gamblers but only in 26% of controls [18]. Individuals with the most severe pathology and comorbid substance use were more likely to carry the D2A1 gene [18]. Altered distributions of other dopamine receptor gene variants (e.g., those encoding the D1 and D4 receptors) have been reported in pathological gamblers [19]. However, these early studies have been criticized on methodological grounds [51], and a more recent study using a better controlled design and more thorough assessments did not replicate these findings [23]. As such, further research is needed to identify precise molecular genetic contributions to pathological gambling.

There are also suggestive data for serotonergic and noradrenergic genetic contributions to pathological gambling. One study found that men with pathological gambling are more likely to have a shorter variant of the gene coding for the serotonin transporter [84]. Other studies have also reported differential distributions of polymorphisms of monoamine oxidase-A-encoding genes in men with pathological gambling [50, 84]. Larger, genome-wide studies are needed to identify more precisely genes implicated in pathological gambling, and to investigate gene-by-environment and gene-by-gene interactions.

The Neuropsychology of Pathological Gambling

To date, few studies have examined neuropsychological functioning in pathological gamblers. Initial studies suggest deficits in executive functioning, not accounted for by intellectual

differences as assessed by standard intelligence quotient tests, in pathological gambling that are similar to those evidenced in substance dependent populations [32, 35, 37]. Consistent with pathological gambling's classification as an impulse control disorder, pathological gamblers demonstrate impairments on response inhibition tasks. The Stroop task assesses cognitive control involving attention, conflict monitoring, and response inhibition. Participants are required to name rapidly the ink color of matched (congruent) or mismatched (incongruent) color-word pairs. On congruent trials, the word "red" may be written in the color red while on incongruent trials the word "red" may be written in blue ink and, therefore, requires that the individual responds "blue". Not surprisingly, incongruent trials present greater difficulty as individuals are required to inhibit the pre-potent reading response. Pathological gamblers show impairment on this task by producing more errors (i.e., reading the word, rather than naming the word's color) and in taking longer to respond [32, 101, 105]. Modified versions of this task, sometimes referred to as Emotional, Drug, or Gambling Stroop Tasks, use emotional, drug-related, or gambling-related words, respectively. Subjects are presented with neutral or theoretically disorder-valenced words in different colored ink. In affected individuals as compared with healthy controls, the variant Stroop tasks tend to produce further delays and errors in processing. For example, in both recreational and pathological gamblers, when the words are theoretically more emotionally or motivationally salient rather than are neutral words (e.g., "dice" versus "door"), a more pronounced Stroop effect is observed [12, 69]. Such findings suggest not only an attentional bias for disorder-related stimuli, but also a certain level of automaticity in processing [12].

The neuropsychological function of pathological gamblers as compared with other subject groups has been examined [35–37]. Four groups, consisting of individuals with pathological gambling, Tourette's syndrome, alcohol dependence, or no psychiatric disorder, were compared on tasks assessing executive functioning [35, 37]. On tasks involving response inhibition, including the Stroop Task, the three clinical groups performed significantly worse than did healthy controls, but did not differ from one another. This trend was also observed on the Wisconsin Card Sorting Task, a measure of cognitive flexibility. However, on tasks of planning and time estimation, pathological gamblers and alcohol-dependent individuals showed significantly poorer performance relative to healthy control subjects and those with Tourette's syndrome.

The Iowa Gambling Task is a neurocognitive measure assessing risk/reward decision-making where individuals can choose between different decks of cards with varying schedules of reward [4]. Two disadvantageous decks confer high rewards, but also present even higher penalties, thereby resulting in a net loss for players. Two advantageous decks provide low rewards, but even lower penalties. Therefore, consistent selections from these decks produce an overall gain in money. Pathological gamblers and alcohol-dependent subjects demonstrated disadvantageous performance compared with the healthy control group as well as the Tourette's syndrome group. These findings are consistent with prior reports that pathological gamblers show disadvantageous performance on this task [15, 86]. The performance profile of the pathological gambling group also showed that they responded faster, made fewer response shifts following losses and demonstrated less conceptual knowledge about the task than did healthy controls [35].These findings suggest an impulsive and perseverative response style, and this profile may relate to loss chasing or altered reward processing in the pathological gambling group. A separate study examining the psychophysiological correlates on the Iowa Gambling Task showed that, unlike healthy controls, pathological gamblers fail to show increases in skin conductance response or heart rate accelerations prior to making a disadvantageous choice [36]. These alterations in psychophysiological responses suggest an impairment in risk assessment related to disadvantageous risk-reward decision-making [36].

Neurocognitive research findings in pathological gambling should be interpreted cautiously as many studies do not control for comorbidity, medication status, gambling severity, or gambling type or provide comparison control groups [35]. Gambling motivations may also be important to consider when examining neurocognitive performance in pathological gamblers [35]. Whether individuals gamble in order to heighten arousal or relieve their dysphoric mood may relate to their performance and its underlying bio-behavioral substrates. Impaired performance on some neurocognitive tasks assessing inhibition and decision-making may represent phenotypic markers in pathological gambling that have potential in predicting relapse [38]. More research is needed to identify intermediate phenotypic or endophenotypic markers that may be used in the diagnosis and treatment of pathological gambling.

Neuroimaging Studies

Neuroimaging studies suggest altered functioning in frontal, temporal, and limbic structures in pathological gamblers. The first published study using functional magnetic resonance imaging in pathological gambling utilized happy, sad, and gambling videotapes [95]. While viewing the videos, participants reported the onset of an emotional (e.g., feelings of sadness) or motivational (e.g., gambling urge) response by pressing a button. During the gambling scenarios (but not the happy or sad ones), pathological gamblers showed signal decreases in frontal and orbitofrontal cortical areas, thalamus, and basal ganglia. These brain changes occurred prior to conscious awareness of an emotional/motivational response, i.e., preceding the button-press. This activation pattern contrasts with those from symptom provocation studies in obsessive compulsive disorder in which increased activation of cortico-basal-ganglionic-thalamic circuitry is observed [107].

During the viewing of the final portion of the gambling scenarios, when the most robust gambling stimuli were presented, pathological gamblers (relative to controls) showed less activation of the ventromedial prefrontal cortex. Subsequent studies using an functional magnetic resonance imaging Stroop task, a decision-making, and a simulated gambling task have also demonstrated relatively diminished activation of the ventromedial prefrontal cortex in association with pathological gambling [94, 102, 116]. The ventromedial prefrontal cortex has been implicated in mood regulation, decision-making, and impulsivity [3, 7, 13, 68]. The ventral striatum, functionally connected to the ventromedial prefrontal cortex, has also been shown to activate less strongly in pathological gamblers [100, 102]. Activation in the ventromedial prefrontal cortex and ventral striatum correlated inversely with gambling severity in pathological gamblers during simulated gambling, further suggesting the relevance of these regions to clinical aspects of pathological gambling [102]. Similar patterns of brain activations, including relatively diminished activation of ventral striatum, have been reported in cocaine-dependent subjects viewing cocaine tapes and pathological gambling subjects viewing gambling tapes, suggesting similar neural contributions to appetitive urge states across disorders [100]. These neurobiological findings support the conceptualization of pathological gambling as a "behavioral" or non-substance addiction.

Although to date fewer than ten neuroimaging studies examining neural correlates in pathological gambling have been published, studies using healthy controls have investigated intertemporal choice, loss aversion and other components influencing decision-making [53, 104, 119]. One functional magnetic resonance imaging study examining the neural correlates of loss-chasing behavior demonstrated increased ventromedial prefrontal cortex activation when healthy individuals tried to win back money lost on previous gambles [14]. Loss-chasing, therefore, appears linked to brain areas involved in reward processing [59] and raises the possibility that recreational gamblers may chase losses because they believe that winning is imminent [14]. The extent to which these findings relate to

pathological gambling requires further, direct investigation.

Treatment

Few pharmacological and behavioral therapies targeting pathological gambling have been investigated with respect to their tolerabilities and efficacies. It is estimated that only 7–12% of pathological gamblers seek formal treatment for pathological gambling [61, 111]. These individuals may seek treatment for various reasons (e.g., threats of spousal divorce, suicide attempts), and thus treatment-seeking pathological gamblers may differ from pathological gamblers in the general population [40].

Behavioral Treatments

Although Gamblers Anonymous is arguably the most widespread intervention for pathological gambling, questions exist regarding its effectiveness. One study reported that most individuals attend only one or two meetings and less than 10% remain in attendance after one year [114]. Cognitive therapies have shown promise in the treatment of pathological gambling. One cognitive therapy targets erroneous cognitions, such as illusions of control over random events, and was found to be helpful in an initial, small, wait-list-controlled study [62]. Following this treatment, approximately 86% of individuals no longer met pathological gambling criteria, and individuals reported greater self-efficacy and perception of control over their gambling problem. This type of therapy may also be effective in group format, and therapeutic gains appear to be maintained after one year [63]. Cognitive behavioral therapy for pathological gambling identifies gambling triggers and cognitive biases, reinforces non-gambling behaviors, teaches coping skills, and addresses finance management and debt settlement [89]. Individuals receiving cognitive behavioral therapy showed greater reductions in gambling problems and time spent gambling than did those attending Gamblers Anonymous. However, both groups demonstrated improvements over time.

Other psychological interventions have been developed including aversive therapy, imaginal desensitization, motivational enhancement, brief guided therapy, self-help workbooks and eclectic therapies. The effectiveness of psychological interventions has been complicated by differences in assessments used to evaluate treatment outcome [82]. However, a review of behavioral therapy outcome studies showed that these interventions are associated with significant improvement both post-treatment and after long-term follow-up when compared with no treatment [82]. It should be noted, however, that drop-out rates in many studies approach 50% [62]. Future studies should examine the efficacy of combining different therapies that target different cognitive and motivational aspects of pathological gambling.

Pharmacological Treatments

Like in behavioral treatments, the evaluation of the efficacies of pharmacological therapies in pathological gambling is complicated by differences in sample sizes, trial durations, dosing strategies, trial designs, and outcome measures.

The findings of low serotonin levels in pathological gambling and blunted ventromedial prefrontal cortex to serotonergic drugs in impulse control disorders [103] suggest that selective serotonin reuptake inhibitors could potentially be useful therapeutic agents for pathological gambling. Several studies have demonstrated that selective serotonin reuptake inhibitors such as fluvoxamine and paroxetine are associated with short-term improvement in pathological gamblers [24, 47, 49, 57]. However, placebo-controlled trials of fluvoxamine and paroxetine have also yielded negative results [10, 39]. Some variability in outcome may relate to heterogeneity of pathological gamblers, and guiding selection of therapies according to presence

of co-occurring disorders (e.g., selective serotonin reuptake inhibitors for individuals with co-occurring pathological gambling and anxiety disorders) may help improve treatment outcomes [41, 98]. Consistent with this notion, a study examining lithium in the treatment of individuals with co-occurring pathological gambling and bipolar-spectrum disorders found lithium superior to placebo in reducing symptoms of both gambling and mania [48].

Three separate studies have found opioid antagonists (naltrexone and nalmefene) superior to placebo in the treatment of pathological gambling [43, 45, 58]. Individuals with a family history of alcoholism may be particularly responsive to treatment with an opiate antagonist [46]. Medications targeting dopamine receptors directly (e.g., the serotonin/dopamine antagonist olanzapine) have been shown in two placebo-controlled trials not to be superior to placebo in the treatment of pathological gambling [31, 70].

Natural Recovery

Like in drug addictions, untreated recovery appears to occur in pathological gambling. Using cross-sectional data, it has been estimated that most pathological gamblers recover without any therapeutic intervention [111]. These findings suggest that pathological gambling in the community may represent an episodic rather than chronic disorder, and which factors influence its course require further investigation [111, 121].

Prevention Efforts

Few studies have investigated prevention efforts for pathological gambling. Primary prevention efforts for gambling might include more stringent regulation of gambling availability and advertisements and education initiatives on risks associated with gambling. The effectiveness of such interventions requires empirical testing. Given the exposure to nicotine and mutagens in some gambling environments, gambling may be associated with significant health risks [54]. Therefore, the amount of tobacco smoke exposure should be considered in discussions of healthy levels of gambling. A less apparent health risk may be related to the significant increases in autonomic arousal associated with gambling [71, 72]; approximately 83% of casino-related deaths may be attributable to sudden cardiac arrests [52].

Identifying those individuals at greatest risk for developing pathological gambling may be important in developing effective prevention strategies. Many health care providers may not inquire about pathological gambling when assessing patients [17]. Like for substance abuse and dependence, screening tools for pathological gambling may be useful for medical practitioners as associations between medical conditions and pathological gambling have been observed in community and medical clinic samples [26, 83, 90, 91, 93]. As discussed above, individuals with Parkinson's disease should be monitored carefully during the course of their treatment to identify any changes in gambling behaviors.

Other prevention efforts include the use of gambling helplines and self-exclusion policies at casinos where individuals can voluntarily ask that they not be allowed on the gambling site premises [61, 92]. The effectiveness of both of these prevention efforts has received relatively little study, although early analysis of self-exclusion programs suggest that they are associated with a 30% self-reported abstinence of gambling activities [61, 64]. Self-exclusion programs may benefit from more extensive reinforcement through professional follow-up [61].

Research Challenges and Future Directions

Over the last decade, several pharmacological and behavioral treatments of pathological gambling have received initial empirical support [44, 76]. However, multiple questions and potentially confounding factors exist. For example, as relatively few pathological gamblers seek treatment, it is not clear whether those who do are representative of the larger pathological gambling

population [76]. Individuals who seek help may demonstrate ambivalence towards treatment. For example, many individuals may still maintain positive feelings about gambling, and completion of even a short six-week treatment study may be difficult to achieve [121]. The issue of monetary incentives for study participation may raise questions as subjects may be motivated to participate by receipt of financial compensation rather than a genuine desire to stop gambling [121]. Moreover, the impetus for change in many pathological gamblers are financial crises that may not be resolved through psychological or pharmacological treatments [121].

Many early treatment outcome studies have excluded individuals with co-occurring disorders. Given that many pathological gamblers suffer from a co-occurring disorder, questions are raised about the generalizability of such studies [76]. Initial studies suggest that co-occurring disorders influence treatment response [98]. Therefore, common co-occurring conditions should be identified and treatment outcome studies evaluated accordingly [76]. Furthermore, the use of a clinical control group in treatment studies, such as groups with other impulse control disorders or alcohol dependence, could be useful in identifying underlying bio-behavioral factors and assessing similarities with other disorders [34].

There are many unique populations affected by pathological gambling. However, research to date has predominantly included Caucasian males. Racial/ethnic differences have been observed with respect to pathological gambling in Asian [85], Black [2], Hispanic [21], and Native American [30] groups. Differences in clinical characteristics of pathological gamblers have also been found to be associated with sexual orientation [42]. Individuals from minority populations may benefit preferentially from specific therapies. With respect to gender, although males and females with pathological gambling may both be willing to seek treatment, differences in clinical features may be important in guiding treatment [40]. For example, gambling triggers in females may be more strongly influenced by mood state, and thus therapy may preferentially target affective symptoms or mood regulation [40].

Pathological gambling and substance dependence appear to involve similar patterns of dysregulation within ventral components of fronto-striatal circuitry, neurocognitive impairments in inhibition and decision-making and neurochemical and psychophysiological markers suggestive of arousal deficits. The frequent co-occurrence of pathological gambling and substance dependence disorders is consistent with the notion that similar mechanisms may underlie both disorders. Additional research may identify more specifically how pathological gambling relates to substance-based addictions and whether classification of pathological gambling as a non-substance addiction is appropriate.

The continued use of brain imaging techniques and the performance of large genetic studies should help advance the knowledge of the bio-behavioral basis of pathological gambling. The use of neuropsychological, neurochemical, neuroimaging, genetic, environmental, physiological, and self-report measures in treatment and community settings should facilitate integration of clinically relevant information [34, 40]. An improved understanding of the relationship among these different facets should aid in establishing clinically relevant intermediary phenotypes for pathological gambling and advancing efforts in better characterization, diagnosis, and treatment of pathological gamblers.

An Addiction Model of Binge Eating Disorder

Jacqueline C. Carter and Caroline Davis

Contents

Introduction

The idea of applying an addiction model to eating disorders has been a controversial one (e.g., [116]). While we agree that an addiction model does not adequately address the core clinical features of the two established eating disorders, anorexia nervosa and bulimia nervosa, our aim is to convince readers of the utility of this perspective for the newly recognized "binge eating disorder". Binge eating disorder is characterized as recurrent episodes of binge eating in the absence of the extreme weight control behaviors (e.g., fasting or self-induced vomiting) seen in anorexia nervosa and bulimia nervosa. In this chapter, we argue that conceptualizing binge eating disorder as an addictive disorder would be useful for both researchers and clinicians in understanding the causes of compulsive overeating and in devising more effective treatment interventions. In presenting our case, we will consider clinical and behavioral parallels between binge eating and drug abuse. We will also discuss the similarities in their biological underpinnings and the overlapping risk factors for their development. Finally, we will consider the treatment implications of an addiction model of binge eating disorder and make several recommendations for integrating an addiction approach into established treatments for this disorder.

History and Background

Although people had written about the enslaving properties of opium and alcohol for centuries, it wasn't until the 1800s that the notion of drug abuse as a disease entity—rather than an issue of moral culpability—entered the general parlance of medical professionals [61]. While the original (seventeenth-century) use of the word *addicted* meant "to give over . . . to someone or some practice", its first appearance with specific reference

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_30,

to narcotics was not until the early twentieth century [12], and for most of that time it was largely confined to the misuse of alcohol and the opiates. With the rise in popularity of psychiatry after World War II and the "rediscovery of addiction" [11], other substances such as cocaine, amphetamine, and nicotine were added to the list of addictive drugs. (Although the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition nomenclature does not include the word "addiction", its "dependence" terminology is closest to this condition.)

In recent years, there has been an interesting clinical and scientific shift in perspective, with many believing that addiction should encompass the compulsive engagement in activities such as gaming, internet use, and shopping, in addition to its conventional relation with pharmacological rewards [46, 52, 78, 84]. Current debate has even extended to the possibility that so-called "behavioral addictions" should include the abuse of *natural rewards*—that is, behaviors that are intrinsically necessary for our survival, and in which we freely engage with pleasure and without social sanction.

A few generations ago, it might have seemed heretical to suggest that food could be an addictive substance and overeating could be an addictive behavior. As testament, we were able to find only six published references to such a viewpoint from 1950 to 1970, almost all of them written by T. G. Randolph (e.g., [86]), the well-known founder of environmental medicine. However, a groundswell of change in perspective has occurred in the past few years, as indicated, for example, by the publication of 15 academic papers, in the first two months of 2008, referring to "food addiction". Discussion of this topic has also been matched—probably exceeded—by its frequency in the popular press.

Drugs as Food

Conventional evolutionary "mismatch" views of addiction propose that substance use is a relatively recent phenomenon in the history of our species and that it occurs largely because of the availability of purified and synthetic drugs and their direct routes of administration [77, 93]. In other words, it is the ubiquity and concentrated doses of these substances that have contributed to widespread human drug abuse. By contrast, Sullivan and Hagen pointed out that human beings shared a co-evolutionary relationship with psychotropic plant substances in prehistory for millennia [100]. Indeed, they frequently ate them as food because their ingestion solved a recurrent problem faced by our ancestors.

The neurotransmitters that are essential for normal human functioning—and most implicated in substance use—are dopamine and serotonin, the precursors of which must be provisioned externally from high-quality nutrients such as protein. During most of our history, due to famines and seasonal food shortages, these precursors were nutritionally constrained and, consequently, people experienced neurotransmitter deficits with considerable regularity. Depletions of this sort tend to affect critical behaviors and emotions adversely, including motor activities, cognitive abilities, and mood.

It is also generally believed that over our evolutionary history, certain plants developed chemical defenses against mammalian predators by producing "neurotransmitter substitutes", which had toxic effects when ingested. Sullivan and Hagen argued that in response to this threat, "behaviourally sophisticated hominids" evolved to counter-exploit the potential benefits of plant toxins [100]. For example, because these "neurotransmitter analogues" imparted energy, prevented fatigue, diminished appetite, and increased tolerance for hunger, they helped to avoid the maladaptive "behavioral sequelae of stress" in the absence of adequate food sources. In other words, plant substances served the dual purpose of substituting for more costly energy and buffering against the biological ravages of prolonged stress.

Thus, it seems reasonable and sensible to conclude that organic compounds in our environment can only be categorized as *beneficial* or *harmful* when we take account of "dosage" and

the relevant characteristics of those who partake of them [45].

Food as Drugs

This last point is particularly relevant when considering the typical macronutrient intake in current Western societies. Diets high in concentrated fats and sugars are not only dense in calories, but metabolically efficient because a large proportion of their energy is provided to the consumer. They also tend to elevate mood by releasing neuropeptides, which reinforce their selective preference [55]. Evolutionary biologists believe that "cravings" for sugar and fat evolved to enhance human energy intake in unpredictable nutritional environments, which were universally the norm until relatively recently [45]. However, in the quantities that many people ingest them today, they have an abuse potential rivaling that of popular addictive drugs [96].

The food industry has become especially savvy in exploiting our natural human desire for sugar and fat by increasing many-fold their "dose" in much of our daily foods. For instance, there was a 42% *per capita* increase in the consumption of added fats and a 162% increase in cheese relative to only a 20% increase in fruits and vegetables between 1970 and 2000 [43]. The sharply reduced cost of sugar and vegetable oils worldwide has greatly contributed to the production of highly palatable processed foods [36]. The incidence of snacking, especially in the form of carbohydrates, has also increased over the past 25 years, in tandem with the increase in daily energy intake [90]. "Junk foods", which are the principal type of snack, have little nutritional value, but are highly appealing because of their high fat and sucrose content.

In the case of conventional drugs, greater potency tends to increase their addictive potential. Directly parallel to the notion of "drug dosage" is the size of the meals we are presently served. Wansink and Van Ittersum described the "portion-distorted embarrassment of food" in today's supermarkets and restaurants [109]. To illustrate, a fast-food restaurant meal—a burger, fries, soft drink, and dessert—can provide almost all of one's daily caloric requirements in a single serving. Moreover, the annual growth rate of "fast food" dining has increased 3-fold in the past generation compared with that of at-home consumption [88]. The size of plates, bowls, and glasses in our homes has also steadily increased over the years, and the serving size of some entrees has virtually doubled in recipe books since the 1930s [109].

In summary, just as different drugs promote different degrees of dependence, foods also differ in their capacity to promote abuse [106]. Experts are now confident in claiming that the nutrients composing fast foods are inherently addictive because of their concentration and high volume of fats and sugars. Also, like drugs of abuse, they have the ability to alter brain mechanisms in ways that contribute to their increasingly compulsive use (see [31, 47, 96]).

Clinical and Behavioral Parallels

In making the argument for overeating as an addictive behavior, it is clearly not appropriate to include all cases of excessive food consumption in this taxon. Nor are we claiming that obesity and addiction are one and the same. However, we do believe that binge eating disorder is a phenotype particularly well-suited to such a conceptualization, and that sound clinical and scientific evidence exists to support this viewpoint. Cassin and von Ranson [20] found, for example, that 94% of their adult binge eating disorder sample described themselves as "food addicts" or "compulsive overeaters" and met the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria for substance dependence disorder [2] when the term "substance" referred to "binge eating". While there is not complete consensus among researchers on the defining features of all addictions, most would agree that there are a common set of defining characteristics. These characteristics include loss of control, tolerance and withdrawal, cravings, and repeated cycles of remission and relapse.

Loss of Control

Perhaps the most clear-cut feature of addiction is the increasingly compulsive use and abuse of the addictive substance or behavior, even in the face of detrimental consequences to health, safety, social relationships, and financial stability. Binge eating disorder is characterized by repetitive and aboulic episodes of overeating, not typically driven by hunger or followed by any compensatory behaviors such as purging, fasting, or excessive exercising. Feeling "out of control" of one's eating behavior is a defining feature of binge eating [2]. Binge eating disorder appears to be a chronic and stable condition [83] with strong links to obesity [32]. Although initially believed to be a disorder of adulthood, there is growing evidence that binge eating disorder also occurs in children and adolescents [17]. In addition to clinical research, there are good experimental paradigms whereby a subset of rats fed an intermittent diet of sugar have developed a pattern of copious consumption resembling human cases of binge eating disorder (e.g., [4, 21]).

Binge eating disorder sufferers typically report distress and guilt about their eating habits, but they have great difficulty controlling these behaviors despite weight gain and ensuing medical problems such as diabetes and hypertension [22]. As a society, we are generally informed and knowledgeable about the negative consequences of poor nutrition and obesity and are sentient of dietary recommendations for good health, so we must conclude that binge eating—like drug addiction—exists despite an awareness of its poor health outcomes.

Tolerance and Withdrawal

In the most general sense, tolerance occurs when a stimulus of a particular magnitude elicits an increasingly diminished response with each repeated exposure and an increasingly higher dose is necessary to achieve the desired effect. This phenomenon is a key characteristic of all drug addictions—and one of the factors that fosters the escalation of intake. Animal studies have demonstrated that a sugar-enhanced diet is associated with increased daily food intake over time [5]. Direct evidence of tolerance in binge eating disorder arises largely from clinical reports of individuals consuming more and more food in each binge as the disorder becomes more chronic. The finding that higher body weight correlates with the frequency and severity of binge eating episodes also provides indirect evidence of tolerance effects [82]. As well, a high proportion of adults with binge eating disorder reported being overweight before the onset of their disordered eating, suggesting that over time, high-calorie diets prompt greater subsequent intake and may contribute to binge eating [87].

The impact of tolerance on the progression of addictive behaviors is made more poignant by its synergy with the debilitating symptoms of withdrawal. Certain foods—particularly sugar—can cause pronounced withdrawal symptoms when removed from the diet, and these effects most clearly resemble the physical signs of distress seen in opiate withdrawal [5]. The most compelling evidence comes from animal research in which rats were initially maintained on a 25% glucose solution (e.g., [5, 110]). Following its removal, they showed aggression, anxiety, a drop in body temperature, teeth chattering, forepaw tremor, and head-shaking—all symptoms associated with withdrawal from drugs such as heroin. While there is also human evidence of "sugar withdrawal", it comes mostly from clinical observation, self-help books, and Internet sites promoting weight-loss diets. They are, however, uniform in describing headaches, irritability, and flu-like symptoms among heavy sugar consumers who become abstinent.

Cravings and Relapse

One of the most distinguishing features of drug abuse is the pronounced sense of craving reported by addicts and their dismal and repeated

failures at giving up the habit. Addiction is rarely an acute illness. A decade ago, Leshner coined the term "chronic relapsing disorder" to describe addictive disorders because total and permanent abstinence seldom occurs after a single treatment episode [59]. For most individuals, there are repeated cycles of cessation and relapse. Human weight cycling is, almost by definition, a sign of repeated defeat in one's effort to curb overeating and is found to be a significant risk factor for the development of binge eating [81].

The addict's powerful cravings that can be elicited from even a small "dose"—as well as from the many conditioned environmental cues—are thought to contribute to poor long-term treatment outcome. Studies have also demonstrated that food cravings are significantly higher in adults with binge eating disorder than in their non-bingeing counterparts of comparable weight [29, 75]. This meshes with other evidence that those with binge eating disorder show enhanced preference for sweet and fatty foods compared with other obese individuals [118]. Craving in animals can only be inferred from their behavior and is typically defined as the enhanced motivation to procure an addictive drug by operant responding [57]. Such behavior has also been observed in rats who lever pressed for 23% more glucose after a 4-week period of a sugar-enhanced diet than at baseline [5].

Neurobiological Parallels

Brain reward circuitry almost certainly evolved to foster our selective engagement in activities like eating, sex, and maternal behavior, which are the essence of our survival as a species. This otherwise highly adaptive neuro-anatomical mechanism is also at the heart of all dependence disorders. Abused substances have psychomotor stimulant properties, which activate the same brain reward pathways as life's natural pleasures. In other words, there is a shared substrate for food and drug reward [79]. Due, however, to the potency of most addictive substances, and to their direct route of administration, the claim that drugs "hijack" the brain has become a popular idiom to describe the downwardly spiralling pattern of drug abuse.

Dopamine neurons in the ventral tegmental area send subcortical projections to striatal regions of the basal ganglia—importantly, the nucleus accumbens—and to various limbic structures such as the amygdala. Ventral tegmental area projections also extend to the prefrontal cortex. This mesocorticolimbic neural network is fundamentally complex and cleverly "designed" to regulate the many emotional, motivational, and cognitive processes involved in reward. For example, our engagement in these behaviors increases our sense of pleasure and well-being—events that galvanize our attention in preference to more neutral, and less essential, activities. Second, we have the desire to repeat these behaviors even in the face of distracting stimuli. They also nurture a strong positive memory, which increases their salience and enhances our appetitive motivation in their direction. Third, we quickly learn the cues in our environment that signal the approach or availability of these rewarding behaviors. Finally, we become resistant (temporarily) to their rewarding properties in order to move on to other activities. Other neurotransmitter systems such as gamma-aminobutyric acid, the opioids, and serotonin are also integral to this process [108]. With respect to food, for instance, dopamine release in the nucleus accumbens is generally associated with its reinforcing effects, while opioid signalling in this area regulates its palatability and hedonic properties [24, 39].

Until relatively recently, the neurobiology of overeating was largely focused on the hypothalamus, while drug addiction research, by contrast, channelled its attention to the mesocorticolimbic pathways [102]. With the increasing sophistication of brain imaging techniques, we are now able to witness the activation of brain reward sites in response to palatable food [6, 92]. Prefrontal systems also play a prominent role in eating and appetite. For instance, increased "dysexecutive" traits have been associated with binge eating and food cravings, just as they are with drug abuse [94].

Experts now generally agree that the reinforcing effects of addictive drugs and palatable foods are regulated, in large part, by the same dopamine pathways [23, 55, 108]. While addictive drugs share with food the property of increasing dopamine in brain reward pathways, the former bypass the adaptive mechanisms of normal reward, such as the habituation that constrains the responsiveness of the brain to food reward [35]. Potent drugs abnormally facilitate Pavlovian incentive learning to drug-conditioned stimuli and sensitize the individual to cravings for the substance [56]. Drugs also cause a tolerance to their rewarding properties by the downregulation of dopamine receptors in the striatum [105] and a decrease in the function of the extended amygdala reward system, which produces the negative affect and anxiety associated with abstinence [56]. There is now compelling evidence that highly palatable foods eaten in abundance have the potential to cause these same neuroadaptations—alterations that increase compulsive use, foster strong cravings, contribute to the symptoms of withdrawal, and make abstinence increasingly difficult [47, 51, 79].

Risk Factor Similarities

Binge eating disorder and drug addiction appear to share certain risk factors for their development. A recent study found significantly higher rates of psychopathology, including substance abuse, in first-degree relatives of women with binge eating disorder compared with relatives of control women [60]. Importantly, however, all the disorders elevated in relatives with binge eating disorder followed a pattern of independent transmission from binge eating disorder, except for substance use disorder, the transmission pattern of which indicated a shared etiology. While the vulnerability for both disorders has many social and cultural parallels, such as availability and cost contributing to their consumption, our review will only focus on certain *psychobiological risks* that they have in common.

Reward Sensitivity

The sensitivity or reactivity of the "common reward pathway" is affected by several biological factors such as the density of dopamine receptors, the amount of dopamine released into the synapse, and the rapidity of its transport back into the cell by the reuptake protein. Individual differences in *reward sensitivity* have been strongly implicated in the risk for drug addictions [15, 58, 62, 76] as well as compulsive overeating [27, 30]. The research is divided, however, about the causal direction of this association.

One argument favors the view that *hypo*-dopaminergic functioning—which has been called a "reward deficiency syndrome"—is a key factor in the development of addiction disorders [13, 53]. The premise is that substances (such as addictive drugs and palatable food) are used as a form of "self-medication" to boost a sluggish dopamine system and increase hedonic capacity. The counterargument is that *hyper*-sensitivity to reward contributes to increased risk for addictive behaviors due to an enhanced motivation to engage in pleasurable activities. For instance, in several studies, heightened reward sensitivity was associated with emotional overeating, preference for high-fat food, binge eating, and food cravings, as well as with hazardous alcohol consumption [26, 41, 62]. One explanation for the apparent disaccord between the two bodies of research may be a *dual vulnerability* to addictions whereby both paths can confer risk, albeit in different individuals and perhaps with different levels of severity.

Impulsivity and Decision-Making Deficits

Poor decision-making skills and difficulties with impulsivity are core symptoms of certain mental health problems but are perhaps most prominently seen in drug dependence [8, 10]. Addicts tend to choose actions that bring immediate

reward, even when this leads to a deleterious later outcome. The human ability to choose *present* options that favorably influence *future* outcomes depends crucially on an accumulated "emotional memory" of the consequences of our *past* interactions with similar events [25]. In other words, we form a probabilistic impression of how a particular action will turn out in the future from an emotionally biasing "gut" feeling, which was generated when that action caused either a positive or a negative reaction in the past. The orbitofrontal cortex, in particular, is critical for activating feelings or emotional states from "thoughts" about rewarding or punishing events that are not currently present in our environment [7, 9].

Much of the early research on decision making came from studying the social impairments of patients with ventromedial prefrontal cortical lesions and observing that their behavioral deficits are typically caused by an inability to assess future consequences advantageously [3, 89]. In other words, they fail to weigh the pros and cons of their actions and to postpone immediate gratification, so their behavior is almost always guided by the negative or positive events present at the moment. A plethora of research using neuropsychological tests of decision-making ability has shown impairment in those dependent on a variety of addictive substances (e.g., [103, 104]). To date, there have been no systematic studies of decision-making deficits in binge eating disorder, although these impairments have been found in individuals with bulimia nervosa and in obese women [14, 16, 28].

Relatedly, *impulsivity*—a personality trait characterized by the diminished ability to inhibit behavior when restraint is the most advantageous and appropriate response in a particular situation—is a key component of decision-making deficits. Impulsive individuals show pronounced weaknesses in learning appropriate associations between reward and punishment, which is essential to making advantageous choices [42]. High expression of this endophenotype has strong links with both binge eating disorder [44, 97] and drug abuse [103, 104]. Due, however, to the difficulties of doing prospective risk-factor research in these areas, it is not clear whether impulsive responding is a precursor to addiction disorders or whether it only occurs because of the brain alterations caused by excessive use.

Treatment Implications

Although binge eating was first identified as a clinically significant pattern of overeating in obesity by Stunkard in 1959 [98], there were no published studies on its treatment until more than 20 years later. Early research suggested that this behavior was associated with higher attrition from weight-loss programs and poorer success rates than obesity without binge eating (e.g., [54]). As a consequence, clinicians such as Marcus and colleagues began to adapt standard behavioral weight-loss treatments to address directly binge eating behavior in an attempt to enhance positive outcomes [67].

Subsequent research found that binge eating in obesity was associated with clinically significant psychosocial distress and impairment and with levels of over-concern about weight and shape similar to that seen in eating disorders (e.g., [63–65]). It was also found to be associated with more chaotic eating habits, more emotional overeating, higher levels of eating disorder psychopathology, and higher rates of psychiatric comorbidity, particularly mood disorders [38, 113, 119]. Binge eaters also reported more social impairment and poorer quality of life compared with obese individuals who did not have binge eating disorder [95]. This evidence stimulated interest in the application of specialized psychological interventions for binge eating disorder, particularly those adapted from treatments for bulimia nervosa. At about the same time, binge eating disorder was included in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition [2] as an example of "eating disorder not otherwise specified", inspiring a wealth of further research on its nature and treatment.

Current Treatments for Compulsive Overeating

Because binge eating is a central feature of both bulimia nervosa and binge eating disorder, most controlled treatment studies of binge eating disorder have evaluated interventions with demonstrated efficacy for bulimia nervosa, particularly cognitive behavioral therapy and certain types of medication. The aim of psychological therapy is to interrupt mental and emotional factors that are believed to perpetuate binge eating problems, whereas pharmacological interventions target mood regulation and the neurobiological basis of food intake regulation. In the ideal situation, effective treatments for binge eating disorder would eradicate the core behavior of binge eating, alleviate associated psychosocial problems, and produce clinically significant weight loss.

Psychological Interventions

While randomized controlled trials have indicated that certain psychological interventions for binge eating disorder can bring about substantial, and in some cases sustained, reductions in binge eating and improvements in psychosocial functioning, most participants do not cease binge eating; nor do they achieve clinically significant weight loss (see [48] for a review). The cognitive behavioral therapy approach employed in most binge eating disorder studies is largely based on the treatment manual developed for bulimia nervosa [40], with only minor modifications [63]. This protocol lasts 16 weeks and involves three stages. The first stage focuses on self-monitoring, the establishment of a pattern of regular eating, and the employment of strategies (e.g., distraction and problem-solving skills) to avoid binge eating. The goals of the second stage are to reduce strict dieting, incorporate "binge foods" into normal meals, and reduce over-concern about eating, weight, and shape. The final stage addresses relapse prevention by anticipating future challenges that could trigger a return of binge eating symptoms. The cognitive model views over-concern about body shape, body weight, and strict dieting as the central maintaining factors in eating disorders. In other words, one of the premises of cognitive behavioral therapy is that increased dietary restraint contributes to increased binge eating—an assumption that is irrelevant for individuals with binge eating disorder who are not engaging in food restriction or compensating for their binge eating episodes. In fact, individuals with binge eating disorder tend to overeat between binge episodes.

Studies have found that treatments involving enhanced dietary restraint produce reductions in binge eating behavior in binge eating disorder. Although standard behavioral weight loss treatment does not directly target binge eating, some studies comparing cognitive behavioral therapy and behavioral weight loss treatment have found comparable effects on binge eating, at least in the short term [1, 66]. However, most studies suggest that cognitive behavioral therapy is superior to behavioral weight loss treatment in terms of reductions in binge eating but without producing clinically significant weight loss (e.g., [34, 49, 74]). Moreover, it seems that only those who rapidly become abstinent from binge eating tend to achieve and maintain a significant amount of weight loss with any treatment approach. Cognitive behavioral therapy for binge eating disorder has also been tested in self-help [19, 49] and CD-ROM formats [91] with promising results. In addition, one study found that combining cognitive behavioral therapy with an exercise program resulted in higher abstinence rates and greater weight loss compared with cognitive behavioral therapy alone [80]. Wilfley and colleagues [111, 114] compared cognitive behavior therapy with interpersonal psychotherapy in two trials. Interpersonal psychotherapy focuses on the resolution of interpersonal problem areas that can trigger binge eating. It was found that both treatments were associated with equivalent significant reductions in the frequency of binge eating behavior at the end of treatment and at 1-year follow-up. However, neither treatment produced substantial weight loss. The greatest

reductions in weight occurred among participants who remained abstinent from binge eating at follow-up.

Although the research is scant, dialectical behavior therapy has also been successful in achieving binge abstinence in a significant proportion of individuals with binge eating disorder [101]. This approach, which has been shown to be effective for treating borderline personality disorder, teaches emotion regulation, distress tolerance, and mindfulness skills to cope with the negative emotions that often trigger binge eating. Finally, Overeaters Anonymous is an alternative treatment approach for compulsive overeaters. Overeaters Anonymous is an international network of self-help groups based on the 12-step Alcoholics Anonymous model that was founded in 1960 [99]. It views compulsive overeating as a disease that sufferers are powerless to overcome and recommends "surrendering oneself to a higher power". We wish to emphasize that this approach is quite different from the addiction model of binge eating disorder being advocated in the current chapter, and we are unaware of any controlled studies of its effectiveness.

Pharmacological Interventions

Several medications for binge eating disorder have been evaluated in placebo-controlled randomized trials, including selective serotonin reuptake inhibitors (e.g., [33, 50, 70]), antiobesity agents (e.g., [112]), and anticonvulsant medications such as zonisamide or, more promisingly, topiramate [68, 69, 71, 72]. There is some evidence that fluoxetine produces reductions in binge eating behavior. However, two recent studies found that cognitive behavioral therapy was superior to fluoxetine for binge eating and weight loss [33, 50]. On balance, sibutramine—a serotonin and norepinephrine reuptake inhibitor alleged to modify internal signals of hunger and satiety—has the best evidence for use in the treatment of compulsive overeating to date [107, 112]. In a recent large multicenter trial, Wilfley and colleagues found that sibutramine was superior to placebo in reducing binge eating and producing clinically significant weight loss over a 24-week period [112].

Integrating an Addiction Perspective

While there is strong empirical support for the use of cognitive behavioral therapy in the treatment of both binge eating disorder and drug addiction [18, 115], a substantial proportion are non-responders, and the rate of relapse is significant. We believe that the clear parallels between drug addiction and compulsive overeating, outlined earlier in this chapter, can provide a helpful framework for developing more effective treatments for binge eating disorder. Importantly, however, a major limitation for compulsive overeaters is the impossibility of completely abstaining from the "addictive substance" as is often recommended for drug addiction. Presenting individuals who have binge eating disorder with an addiction model of compulsive overeating—with the implicit message that they may be fighting a strong neurobiological drive to overeat in an environment that exploits these urges—may help foster a therapeutic sense of self-empathy as well as an understanding that treatment is likely to involve learning effective strategies and enduring lifelong efforts to resist overeating and prevent relapse.

All addictive behaviors may be used to increase positive feelings or sensations. For compulsive overeaters, the rewards may include the pleasant taste, the increased energy from rises in blood glucose, and an improved mood. Recognition of these effects points to the importance of helping individuals with binge eating disorder find alternative sources of reward and pleasure in their lives besides food and eating. Clinical experience suggests that individuals with binge eating disorder often report an overemphasis on food as the only source of enjoyment in their lives.

On the other hand, negative emotions are also major triggers for both binge eating and substance use since both food and drugs can also dull or distract from emotional distress.

Overcoming an addiction requires an individual to learn to tolerate negative emotional states, including cravings and urges for the addictive substance, without acting on them. That is why the development of emotion regulation and distress tolerance skills is central to the treatment of both binge eating disorder and drug addiction. Emotion regulation skills are strategies used to calm oneself down and feel better without engaging in self-destructive behaviors such as substance abuse or binge eating. Similarly, distress tolerance skills involve learning to sit with upsetting feelings and let them pass without acting on maladaptive urges. Those with binge eating disorder find it particularly distressing to experience a food craving or the urge to eat—even when not physically hungry—without acting on it. This is a skill that they must learn to master.

Drug addiction and compulsive overeating also require the interruption of deeply ingrained learned habits and stimulus preferences that are maintained by the reinforcing properties of powerful rewards. Both behaviors are conditioned responses to certain triggers and are generally followed by highly reinforcing consequences. Use of stimulus control strategies, such as limiting the availability of "binge foods" and confining eating to only one place in the house, may be helpful. As in drug addiction, it is possible that the consumption of "binge foods", typically high-calorie, high-fat foods, has a priming effect that can trigger compulsive overeating [106]. Whereas the cognitive behavioral therapy model recommends incorporating binge foods into one's daily meal plan, from an addiction perspective, avoiding trigger foods is the recommended course of action for binge eating disorder. As impulsivity is strongly associated with compulsive overeating and binge eating disorder (see earlier review), effective treatments also need to address problem-solving and decision-making skills to improve impulse control.

A final area worthy of further study is motivational interviewing—a client-centered but directive approach designed to help individuals explore and resolve ambivalence about change, thereby increasing intrinsic motivation to change problematic behaviors [73]. Ambivalence about change is common in both binge eating disorder and drug addiction. This is because, despite its negative consequences, the addictive behavior typically has many benefits for the individual. In the addiction field, it was shown that 4 sessions of motivational interviewing were superior to 12 sessions of cognitive behavioral therapy for alcohol abuse [85]. To our knowledge, only one study has examined motivational interviewing for binge eating disorder [37]. In this study, a single session of motivational interviewing plus unguided self-help was compared with self-help alone. No differences were found in terms of compliance with the self-help program or binge eating outcome. However, this may be because a single session was not of sufficient intensity to produce an effect. In order to recover, individuals with binge eating disorder, like those with drug and alcohol addictions, must resist strong biologically based urges to consume substances with powerful reinforcing properties. Enhancing and maintaining the motivation to do this in the long term is likely to be as important to the treatment of binge eating disorder as it has been shown to be in the treatment of drug and alcohol addiction.

Summary and Conclusions

In this chapter, we have presented an addiction model of compulsive overeating and binge eating disorder. We have reviewed evidence for this perspective, including overlapping clinical features, shared neurobiological mechanisms, and risk factor similarities. In addition, we have presented several recommendations for integrating this perspective into established treatments for binge eating disorder.

To date, studies on the psychological treatment of binge eating disorder have found that rapidly achieving and maintaining abstinence from binge eating is a crucial first step in achieving effective outcomes. While cognitive behavioral therapy may be the most widely used psychological treatment, an important limitation of

this approach is that it does not produce significant weight loss, does not sufficiently address the lack of dietary restraint in binge eating disorder, and results in a substantial proportion of non-responders [117]. As outlined in this chapter, we believe that integrating an addiction perspective that considers the similarities between treating drug addiction and treating compulsive overeating will improve outcomes.

Pharmacological treatments of binge eating disorder, particularly topiramate and sibutramine, have also had some success, but research in this area is limited by short treatment duration, small sample sizes, and lack of follow-up data following medication discontinuation. Currently there is no convincing evidence that combining medication with psychotherapy provides any added benefit beyond that afforded by psychotherapy alone.

Compulsive Buying

Joanna M. Marino, Troy W. Ertelt, James E. Mitchell, and Kathy Lancaster

Contents

Introduction

Kraepelin and Bleuler first identified "oniomania" or the "urge to buy" in the early 1900s [9, 35]. Today, compulsive buying is likely a much different phenomenon from what it was when Kraepelin and Bleuler first conceptualized the disorder. In the United States, and likely in all industrialized nations, consumer spending takes place in both public places such as shopping centers, discount stores, or rummage sales and in private homes through the use of online shopping and television shopping networks. The set of symptoms known as compulsive buying, pathological buying, or buying disorder has recently received increased attention in both the consumer and mental health literatures although data on the topic remain limited.

Diagnosis and Classification

Characteristics of compulsive buying include disinhibition or limited control over buying behavior [5]. Compulsive buying is not included in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision; however, McElroy and colleagues [42] have outlined criteria consistent with the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision format, and these have been widely adopted in defining and studying compulsive buying (Table 1).

Some have suggested that compulsive buying fits into the grouping of addictive and impulsive behaviors [29]. An individual with compulsive buying behavior may experience a cycle of urges and impulses, followed by pleasure or euphoria while shopping, and guilt after purchasing items, along with a drive to continue the behavior [29, 51]. Impulse control disorders involve impulses or drives that the individual cannot

Table 1 Diagnostic criteria for compulsive buying

Diagnostic criteria
(1) Maladaptive preoccupation with buying or shopping, or maladaptive buying or shopping impulses on behavior, as indicated by at least one of the following:
(A) Frequent preoccupation with buying or impulses to buy that is/are experienced as irresistible, intrusive and/or senseless.
(B) Frequent buying of more than can be afforded, frequent buying of items that are not needed, or shopping for longer periods of time than intended.
(2) The buying preoccupations, impulses or behaviors cause marked distress, are time consuming, significantly interfere with social or occupational functioning, or result in financial problems (for example, bankruptcy).
(3) The excessive buying or shopping behavior does not occur exclusively during periods of hypomania or mania.

Adapted from McElroy et al. [42]

resist, and these urges are harmful to oneself or another person [51].

According to its current classification, compulsive buying is a "disorder of impulsive control-not otherwise specified" due, in part, to the limited research on this topic [5]. Some researchers have hypothesized that compulsive buying falls onto a spectrum since the urge to buy may be variable in some individuals, or increasing and decreasing in certain situations, and the onset of compulsive buying behavior may be gradual [12].

However, research has yet to determine whether compulsive buying fits better with obsessive-compulsive, addictive, or impulse control disorders. Black [4] conceptualized compulsive buying as obsessive thoughts followed by the compulsion to buy, and Frost and colleagues [23] found that compulsive buyers had higher scores on an obsessive-compulsive symptomatology scale when compared with controls. Christenson and colleagues [11] also suggested that compulsive buying might have features of both impulsive and compulsive disorders. Further research needs to delineate the relationship of compulsive buying to each of these theories.

Common factors among compulsive buying behavior are the desire, relief, and feeling of well-being that come from purchasing. Compulsive buyers may believe that their material possessions, not necessarily their personal characteristics, determine their identity. By purchasing, such individuals may feel that they are presenting a more desirable self to the world while hiding their shame over their debt and ongoing purchases. In addition, some research has suggested that a better conceptualization of compulsive buying may include compulsive acquisition, meaning that some individuals who exhibit compulsive buying behavior may feel the need to pick up or gather free items such as brochures or fliers [23].

Individuals who exhibit compulsive buying behavior often appear to be upset over their own lying, such as hiding new packages from a spouse. For many compulsive buyers, the act of purchasing, rather than what they buy, is what leads to gratification [12]. Many who suffer from compulsive buying do not use the items that they purchase [20]. Some individuals may return or sell the item, though many keep the items [11, 26]. This collection of items can lead to clutter or result in hoarding behavior. Some individuals with compulsive buying disorder spend their money on themselves, while others buy gifts [20]. Some have reported that their urge to shop has led them to seek out and rummage trash cans and dumpsters.

Prevalence Rates and Subject Characteristics

The available data on prevalence rates of compulsive buying have proved to be variable. Koran

and colleagues [33], after conducting phone surveys, found a point prevalence of 5.8% in the United States, with female prevalence rates somewhat higher than males, at 6.0 and 5.5%, respectively. These numbers decreased to 1.4% point prevalence when the Compulsive Buying Scale cut-off score was increased. Compulsive buying respondents tended to be middle-aged, to have incomes below $50,000, to be more likely to make minimum payments on credit cards, and to be within $500 of maximum credit limits [33]. Individuals with compulsive buying behavior also usually spend over $100 during compulsive buying episodes [11]. Christenson and colleagues [11] found that most individuals who exhibited compulsive buying behavior were experiencing indebtedness and that an average of almost half of the household's income went toward attempts to resolve debt caused by compulsive buying behavior. Differences in shopping tendencies between genders, among individuals of varying incomes, and during special events (e.g., holidays, birthdays, or anniversaries) are important considerations in studying compulsive buying behavior [5].

One additional key feature of compulsive buying is the use of credit cards. O'Guinn and Faber [52] found that individuals who exhibited compulsive buying behavior, on average, tended to have more credit cards than general consumers and that more compulsive buyers' credit cards were within $100 of their limit. Access to credit cards is abundant in the United States, and cognitions associated with the use of credit cards (e.g., "I'm not paying for this right now", "I can afford this next month", or "I can pay off this credit card with another card") can often lead to the cycle of overspending. Additionally, the desire for and value placed on the need to attain and have the most items possible are likely key aspects for many compulsive buyers. Others diagnosed with compulsive buying disorder may feel driven to purchase items because they have a "collection" of specific items. Still others feel the allure of the sense of "saving" when they see a sales rack, even when they spend money on an item that they do not need.

Economics and Consumerism

Economists have long studied the behavior of buyers. Some believe that it is best to conceptualize compulsive buying on a continuum with "normal" spending. However, compulsive buying is a disorder involving more than just indebtedness. Whereas individuals with compulsive buying behavior do have control over their spending, there are other factors influencing and sustaining the impulse to buy that make those with compulsive buying disorder feel that they can no longer control their buying.

External forces may have etiological importance in the development of compulsive buying. For example, in the United States, there appears to be a sense of importance attached to having higher end goods such as new, expensive cars and designer fashions. Others may feel pressures from the American culture's pursuit of "youth". Individuals may experience a sense of psychological well-being when purchasing objects that fall into these categories and may think that these objects will make others perceive them as successful. Nevertheless, each individual may feel driven by a different factor or factors, and the concept of "success" may be different among individuals in different socioeconomic strata. Indeed, compulsive buying appears to affect individuals in varying socioeconomic categories [12].

Shopping in the United States is a somewhat gender-specific leisure activity. Black [5] suggested that compulsive buying behavior and compulsive gambling behavior might be gender-specific variants of the same underlying pathology, with compulsive buying behavior manifesting itself in women and compulsive gambling behavior being more prevalent among men. Those with compulsive buying disorder often find themselves drawn to shopping for clothing, shoes, music CDs, jewelry, makeup, groceries, and décor for the home [4, 44]. Larger items such as cars are also possible purchases, and for this reason, purchases differ depending on access to disposable income.

Etiology and Course

No one has examined extensively the possible etiologies of compulsive buying, although it will likely fit into a biopsychosocial etiological model [19]. The course for compulsive buying is probably chronic, with one study finding the mean age of onset in late adolescence to be about 18 years [11]. Identification of the buying as a problem tends to occur later, in one's late twenties or early thirties [11]. In many cases, the main thing that identifies compulsive buying is the large debt that subjects have accrued, followed by feedback from friends or family, legal problems, or guilt [11].

Levels of materialism and youth are predictors of compulsive buying tendencies [16]. Women are more likely to be diagnosed with compulsive buying disorder, perhaps since predominantly females hold the "shopping" role in families [11, 16, 42, 57]. Indeed, women are more likely to carry a diagnosis of compulsive buying. Additionally, women have had higher scores on compulsive buying inventories, suggesting that compulsive buying may be more severe in females [12]. Compulsive buying is also related to low self-esteem and to problem credit-card use [12, 13, 20, 52, 56].

Several variables may be important in determining etiological factors for compulsive buying behavior as well as differences in compulsive buying among younger individuals. Survey results of adolescents suggest a positive relationship between hours of television viewed per day and compulsive buying behavior. This may be due to the influence of materialism viewed on television [13]. There is also a significant correlation between compulsive buying behavior in adolescence and perceptions of parental compulsive buying behavior, possibly suggesting that compulsive buying is a learned behavior identified through modeling [13]. Adolescent girls also have had higher compulsive buying scores than boys, which speaks to the differences in diagnosis or shopping behavior between the genders [13]. Predictive modeling of adolescent compulsive buying behavior suggests that gender, younger age, peer influence, parents' compulsive buying behavior, tangible family resources, family stressors, and lesser family communication may predict compulsive buying [13, 25]. Others have found significant relationships between compulsive buying behavior and risk-taking behaviors such as smoking, alcohol and drug use, and unsafe sexual practices [53], which may speak to the relationship of impulsivity to compulsive buying behavior.

Developmental learning may also affect the formation of compulsive buying. In examining retrospective recall of childhood buying behavior, d'Astous [12] found that the likelihood of compulsive buying increased in individuals who reported a history of being likely to spend money quickly after receiving it in childhood, as well as when they reported their parents buying "everything" they wanted [12]. Additionally, susceptibility of influences from friends or social situations (e.g., feeling important when making a purchase, frustration when having fewer things than others do) was related to compulsive buying behavior [12]. Further research could better assess similarities in childhood experiences or modeling that may be precursors to compulsive buying.

There has been little research regarding the personal financial costs of compulsive buying. Miltenberger and colleagues [44] found that debt ranged from $0 to $30,000 in a small sample of individuals who exhibited compulsive buying behavior. Compulsive buying episodes can vary in duration from less than an hour to hours of shopping [44].

A range of emotions can lead to compulsive buying episodes. Individuals with compulsive buying symptoms suggest that they often experience negative emotions before shopping, though some report elation, power, and joy beforehand [11]. Miltenberger and colleagues [44] also found that ratings of sadness or depressed mood were significantly higher before shopping when compared with mood during the shopping episode. Faber and Christenson [19] also reported that boredom, depressed mood, and anxiousness were moods experienced prior to shopping. Euphoria and excitement ratings were

significantly higher during shopping episodes than afterwards [44]. These findings suggest that a negative mood state occurs before shopping and that shopping leads to a more positive change in an emotion. After shopping, a negative mood state is likely to emerge as individuals realize they are unable to afford the purchased items. In most cases, negative emotion (e.g., tension/anxiousness, anger/irritation, self-criticalness, and boredom) scores were highest before shopping and decreased during and after the shopping episode [44]. This model of negative reinforcement may sustain compulsive buying behavior [44].

Researchers have attempted to connect obsessive-compulsive spectrum disorders or impulse control disorder to compulsive buying, considering the possible role of serotonin in compulsive buying symptoms. In the only study directly examining this relationship, no differences emerged between compulsive buying participants and control participants in the rate of occurrence of two polymorphisms related to the serotonin transporter [15].

Comorbidity

A number of studies have examined the relationship of compulsive buying with other psychiatric disorders. The most commonly reported comorbidities include mood disorders, anxiety disorders, substance use disorders, impulse control disorders, and eating disorders [19, 42, 57]. For example, when compared with control groups, it appears that those with compulsive buying disorder are more likely to have a mood disorder or another psychiatric disorder than would be expected in the general population [7]. In individuals with compulsive buying disorder and their family members, depression and anxiety appear to be common [7, 20, 23].

The relationship between compulsive buying and mood disorders is reasonably well established. In his examination of several case series, Black [5] identified comorbidity rates for compulsive buying disorder and mood disorders ranging from 28 to 95%. It is important to note that compulsive buying behavior is distinct from the symptoms of a manic or hypomanic episode. Additional research on how spending and buying differ in manic episodes compared with compulsive buying episodes would be useful in understanding the distinction.

Researchers have drawn a strong link between compulsive buying disorder and binge eating disorder [21]. Faber and colleagues [21] performed two studies to assess the link between these two disorders. In the first study, they examined compulsive buying in women diagnosed with binge eating disorder. The authors found that the women diagnosed with binge eating disorder had significantly more symptoms of compulsive buying than did matched controls. In the second study, the authors compared a group of participants (mostly women) with compulsive buying behavior with a group of participants whose buying behavior was normal. The authors found that those with compulsive buying behavior were significantly more likely to engage in behaviors characteristic of binge eating disorder. Additionally, McElroy and colleagues [43] contributed a theoretical link between compulsive buying disorder and binge eating disorder, in that both disorders likely belong on the compulsive-impulsive behavior spectrum. Concerning other eating disorders, no one has shown a strong link between compulsive buying disorder and anorexia nervosa or bulimia nervosa [45].

As mentioned previously, some have suggested that compulsive buying disorder is part of the obsessive-compulsive spectrum [5]. Interest in the obsessive-compulsive spectrum has increased over the last several years, and some have suggested that up to 10% of the population in the United States has an obsessive-compulsive spectrum problem that includes intrusive thoughts and/or repetitive behaviors [28]. However, the relationship of compulsive buying disorder to obsessive-compulsive disorder and obsessive-compulsive spectrum disorders is unclear. For example, Bienvenu and colleagues [3] examined a sample of individuals diagnosed with obsessive-compulsive disorder and their first-degree relatives. They

identified only one case where compulsive buying disorder co-occurred with obsessive-compulsive disorder. Additionally, Jaisoorya and colleagues [30] examined a large sample of individuals with obsessive-compulsive disorder and found only one individual with comorbid compulsive buying disorder. While compulsive buying disorder symptoms seem to relate to the general symptoms of obsessive-compulsive disorder, it appears that the relationship between compulsive buying disorder and obsessive-compulsive disorder may be unremarkable.

Some have identified a relationship between compulsive buying disorder and kleptomania. McElroy and colleagues [43] presented a theoretical paper closely linking kleptomania and compulsive buying disorder. Lejoyeux and colleagues [40] identified a relative risk of comorbid kleptomania of 8.5% for those with compulsive buying disorder. It also seems possible that behaviors associated with kleptomania (e.g., shoplifting) may become more common in those with compulsive buying disorder as their financial situations deteriorate and they are unable to purchase the goods that they are compelled to obtain. Another disorder that some have speculated is closely related to compulsive buying disorder is pathological gambling. As noted above, Black [5] has conceptualized compulsive buying and pathological gambling as being gender-specific manifestations of a similar underlying psychopathology. In a sample of pathological gamblers, 23% had a lifetime history of compulsive buying disorder [6]. Christenson and colleagues [11] found no difference between individuals who exhibited compulsive buying behavior and age-matched control subjects across trichotillomania, pyromania, kleptomania, intermittent explosive disorder, or pathological gambling. However, compulsive buying subjects were more likely to have any impulsive control disorder when compared with the age-matched control group [11]. Further research about the comorbidity among compulsive buying, kleptomania, and pathological gambling could help to explain the complex relationship observed among these disorders.

Schlosser and colleagues [57] reported on a sample of 46 individuals who met criteria for compulsive buying. Participants completed two assessments (Structured Interview for *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition, Revised, Personality Disorders and Personality Diagnostic Questionnaire Revised), and the authors examined the extent to which the two instruments identified the same personality pathology. The most frequently identified personality disorder within the sample was obsessive-compulsive personality disorder. Twenty-two percent of the sample met the criteria for obsessive-compulsive personality disorder on both the Structured Interview for *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition, Revised, Personality Disorders and Personality Diagnostic Questionnaire Revised. Avoidant personality disorder and borderline personality disorder were both present in 15% of the sample. Overall, 59% of the sample met criteria for a personality disorder on both the Structured Interview for *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition, Revised, Personality Disorders and Personality Diagnostic Questionnaire Revised [57].

The literature on hoarding is too large to review in this chapter; however, the literature regarding compulsive buying and hoarding is worth mentioning. Frost and Hartl [22] identified several important features of compulsive hoarding, including the acquisition of seemingly useless possessions and the inability to discard them, the negative effect of clutter created from compulsive hoarding on the activities of daily living, and the distress and impairment experienced because of compulsive hoarding. Others have suggested that those who compulsively hoard possessions attach sentimental meaning to items while others do not [59]. Hoarding behavior is more likely in those with compulsive buying disorder compared with a non-compulsive buying group [23]. No one thus far has proposed a diagnostic specifier for identifying hoarding behavior in compulsive buying; however, it may be that a hoarding specifier could help in differentiating compulsive buying disorder subtypes.

That is, those with compulsive buying disorder who choose to give their items away may differ from those buyers who hoard items or see some sentimental value in the possession [23]. Indeed, Mueller and colleagues [48] suggested that compulsive buying behavior might be more severe in those compulsive buying subjects who hoard compared with those who do not hoard items. Moreover, compulsive buying subjects with hoarding behavior are more likely to have an affective disorder, substance use disorder, eating disorder, or anxiety disorder than those subjects who only hoard, suggesting more comorbid psychopathology in those with both hoarding and compulsive buying behavior [48]. Further research is needed to identify whether those individuals with hoarding traits are different from those with compulsive buying without hoarding behavior and to determine how treatment may differ between these two groups.

Almost half of one compulsive buying sample had a substance abuse problem, with most subjects abusing or dependent on alcohol [23]. Researchers have shown that substance abuse is comorbid with compulsive buying behavior, although no research to the authors' knowledge has directly examined the relationship between the two disorders.

Cultural Considerations

Researchers have investigated compulsive buying in several countries, including the United States, Canada, Germany, Belgium, and the United Kingdom, with prevalence rates from 2 to 10% found in the United States, United Kingdom, and Germany [50]. Compulsive buying increased in Germany from 1991 to 2001 [50]. Research in other countries has not yet determined whether compulsive buying behavior is on the rise.

Data comparing American and German samples suggest that the severity of compulsive buying in both samples is largely equivalent [49], while German buyers were more likely to have a current or past psychiatric disorder and have a history of more psychiatric disorders, especially affective and anxiety disorders [49]. Substance abuse and binge eating were also highly comorbid disorders in the German sample [49]. Gwin and colleagues [25] have identified some significant predictors (e.g., gender, parents' compulsive buying, tangible family resources, communication style, and family stress) for compulsive buying tendencies in an adolescent sample from Mexico.

A study in South Korea comparing compulsive buying in American and South Korean college students revealed some similarities in their behavior [38]. However, different patterns emerged when the authors administered the Diagnostic Screener for Compulsive Buying, as developed by Faber and O'Guinn [18], to samples from both the United States and South Korea. In the United States, the Diagnostic Screener for Compulsive Buying is unidimensional; however, in South Korea, the authors observed a bidimensional structure of the same measure [37]. The two dimensions suggested for the South Korean samples related to "financial outcomes" and "unfettered spending" [37]. The authors interpreted this difference in response to the Diagnostic Screener for Compulsive Buying as being indicative of culturally different manifestations of compulsive buying disorder.

In an analysis of Israeli consumers, Shoham and Brenčič [58] found that predictors of compulsive shopping behavior included unplanned purchasing, the tendency of consumers to buy items that were not on a list, and gender (i.e., females). The authors concluded that the "in-store decision-making" might lead to compulsive buying behavior.

Assessment

When assessing for compulsive buying, several factors are important to consider. First, the behavior cannot be better accounted for by another disorder such as mania or bulimia nervosa (in which individuals may buy large quantities of food to eat) or by an organic problem such

Table 2 Instruments useful in the assessment of compulsive buying

as a brain injury [5]. Several instruments used in research and designed to characterize compulsive buying behavior (Table 2) also would be helpful in clinical populations.

Treatment

Impulse control disorder treatment often involves problem solving, learning and employing alternative behaviors, cognitive restructuring, and relapse prevention interventions [27]. Compulsive buying has its own complexities, as buying behavior cannot ever be fully eliminated [52]. Randomized controlled trials in either individual or group formats of cognitive therapy have yet to be conducted, and no self-help manuals have been studied in the treatment of compulsive buying disorder; however, research in this area is developing.

Mitchell and colleagues [46] have created a self-help and group therapy manual that appears to be beneficial in the treatment of compulsive buying disorder. The following outline would typify a 10-week treatment plan:

- Week 1: Individuals are encouraged to calculate current debt, which is also essential in order for participants to determine a plan to resolve the debt that they have accrued. Many times, credit counselors are options for participants who are overwhelmed by their debt.
- Week 2: Like most cognitive-behavioral models, compulsive buying disorder treatment begins by encouraging individuals to identify their problem buying behaviors and the cues that lead to these behaviors (Fig. 1). Each week, subjects are required to complete a purchasing record to aid in the identification of problematic buying behavior.
- Week 3: Individuals who exhibit compulsive buying behavior are coached on how to avoid problematic situations, restrict their stimulus field (e.g., stopping only at specific, "low-risk" stores), and increasing more desirable behaviors and activities. Delaying the response to buy by waiting at least 24 h can work to remedy impulse shopping.
- Week 4: Compulsive buying participants learn cash management techniques such as carrying small amounts of cash, paying off credit card debt, determining how much money they should place in a savings account each week, and balancing a checkbook. Following an introduction to healthy buying behavior, participants begin to identify hoarding behavior as well as how to resolve this behavior.
- Week 5: There is a discussion of thoughts, feelings, and behaviors related to compulsive buying. Participants identify how cues lead to specific emotions, behaviors, and thoughts, and what consequences ensue.
- Week 6: There is a discussion of cognitive restructuring, especially challenging nonproductive thinking (e.g., "I can't live without my credit card" or "I have to go to the mall to feel better").
- Week 7: There is an examination of self-esteem, especially in relation to shopping and self-image.
- Weeks 8 and 9: In addressing exposure, stress managements, and problem solving skills, participants are encouraged to allow themselves into situations where they can identify and control their urge to buy and implement a new strategy for dealing with negative mood states.
- Week 10: In a discussion of relapse prevention plans, individuals learn to identify

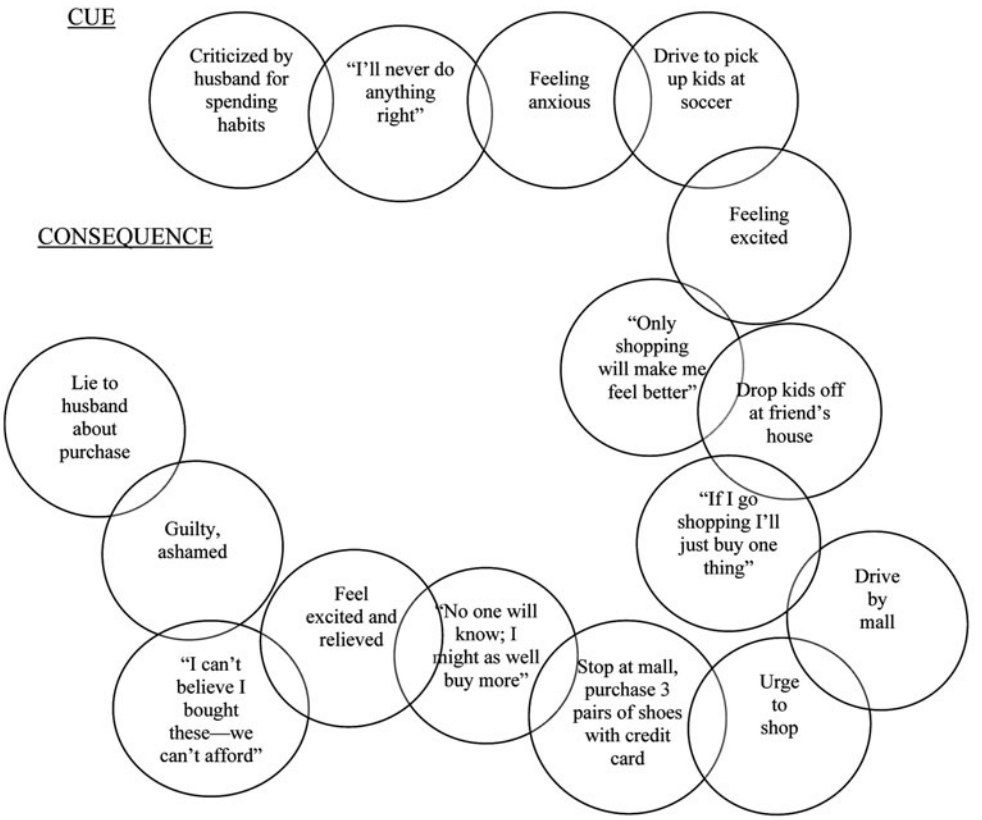

Fig. 1 Cue and consequence diagram

high-risk situations that may lead to lapses in compulsive buying behavior. They also identify how they can respond if a setback in buying occurs.

An examination of this cognitive-behavioral type therapy approach suggests positive results at the end of treatment and a 6-month follow-up, although the sample size in this pilot study was small [46]. Education about credit card use may be the key, as the use of cash and debit cards may have a very different impact on continued compulsive shopping, when compared with the continuing use of credit cards [12, 46]. Post-treatment debts may be a concern in the resolution of mood symptoms [46]. Authors have also concluded that materialistic feelings and attitudes may be important predictors and subsequently important treatment factors in compulsive buying therapy [16].

Additionally, a small case series ($n = 4$) of individuals with compulsive buying symptoms was treated with psychoanalysis [36]. The author suggested that internal emptiness is what created and maintained the compulsive buying behavior. There were no specific outcome data reported for this case series.

Support groups for treating addictions, such as Alcoholics Anonymous for alcoholism, have long been in use. Compulsive buying support groups have not become as common as other treatment groups although Debtors Anonymous has been able to assist in debt management [41]. Additionally, Brazer [10] outlined his method for aiding individuals with "money disorders", which includes the use of Debtors Anonymous in combination with psychoeducational group formats that discuss the disease model of addictions, educate individuals on debtors, deal with negative emotions such as anger and depression,

improve self-esteem, and plan for the future. One major concern with using Debtors Anonymous is the group's limited number of locations. Black [4] also noted that several self-help books have been developed [2, 14, 61].

Research on pharmacological treatment interventions has been mostly inconclusive although researchers have studied several classes of medication. Case studies have suggested that naltrexone may be beneficial in the treatment of compulsive buying since the medication specifically targets the urge to shop [24].

Fluvoxamine has treated several psychological disorders including obsessive-compulsive disorder and depression. Black and colleagues [8] found similar and substantial improvement in a 9-week, double-blind comparison of fluvoxamine and placebo in compulsive buying subjects. Ninan and colleagues [51] found equivocal results between the control and fluvoxamine groups. However, in both studies, the authors suggested that psychoeducation related to compulsive buying symptoms and nonspecific therapeutic variables may have aided in the improvement of subjects [8, 51]. These results suggest that self-help manuals or generalized therapeutic attention via more cost-effective support groups may be beneficial for individuals with compulsive buying disorder.

Koran and colleagues [34] investigated the use of escitalopram in conjunction with relapse prevention in compulsive buying and found that a similar number of both placebo and escitalopram subjects experienced relapses. Many of the subjects who relapsed in both groups appeared to have comorbid depression symptoms at the time of relapse or at baseline, suggesting the possibility of negative mood states as an etiological factor to compulsive buying [34].

Koran and colleagues [31] also reported on open-label trials using citalopram for compulsive buying. The results appeared positive as all subjects showed decreased scores on the Yale-Brown Obsessive-Compulsive Scale-shopping version and a depression scale [31]. Again, these authors suggested that the attention that individuals exhibiting compulsive buying behavior received in a clinical setting or the shopping logs that they completed might have had an important impact in the resolution of the compulsive buying systems, and that research with citalopram treatment alone is needed [31]. In a later study, Koran and colleagues [32] again found beneficial outcomes for all seven individuals randomized to the citalopram group in a double-blind study.

Aboujaoude and colleagues [1] conducted a 1-year follow-up with individuals who had exhibited compulsive buying behavior in Koran and colleagues' [31] sample. At 3, 6, 9, and 12 months, over 70% of initial responders to citalopram were in remission [1]. Yale-Brown Obsessive-Compulsive Scale-shopping version scores appeared to increase somewhat in those who initially responded to citalopram, while total debt and shopping expenditures decreased [1]. Those who did not appear to respond to citalopram during the initial study showed poorer long-term outcomes [1].

One clear problem with the pharmacological treatment studies thus far is small sample sizes. Further research clearly needs to determine how individuals will respond to varying selective serotonin reuptake inhibitors and other agents and what impact clinical attention has in these studies.

Future Research

Compulsive buying, while first identified nearly a century ago, apparently has become an increasingly common problem. This has led to increases in research in this area, but further study of the problem will need to determine which individuals on the compulsive buying spectrum will benefit from cognitive-behavioral therapy, behavioral therapy, or medication. Current literature on compulsive buying examines only cognitive-behavioral interventions; therefore, future research should likely examine other treatment interventions such as interpersonal therapy or behavioral therapy. Additionally, compulsive buying treatment will likely need to address compulsive buying comorbidity. Finally, there needs to be further

delineation of possible compulsive buying subtypes. The current chapter identified the state of research in this area, and further advances will help to identify and treat more appropriately those struggling with compulsive buying.

Sexual Behavior as an Addictive or Compulsive Phenomenon

Kimberly R. McBride, Michael Reece, and Brian Dodge

Contents

Introduction

Due to the magnitude of the human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS) epidemic, and its profound impact on public health and social structures, an emphasis on the behavioral, social, and cultural factors associated with sexual risk and its relation to HIV transmission has been essential. However, an unanticipated artifact of disease-focused research is that much of the contemporary knowledge related to sexual behavior has been constructed in the context of HIV. Apart from Kinsey and colleagues' pioneering studies [42, 43] and a series of national health surveys which contain items on sexuality, scientists still know relatively little about sexuality issues in the general population in comparison with other aspects of health and human behavior [45].

This void of knowledge has led to an increase in the "pathologizing" of sexual behaviors that are viewed as "atypical" or "amoral", with little empirical evidence from representative studies [34]. A vivid example of this phenomenon can be seen in the recent social construction of "sexual addiction" as a clinical disorder. Although there has been substantial debate and skepticism surrounding the nature and existence of sexual addiction (or sexual compulsivity) as a pathological condition, the concept has been widely studied and measured in recent sexological, psychological, and public health research [46]. In addition, numerous clinicians and self-help groups have increased awareness of, and "treatments" for, sexual addiction and sexually compulsive behavior. As yet, however, studies of sexual compulsivity and its associations with sexual behavior have been primarily assessed

among individuals who are already considered to be at "high risk" for sexual health problems. Additionally, researchers have rarely focused on relations between sexual compulsivity actual negative health outcomes (physical or otherwise). Indeed, research on the topic to date has thus far raised more questions than answers.

History of Sexual Addiction and Sexually Compulsive Behavior

The earliest descriptions of sexually compulsive behavior can be traced to Greek myths of satyrs and stories of the god Dionysius [26, 51]. The term "nymphomania", used to describe female sexual excess, is derived from Greek. In the nineteenth century, the term "Don Juanism" was used in reference to male sexual excess [26]. In the late nineteenth century, Krafft-Ebing presented one of the first case studies detailing the effects that compulsive or "out-of-control" sexual behaviors had on the life functioning of a male client [44].

The notion that sexual behavior can be conceptualized as an addiction or compulsion warranting psychiatric treatment is relatively recent [31, 41]. During the mid-to-late twentieth century, case reports were published describing similar clinical presentations from individuals reporting out-of-control sexual behaviors; however, the terms used to describe the behavior and the conceptualizations of etiology varied widely [3, 17, 22, 24, 35, 53, 54, 62]. Terms ranged from nymphomania and Don Juanism to perversions and paraphilias, compulsive sexual behavior, impulse control disorders, sexual addiction, and sexual compulsivity.

Currently, a universally accepted term and a clear definition of out-of-control sexual behavior do not exist. The terms most often used by researchers and clinicians in reference to out-of-control sexual behavior include: compulsive sexual behavior; sexual addiction; sexual compulsivity; sexual impulsivity; and hypersexuality [7, 12, 13, 18, 27, 33, 36, 50, 60]. In general, these terms are used to describe sexual behavior that is beyond an individual's control which leads to impairment in life functioning and a range of negative outcomes. There is no single treatment strategy that is widely accepted, rather approaches range from cognitive behavioral therapy to the use of selective serotonin reuptake inhibitors and naltrexone to 12-step group interventions.

Sex Outside the Norm

Over the past 30 years, the idea that sexual behavior can become a clinical disorder leading to significant impairment in life functioning has appeared in the scientific literature with increasing frequency. Prior to the emergence of HIV and AIDS in the late 1970s and early 1980s, interest in the phenomenon of out-of-control sexual behavior was primarily limited to psychological researchers and clinicians. It was not until the early 1980s that the terms "sex addict" and "sexual compulsive" were used in scholarly writing and popular culture to refer to individuals whose sexual behaviors rested outside of accepted socio-cultural norms. However, the emergence of HIV brought attention to sexual behaviors that increased the likelihood for transmission. Among the factors that were identified as high risk was sexual behavior that is perceived to be beyond an individual's control.

In the decades following the initial HIV crisis there has been a rapid proliferation of research aimed at understanding the etiology and consequences of out-of-control sexual behavior as well as approaches to treatment. Much of the existing research has focused on the sexual behaviors of gay men, clinical samples of pedophiles and self-identified "sex addicts", and, in particular, sexual risk-taking behaviors such as unprotected intercourse. Fewer studies have focused on identifying sub-clinical levels of out-of-control sexual behavior and non-clinical populations, particularly women. However, researchers have devoted a significant

amount of attention to studying the relationship between out-of-control sexual behavior and sexual health outcomes, such as the transmission of HIV and sexually transmitted infections. Research has linked out-of-control sexual behavior to participation in high-risk sexual behaviors following an HIV diagnosis, the acquisition of sexually transmitted infections, substance abuse disorders, and psychiatric comorbidity [8, 36, 37, 55, 57–59].

While documentation linking out-of-control sexual behavior to psychological distress and sexual health consequences exists, the construct remains controversial within the scientific community. Scholars have argued that definitions of normative sexual behavior are subject to social and psychological theories unique to culture and time in history and often reflect socio-cultural mores governing behavior [29, 41]. Much of this debate centers around fundamental issues associated with defining out-of-control. Until recently, the universal gold standard for identification was behavioral frequency. Sex researcher John Bancroft and colleague Zoran Vukadinovic wrote a critical review of the construct of out-of-control sexual behavior, calling for scientific evidence that the behavior is qualitatively different from normative sexual behavior that occurs at the high end of the continuum. In their article, Bancroft and Vukadinovic maintain that it is negligent to assume that engaging in frequent sexual activity is inherently risky or problematic without documenting the occurrence of negative consequences [4].

Others have argued that perceptions of control over sexual behavior are social constructions, and that the importance and meaning of "out-of-control" models might reflect notions of self-control and self-consciousness unique to the American culture [32, 61]. It has been suggested that the idea of diagnosis, and subsequent labeling, reflect attempts to pathologize and medicalize sexual behaviors [32]. These scholars often cite the fact that homosexuality was listed as a mental disorder in the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association until the late 1970s. This point is central to understanding the lack of consensus among the scientific community given the rapidly emerging possibilities for the expression of sexuality and the diverse range of sexualities that exist in contemporary society. There remains a need for research that takes into account that sexual behaviors and norms vary among individuals and cultural groups. Indeed, what may be viewed as problematic for one individual, or within one culture, may be normative within another. Such variations in sexual behavior and behavioral frequency make it critical to link behavior to the actual occurrence of negative outcomes, and to understand the role of associated factors, in order to avoid errors in identifying and treating problematic sexual behaviors.

Clinical Criteria

While researchers and clinicians have identified out-of-control sexual behaviors as problematic and have linked such behaviors to negative psychological and sexual health outcomes, the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition has no specific diagnostic criteria or category for classification [1]. Rather, according to the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, out-of-control sexual behaviors can be classified under one of three major categories: paraphilia, either one or more specifically identified or paraphilia not otherwise specified; impulse control disorder not otherwise specified, or sexual disorder not otherwise specified. The absence of an accepted nomenclature and diagnostic criteria limit the diagnosis and treatment of problematic behavior.

Despite the ambiguity surrounding diagnosis, there is an over-whelming consensus among researchers regarding the comorbidity of sexual compulsivity with psychological and substance abuse disorders. The literature consistently links out-of-control sexual behaviors to psychological distress and substance use and dependency [19, 38, 39, 56, 58, 64, 65]. Benotsch et al.

found that among their sample ($N = 294$), individuals with higher sexual compulsivity scores also scored higher on indicators of depression, anxiety, borderline personality traits, obsessive-compulsive personality traits, and hopelessness [8]. Likewise, Wan et al. found that 39% of their treatment sample ($N = 59$) reported at least one pre-existing psychiatric diagnosis [64]. Kalichman and Cain found that higher levels of sexual compulsivity were linked to higher usage rates of alcohol, powder cocaine, crack cocaine, and inhalants [38]. Bancroft and Vukadinovic reported that among their sample of self-identified sex addicts ($N = 31$), one-third reported other addictive patterns, including alcohol, drugs and alcohol, overeating, computer games, and shopping [4].

The above studies represent only a few examples of published findings describing the comorbidity of psychiatric disorders and substance abuse disorders and out-of-control sexual behavior. However, findings from additional studies consistently report similar links. These findings raise questions for some about whether such associations provide evidence that out-of-control sexual behavior is a unique disorder or condition, or whether it should be conceptualized as the behavioral expression of another underlying disturbance. While it is possible that out-of-control sexual behavior does warrant its own classification, it is also possible that individuals who suffer from other disturbances use sex as a means of self-medication to alleviate or temporarily escape discomfort deriving from underlying distress. This point becomes particularly important when we consider the notion of excessive sexual behavior among non-clinical samples, as studies have shown that non-clinical negative mood states can influence sexual interest among some individuals.

The way in which psychological disorders or mood states affect sexual behavior is somewhat unclear. For example, it has long been established that clinical depression and anxiety can lead to a decrease in sexual interest and response, however recently attention has been given to the idea that among non-clinical samples depression and anxiety may actually serve to increase sexual interest [2, 5, 6, 47]. A recent study which looked at the relationship between mood and sexuality in heterosexual men and women found that 10% of men and 9.5% of women reported increase sexual interest when feeling depressed, and 25% of men and 23% of women reported an increase in sexual interest when feeling anxious [47]. A similar study investigating the relationship of mood and sexuality in heterosexual men found that 12% of the sample reported increased sexual interest when depressed [6]. The increase in sexual interest was markedly greater for anxiety, with 23% of the sample reporting higher levels of sexual interest during times of anxiety or stress. Among gay men, similar patterns have been noted. A study that explored mood and sex among a sample of gay men found that 21% of men reported an increase in sexual interest when depressed, while 17% reported an increase in sexual interest related to anxiety or stress [6]. Finally, a study investigating sexual functioning and self-reported depressive symptoms among a sample of college women found that women with higher levels of depression reported significantly more desire for masturbation when compared with controls, though desire for sex with a partner did not differ significantly [30].

Exploring out-of-control sexual behavior among both clinical and non-clinical samples may help clarify the relationship between psychological disorders, and/or mood states, and sexual behavior. Whether out-of-control sexual behavior is understood as a distinct psychological disorder, the symptom of underlying pathology, or a coping mechanism for alleviating non-clinical negative mood states has important implications for how such behavior is explained theoretically.

Etiology

Several researches have attempted theoretical explanations of out-of-control-sexual behavior and, as a result, various theories and models of

causation exist. Among the most widely cited etiological explanations are Carnes' Addiction Model, Coleman's Compulsive Sexual Behavior Model, and Kalichman's Impulse Control Model [14, 19, 39]. Each of these conceptualizations provides theoretically based explanations of etiology; however, overwhelming empirical support favoring any of these explanations is markedly absent. In fact, there is a clear divide among the research community on whether or not the phenomenon exists at all, with some scholars arguing that more substantial and convincing evidence is needed to support the notion of out-of-control or compulsive sexual behavior.

Carnes' Addiction Model

Carnes believed that sexual addiction is a chronic illness, and defined it as an extremely intense sex drive or obsession with sex [14]. Further, sex becomes the most important need, driving the individual's behaviors [15]. Carnes operationally defined sex addiction as a pathological relationship with a mood-altering experience, and believed that the hallmark of sexual addicts is the lack of ability to control their sexual feelings, thoughts, and behaviors [16, 63]. Rather than sex being a pleasurable act for the individual, Carnes asserted that for the addict, sex becomes a tool to ameliorate pain and relieve stress; at the core of the addiction is the fear of abandonment and shame [14, 15]. Carnes, and others who have supported his addiction model, likened the biological, neurological, and physiological responses that result from sexual stimulation to responses resulting from the consumption of alcohol and other drugs [25, 65].

In terms of treatment, Carnes advocated a 12-step approach adapted from the Alcoholics Anonymous model. The underlying premise of the approach is that the individual is an addict and is, therefore, powerless over the amount or type of sexual activity in which he or she engages [14, 51]. A key component to this approach is the belief that the individual is overwhelmed by shame, and in order to recover must progress through the 12-step process.

Coleman's Compulsive Sexual Behavior Model

Coleman first introduced the Compulsive Sexual Behavior Model of sexual compulsivity in 1990. Coleman theorized that compulsive sexual behavior is a disorder in which the individual experiences intense sexually arousing fantasies, urges, and associated sexual behaviors that are intrusive, driven, and repetitive [19]. Individuals with compulsive sexual behavior are described as being unable to control their sexual behavior and may perceive their behavior as excessive. Further, these individuals often experience serious co-morbid symptoms and associated consequences including, anxiety; depression; somatic complaints; alcohol or drug abuse or dependency; HIV or other sexually transmitted infections; unwanted pregnancy; relationship problems; domestic violence; sexual dysfunction; or child abuse [20]. According to Coleman et al., compulsive sexual behavior may lead to ethical, social, and legal problems, as well as psychological distress [20].

Coleman conceptualized compulsive sexual behaviors as fitting into one of two distinct categories, either paraphilic or nonparaphilic. Whereas paraphilic compulsive sexual behavior is comprised of non-normative sexual behavior that involves both distress and recurrent fantasies, nonparaphilic compulsive sexual behavior involves the excessive and compulsive engagement in normative sexual behaviors [19]. The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, classifies eight paraphilic disorders: exhibitionism, fetishism, frotteurism, pedophilia, sexual masochism, sexual sadism, transvestic fetishism, and voyeurism. While there have been attempts to declassify a number of these paraphilias, Coleman et al.

pointed out that in order to meet clinical criteria an individual must experience sexually arousing fantasies, sexual urges, and behaviors that cause clinically significant distress in social, occupational, or other important areas of functioning [1, 20]. Coleman et al. asserted that, by nature, paraphilic behaviors impair an individual's ability to form reciprocal love relationships and sense of well-being [20]. The term "nonparaphilic compulsive sexual behavior" was used by Coleman to refer to the phenomenon under investigation in this study. There is no clear diagnostic category for nonparaphilic compulsive sexual behavior listed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition [1]. However, Coleman et al. contended that an example can be found under the category "sexual disorder not otherwise specified" [20]. The example referred to by the author's states: "distress about a pattern of repeated sexual relationships involving a succession of lovers who are experienced by the individual only as things to be used." Nonparaphilic compulsive sexual behavior is thought to have at least 7 subtypes: compulsive cruising and multiple partners, compulsive fixation on an unattainable partner, compulsive autoeroticism (masturbation), compulsive use of erotica, compulsive use of the internet for sexual purposes, compulsive multiple love relationships, and compulsive sexuality within a relationship [11, 20]. Nonparaphilic compulsive sexual behavior is thought to lead to serious mental, sexual and physical health problems.

Coleman et al. acknowledged that there is no clear division between subclinical symptoms and a diagnosable clinical condition, and that individuals may experience problematic sexual behaviors without meeting the clinical threshold for compulsive sexual behavior [20]. Despite the lack of clear demarcation, Coleman et al. provide clinical criteria for diagnosing compulsive sexual behavior [20]. According to the guidelines, criteria for compulsive sexual behavior are met when the individual has recurrent and intense normophilic or paraphilic sexually arousing fantasies, sexual urges, and behaviors that cause clinically significant distress in social, occupational, or other areas of functioning; and these fantasies, sexual urges, and behaviors cannot be accounted for by another medical condition, substance use disorder, Axis I or II disorder, or developmental disorder. Further, gender, sexual orientation, and sociocultural norms must be taken into account.

The etiology of compulsive sexual behavior is described as complex and likely involving a variety of physiological and psychological factors [20, 56]. Coleman discussed links to both neuropsychiatric conditions such as temporal lobe lesions, epilepsy, and head trauma, as well as psychological disorders, particularly anxiety and depression. Coleman contended that neuropsychiatric causes should be considered when the onset of compulsive sexual behavior is subsequent to a trauma, surgery, illness, or the use of a substance (prescribed or not). If neuropsychiatric causes are ruled out, it is important to consider psychological factors [20, 56].

The suggested treatment for compulsive sexual behavior is a combination of pharmacotherapy and psychotherapy. According to Coleman's treatment paradigm, psychotherapy for compulsive sexual behavior explores environmental and psychodynamic stressors that contribute to the behavior. In addition, clients are taught coping mechanisms to manage stress, anxiety, and depression. A group treatment approach is recommended however such groups are not widely available. Because there are many types of compulsive sexual behavior, Coleman suggested tailoring therapy to individuals within the group setting [20]. Couples and/or family therapy, in conjunction with individual or group treatment, may help facilitate healthy sexual and/or intimacy functioning. Favored pharmacological interventions include the use of selective serotonin reuptake inhibitors or naltrexone. The body of evidence supporting the efficacy of selective serotonin reuptake inhibitors for treating compulsive sexual behavior comes from several small sample studies and case reports [10, 11, 21, 35]. Likewise, there have been few studies examining the efficacy of naltrexone for treating compulsive sexual behavior [56]. Instead, much of the literature supporting the efficacy of

naltrexone studied a variety of other disorders, including: alcoholism, cocaine abuse, eating disorders, and pathological gambling.

Kalichman's Impulse Control Model

Kalichman's primary interest in the notion of out-of-control sexual behavior grew out of the desire to understand mediating factors associated with HIV risk and the resistance to adopting risk reduction strategies [40]. According to Kalichman, sexual compulsivity is a heterogeneous psychological construct that can include a preoccupation with sexual desires and behaviors to the degree that disruptions in social relationships, occupational difficulties, and problems in daily living are experienced by the individual [38]. Further, Kalichman denoted that this conceptualization of sexual compulsivity is not synonymous with sex addiction, hypersexuality, or other clinically defined categories [38]. Kalichman defined sexual compulsivity as the propensity to experience sexual disinhibition and under-controlled sexual impulses and behaviors as self-identified by the individual [38]. In addition, Kalichman believed that sexual compulsivity most likely has multiple forms and etiologies.

Because Kalichman's conceptualization of sexual compulsivity is non-clinical, the bulk of his work on the topic has been devoted to documenting the relationship between sexual compulsivity and HIV/sexually transmitted infection risk, rather than trying to articulate theoretical underpinnings. Simply, he believes that individuals can only be identified as sexually compulsive when they self-report multiple markers of sexual preoccupations and under-controlled sexual impulses, and that this is likely related to a lack of impulse control [8, 38].

Measurement

A range of measures have been developed and used in research related to sexually compulsive behaviors. The primary measures include the Compulsive Sexual Behavior Inventory and the Sexual Compulsivity Scale [19, 36]. More recently, a new scale has been developed to assess whether one's sexual behaviors are associated with the negative cognitive and behavioral outcomes that have been proposed by groups such as the Society for the Advancement of Sexual Health [48, 49].

Compulsive Sexual Behavior Inventory

The Compulsive Sexual Behavior Inventory was developed in response to the lack of existing scales that attempted to identify individuals with compulsive sexual behavior [19]. According to the authors, previous attempts to develop such a scale failed to incorporate all of the major components of the phenomenon. The Compulsive Sexual Behavior Inventory was intended to create a standardized, reliable, and valid assessment tool for clinicians and researchers. For validation purposes, it was hypothesized that groups of individuals with paraphilic and nonparaphilic compulsive sexual behavior would not differ significantly on the measure but would differ significantly from controls.

The preliminary study of reliability and validity of the Compulsive Sexual Behavior Inventory included three groups, individuals diagnosed with paraphilic compulsive sexual behavior recruited from a sex-offender treatment program ($N = 35$), individuals with nonparaphilic compulsive sexual behavior recruited via advertisements ($N = 15$), and control participants recruited via advertisements ($N = 42$). The initial inventory consisted of 42 items related to sexual control and various aspects of behavior associated with both paraphilic and nonparaphilic compulsive sexual behavior [19]. Participants were directed to rate their responses to items on a scale ranging from 1 = Very frequently to 5 = Never. A principal components factor

analysis using varimax rotation was performed on the data. Factor loadings that exceeded 0.60 after rotation were retained for the final scale. The reliability of the retained factors was tested using Cronbach's alpha and the data were tested using linear discriminant function analysis to determine the scale's ability to differentiate individuals with compulsive sexual behavior from controls. In addition, three analyses of variance were conducted to explore mean differences for each group on the identified subscales. A plot of data from the entire sample indicated that a three-factor solution had the best fit. The three-factor solution accounted for 58% of the variance in the data, with the first factor explaining 42% of the variance. The second factor explained 10.1% of the variance (eigenvalue = 4.26), and the third factor accounted for 5.9% of the variance (eigenvalue = 2.46). The retention of items on each factor was determined by the magnitude of the factor loading and subsequent assessments of face validity. A total of 28 items were retained, and the factors appeared to measure control, abuse, and violence.

Initial tests of validity were conducted using linear discriminant function analysis, testing the scale's ability to distinguish between groups believed to have compulsive sexual behavior versus those who did not. The classification matrix was reported to have correctly identified 92% of cases, with one normal control being incorrectly classified as compulsive and six compulsives being identified as normal. Further explorations of validity used the three subscales as independent variables in analyses of variance to explore group differences. The findings revealed significant effects for group on the control subscale. Further, pairwise comparisons demonstrated that pedophiles scored significantly lower on the subscale when compared with the other two groups. A significant main effect was also found for the violence subscale, and subsequent pairwise comparisons revealed that controls differed significantly from pedophiles. Table 1 provides the measures contained in the Compulsive Sexual Behavior Inventory.

Sexual Compulsivity Scale

Kalichman posited that intrinsic factors such as personality disposition might play a role in HIV risk behaviors; particularly, he was interested in Zuckerman's work on sensation seeking. Based on findings from previous studies that linked sensation seeking to high-risk sexual behaviors, Kalichman theorized that sensation seeking might be an important predictor of HIV risk and resistance to behavioral change [28, 40, 52]. In order to test his theory, Kalichman adapted the Sensation Seeking Scale to measure sensation seeking specific to sexual behavior and, in addition, developed a measure of sexual compulsivity [66].

The Sexual Compulsivity Scale was designed to measure two aspects of sexuality: hypersexuality and sexual preoccupation, and items reflect "excessive preoccupation with sex acts and encounters" [36]. The scale has been widely used to investigate high-risk sexual behaviors. The scale consists of 10-items and directs respondents to indicate the extent to which they agree with statements ranging from "not at all like me" to "very much like me". The 10 items used in the Sexual Compulsivity Scale were derived from a 12-step self-help recovery manual for sex addicts [16, 53].

Scale reliability and validity were tested in two samples. The first sample consisted of self-identified gay men ($N = 286$). Sixty-three percent of the sample was white, and 72% reported an annual income over $20,000. Participants were recruited through fliers were placed in bars and social organizations in Milwaukee, Wisconsin. The second sample consisted of inner-city men ($N = 60$) and women ($N = 98$) at high-risk for HIV. Ninety-five percent of the sample identified as African-American, and 94% reported an annual income of less than $20,000. Participants in this sample were recruited through local community agencies in Milwaukee, Wisconsin. Tests of reliability were performed by computing alpha coefficients. Internal consistency for sample 1 was reported to be alpha = 0.86, and for sample 2 to be

Table 1 Compulsive sexual behavior inventory

Please mark the response that best describes your behaviors or experiences[a]:
How often have you had trouble controlling your sexual urges?
Have you felt unable to control you sexual behavior?
How often have you used sex to deal with worries or problems in your life?
How often have you felt guilty or shameful about aspects of your sexual behavior?
How often have you concealed or hidden your sexual behavior from others?
How often have you been unable to control your sexual feelings?
How often have you made pledges or promises to change or alter your sexual behavior?
How often have your sexual thoughts or behaviors interfered with the formation of friendships?
How often have you developed excuses and reasons to justify your sexual behavior?
How often have you missed opportunities for productive and enhancing activities because of your sexual activity?
How often have your sexual activities caused financial problems for you?
How often have you felt emotionally distant when you were engaging in sex with others?
How often have you had sex or masturbated more than you wanted to?
Were you sexually abused as a child?
Were you physically abused as a child?
Other than parents or siblings, did you experience sexual activity as a child with someone more than 4–6 years older than you?
Did you have sexual experiences with any of your siblings?
Have you been forced to have sex with a stranger, casual acquaintance or friend?
How often have you been arrested or legally apprehended for your sexual behavior?
Have you forced anyone against his or her will?
Did you have sexual experiences with either of your parents?
Have you ever hit, kicked, punched, thrown, chocked restrained or beaten any of your sexual partners?
Have you given others physical pain for sexual pleasure?
In fighting, have you been hit, kicked, punched, slapped, thrown, chocked, restrained or beaten by your current or most recent partner?
Have you received physical pain for pleasure?
Have you received money to have sex?
Have you been forced to have sex with your husband, wife, or lover?
Have you been watched masturbating or having sex without giving permission?

Adapted from Coleman et al. [19]

[a]Measured with a five-point response scale that includes: very frequently, often, occasionally, rarely, never

alpha = 0.87. A 3 month retest was performed on both groups. For sample 1 (N = 195) alpha = 0.64, and for sample 2 (N = 52) alpha = 0.80. Construct Validity was established by exploring associations between scores on the Sexual Compulsivity Scale and risk behaviors. For sample 1, positive associations were found between scores on the Sexual Compulsivity Scale and substance use and sexual risk-taking behaviors, and inverse associations with self-esteem and the intention to reduce risk-taking behaviors. In sample 2, positive associations were found between increased frequencies of unprotected sex, higher number of sexual partners, and were associated with pleasure activities. In addition, an inverse association was found with the intent to reduce risk. Follow-up studies using the Sexual Compulsivity Scale have reported similar results [8, 9].

The Sexual Compulsivity Scale has not been without critique in the literature. For the most part, since its initial publication, the scale has only been used to assess sexual compulsivity and its relations to "risky" sexual behaviors among individuals who are members of "high-risk" groups for HIV infection (i.e., men who have sex with men, heavy substance abusers, etc.) or who are already HIV positive. In an attempt to examine how the scale functions in a more "general population," Dodge et al. found support for reliability and construct validity of the Sexual Compulsivity Scale in a sample of nearly 900 heterosexual college students [23]. Construct validity was substantiated by the presence of significant relationships of sexual compulsivity with higher frequencies of solo and partnered sexual behaviors and numbers of sexual partners. The scale was also displayed

relations to gender and age, such that men and younger individuals scored higher on the Sexual Compulsivity Scale. As in "high-risk" samples, sexual compulsivity scores were associated with higher frequencies of unprotected sexual behaviors. Relationships between sexual compulsivity and solo, partnered, and unprotected sexual behaviors remained significant after controlling for demographic variables. Although the researchers found support for construct validity of the Sexual Compulsivity Scale in this sample, they also noted that it is not clear whether the scale distinctly measures sexual compulsivity or taps into other constructs, such as sexual desire and sexual exploration. Table 2 provides the items of the Sexual Compulsivity Scale.

Cognitive and Behavioral Outcomes of Sexual Behavior Scale

The Society for the Advancement of Sexual Health has offered a list of outcomes that could suggest that a person or their behaviors are sexually compulsive. The outcomes outlined by the Society for the Advancement of Sexual Health span six domains of life functioning: social, emotional, physical, legal, financial/occupational, and spiritual. An outcomes-based understanding of sexual compulsivity would suggest that individuals and their behaviors could be considered sexually compulsive if they find that their sexual behaviors (including behaviors that they do alone such as masturbation and those that they do with other people such as having intercourse) are leading to negative consequences in various areas of their lives. For example, that a person spends a great deal of time viewing sexually-explicit materials on the Internet may not necessarily be indicative of sexual compulsivity, but if that behavior results in the individual's inability to relate to a romantic or relational partner or creates other challenges then it might indicate that their Internet-based sexual activities have become problematic [9].

Recently, scales assessing cognitive and behavior outcomes of sexual behavior were developed to assess both the extent to which a participant was concerned about negative outcomes resulting from their sexual behaviors, and the extent to which such outcomes were actually experienced by participants [48, 49]. The scales were constructed based on 6 domains of impact of sexually compulsive behaviors identified by the Society for the Advancement of Sexual Health. The 6 domains are identified as: financial, legal, physical, psychological, spiritual, and social. The cognitive outcomes scale, consisting of 20 items, asks participants to rate on a four-point scale ranging from "never" to "always" the extent to which they worry that the things they have done sexually may result in a specified outcome. The 16 behavioral outcome items are measured dichotomously "yes" or "no" using 16 items to assess whether a participant

Table 2 Sexual compulsivity scale

Please indicate the extent to which the following statements apply to you[a]:
My sexual appetite has gotten in the way of my relationships.
My sexual thoughts and behaviors are causing problems in my life.
My desires to have sex have disrupted my daily life.
I sometimes fail to meet my commitments and responsibilities because of my sexual behaviors.
I sometimes get so horny I could lose control.
I find myself thinking about sex while at work or in class.
I feel that my sexual thoughts and feelings are stronger than I am.
I have to struggle to control my sexual thoughts and behavior.
I think about sex more than I would like to.
It has been difficult for me to find sex partners who desire having sex as much as I want to.

Adapted from Kalichman and Rompa [36]

[a]Measured with a four-point response scale that includes: never applies to me, sometimes applies to me, often applies to me, always applies to me

has actually experienced an outcome. Cognitive subscale scores were created from mean scores of the items making up each factor. Behavioral outcome scores were the sum of the "yes" (1 point) versus "no" (0 points) answers to the items for each factor.

Tests of scale reliability and validity were conducted in a cross-sectional sample of 391 young adults, largely comprised of women (70.3%, $N = 274$). The sample was chosen to explore whether negative cognitive and behavioral outcomes associated with sexual behavior could be detected in a non-clinical population at sub-clinical levels. The majority of participants were 21 years of age or younger (86.2%, $N = 336$) and identified as heterosexual (95.4%, $N = 372$).

Analyses were conducted to assess the psychometric properties of the Cognitive and Behavioral Outcomes of Sexual Behavior Scale and the extent to which those in the sample reported experiencing negative outcomes resulting from their sexual behaviors. Reliability of the Cognitive and Behavioral Outcomes of Sexual Behavior Scale was assessed using Cronbach's Alpha for internal consistency reliability; separate analyses of the cognitive and behavioral items were conducted. Internal consistency for the 20-item cognitive scale was high ($\alpha = 0.89$) with a slightly lower level of reliability ($\alpha = 0.75$) for the 16-item behavioral scale. However, given that the response scale for the behavioral items was "yes" or "no"; this level is quite acceptable.

Construct validity for the 20 cognitive outcomes items was tested using a Principal Component Analysis with varimax rotation, specifying six factors because items were constructed to focus on the six outcome categories articulated by the Society for the Advancement of Sexual Health. Overall, the six-factor solution explained 74.8% of the total variance. The inter-item correlation matrix did not yield correlations high enough to suggest that the scale is unidimensional. Separate reliability estimates were calculated for each of the six factors (or subscales). Cronbach's Alpha for internal-consistency was found to be high for all of the factors, or subscales, indicating scale reliability in this sample. Table 3 contains the Cognitive and Behavioral Outcomes of Sexual Behavior Scale.

Implications for Clinical Practice

Recent research indicates that, at some point, sexual behavior can lead to negative outcomes that include sexual risk-taking behavior and psychological distress [48, 49]. These findings have important implications for the prevention of HIV and other sexually transmitted infections, as well as negative consequences beyond risks to sexual health. In fact, it may be that an outcomes focused assessment tool is most appropriate for screening individuals with sub-clinical levels of sexual compulsivity and populations whose clinical presentations may be different from those traditionally studied in sexual compulsivity research. For example, research indicates that women may experience negative outcomes in the form of psychological, spiritual, and social distress suggesting that practitioners may need to reconceptualize their approaches to both assessment and treatment [48, 49]. Research indicates that men may primarily manifest sexual compulsivity in terms of physical outcomes, particularly those related to disease and pregnancy.

However, there is also evidence to suggest that young men experience disruptions in their social lives and other areas of functioning. Therefore, it may be appropriate to develop risk-reduction and intervention strategies aimed at sexual-risk taking, while providing other forms of treatment, such as psychotherapy, to address the psychological and social aspects of out-of-control sexual behaviors.

Regardless of theoretical orientation, the majority of practitioners favor approaches that incorporate cognitive and behavioral dimensions related to developing and maintaining control. This being the case, the Cognitive and Behavioral Outcomes of Sexual Behavior Scale may serve as a useful tool, used in conjunction with other screening measures, for clinical

Table 3 Cognitive and behavioral outcomes of sexual behavior scale

Cognitive Outcomes
Below is a list of things that some people worry about as a result of their sexual activities (including things people do alone and those they do with others). Please indicate the extent to which the following apply to you. I am worried that the things I have done sexually[a]:
Might have placed me or one of my sex partners at risk for pregnancy.
Might have placed me or one of my sex partners at risk for a sexually transmitted infection (like herpes, gonorrhea, or crabs).
Might have placed me or one of my sex partners at risk for HIV.
Might have caused one of my sex partners to experience pain, injury or other problems.
Might have resulted in pain, injury or other problems for myself.
Might have presented the potential for serious physical injury or death.
Might be leading to problems with my friends.
Might be leading to problems with my family members.
Might be leading to problems with my boyfriend/girlfriend/spouse.
Might have placed me at risk of being arrested.
Might have been against the law.
Might have led to financial problems.
Might have caused me to waste my money.
Were interfering with my ability to complete tasks for work or school.
Might have had presented the potential for me to lose my job.
Could lead to school-related problems, such as probation, expulsion or other sanctions.
Were inconsistent with my spiritual beliefs.
Were inconsistent with my religious values.
Were making me feel guilty.
Were making me ashamed of myself.
Behavioral Outcomes
Below is a list of things that sometimes happen to people as a result of their sexual activities (including those they do alone and those they do with others). Please indicate whether these things have happened to you during the last year as a result of your sexual activities. In the past year, as a result of the things you have done sexually, did the following happen to you[b]:
I or my sexual partner (s) became pregnant.
I contracted a sexually transmitted infection.
I contracted HIV.
I gave someone else a sexually transmitted infection.
I gave someone else HIV.
I caused pain, injury or other physical problems for myself.
I caused pain, injury or other physical problems for a sex partner.
My relationships with friends and/or family members were damaged.
My relationships with a spouse or other relationship partner were damaged.
I was arrested.
I experienced financial problems.
I experienced problems at school.
I experienced problems at work.
I experienced spiritual distress.
I was embarrassed or ashamed of myself.
I felt guilty.

[b]Measured with a dichotomous response scale that includes: yes, no

practitioners, as it would allow them to identify areas on which to focus treatment. Further, because research indicates gender differences in negative outcomes associated with sexual compulsivity, clinicians may need to take different approaches to assessment and treatment of sexual compulsivity in women and men. The literature consistently reports that women score lower on measures of sexual compulsivity and less often present for treatment. It may be that

women are less likely to self-report problems related to out-of-control sexual behavior due to social and cultural stigma related to high levels of sexual frequency or the behavioral expression of sexuality. Clinicians must take these issues into consideration, and ensure that they are conducting adequate assessments. While a body of research indicates that selective serotonin reuptake inhibitors and naltrexone may enhance the efficacy of treatment outcomes when used in conjunction with cognitive behavioral therapy, additional documentation is necessary as these studies were limited to small samples and case reports [10, 11, 21, 56].

Many providers may have little or no training in the identification and treatment of sexual compulsivity. Because mental health professionals play a critical role in promoting health and well-being, it may be necessary to provide specialized training on the assessment and treatment of sexual compulsivity, particularly in terms of identifying negative consequences resulting from behaviors. Not only do providers need to be aware of the obvious risks to sexual and psychological health, but also the potential for negative consequences in a variety of life domains.

Implications for Future Research

Until recently, sexual compulsivity has been primarily conceptualized as a phenomenon leading to sexual risk-taking behavior with little focus on consequences beyond sexual health. Recent research findings provide support for construct validity and, further, suggest that qualitative differences exist. Further, research indicates that negative outcomes related to sexual behavior that may be indicative of sub-clinical levels of sexual compulsivity occur in non-clinical populations. Thus, it may be useful to conduct longitudinal studies to determine whether those who score high on measures of sexual compulsivity show a progression in their experiences of negative cognitive and behavioral consequences. It may be that sexual compulsivity exists on a continuum, whereas initially individuals experience minor consequences, primarily limited to cognitive distress, and later progress to experiencing negative behavioral consequences as the level of compulsivity increases. Studies including clinical measures of psychological distress may provide insight into psychiatric comorbidity that many have suggested is linked to sexual compulsivity. If sexual compulsivity is, indeed, a mechanism of mood regulation or "self-medication" for underlying psychiatric condition, such studies might further our understanding of these associations.

Last, more studies are needed to determine the practical significance of sexual compulsivity in diverse populations [23]. These studies should evaluate the presence of actual negative health outcomes in individuals who score higher on measures of sexual compulsivity and who engage in more frequent sexual risk behaviors so that health professionals may develop and tailor HIV/STD education and intervention efforts as needed. Researchers should also design, test, and refine potential therapeutic treatments and interventions for sexual compulsivity, as its existence as a clinical condition becomes clearer through further scientific inquiry.

Summary

The idea that sexual behavior can go beyond the control of an individual has received a great deal of attention over recent decades, particularly in the context of sexual risk-taking behaviors that present the potential for the transmission of HIV and other sexually transmitted diseases and infections. Though many scientists and researchers support the notion that sexual compulsivity exists, others have argued that no such phenomenon exists but, rather, that normative sexual expression at the high end of the behavioral continuum is being pathologized. To complicate the issue, the opportunities for the behavioral expression of individual sexuality continue to broaden, with technological advances such as the Internet presenting new

avenues for sexual engagement. Further, shifting cultural and social norms allowed for more open expressions of a range of sexualities and sexual behaviors, calling into question previous understandings of human sexuality and blurring the boundaries of "normal".

Despite these changes, there has been evidence to suggest that there is a point where sexual behavior becomes out-of-control, leading to negative consequences for the individual. However, until now, there has been virtually no evidence to document the occurrence of negative consequences above risks to sexual health. The results from recent research suggest that, indeed, a variety of negative consequences are associated with sexual behaviors and perhaps is therefore a more solid criteria for establishing the point at which a behavior becomes "out-of-control." Such findings are an important first step to understanding the phenomenon and provide evidence to support the validity of the construct. Clearly, the results suggest that individuals experience a sense of loss of control associated with their sexual behaviors or the outcomes of those behaviors. Further, recent findings have provided documentation that indicates sexual compulsivity can impact several dimensions of a person's life. For example, impairment in social functioning and psychological distress were found to be associated with out-of-control sexual behavior. Whether these are simply outcomes resulting from the behavior, or underlying etiological mechanisms that influence the development of sexual compulsivity, remains to be determined.

An outcomes-focused approach to understanding sexual compulsivity may move us in a new conceptual direction. Engaging in frequent sexual encounters is not inherently problematic, particularly if an individual uses appropriate protection. Therefore, the disease-focused arguments relating to out-of-control sexual behavior are limited to sexual compulsivity as it influences instances of unprotected sex. An outcomes focus broadens the conceptualization, as an individual who experiences a loss of control may have little risk for disease but may be experiencing negative consequences in other areas, such as financial problems resulting from the use of online pornography, or psychological distress relating to uncontrolled masturbation. Adopting a broader, outcomes-focused approach to understanding out-of-control sexual behavior will allow scientists and practitioners to obtain a more thorough understanding of the phenomenon, and hopefully lead to better screening tools and treatment strategies.

Instant Messaging Addiction Among Teenagers: Abstracting from the Chinese Experience

Hanyun Huang and Louis Leung

Contents

Introduction

Instant messaging is a computer application that allows synchronous text communication between two or more people through the Internet. Such communication can be characterized in that parties at both ends of a conversation see each line of text right after it is typed (line-by-line), thus making it more like a telephone conversation than an exchange of letters [3]. Instant messaging is also a computer-based, one-on-one communication tool—a hybrid of e-mail, chat room, pager, telephone, voice mail, caller ID, and bulletin board with a multiparty "chat" model [13]. The instant messaging systems discussed in this chapter include MSN Messenger, QQ (Oh I Seek You), ICQ (I Seek You), and Yahoo!Messenger, Skype, as well as other instant messaging applications. QQ is the most popular instant messaging channel in China, like ICQ in the West.

As a relational maintenance tool, instant messaging has been used for entertainment, work, and team relationships [22, 41, 44]. Instant messaging has been found useful when discussing topics that are uncomfortable to talk about in face-to-face situations [31]. As Internet and computer-mediated communications undergo further development, instant messaging is becoming even more popular among Internet users. As this continues, teenagers could become more vulnerable to being addicted to this widely adopted social interaction tool.

Traditionally, the concept of addiction was based on a medical model and was properly reserved for bodily and psychological dependence on a physical substance. Other scholars have argued that the concept of addiction should be widened to cover a broader range of behaviors [30, 39, 49]. Griffiths proposed

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_33,

the concept of "technological addiction", which is non-chemical but behavioral addiction that involves excessive human-machine interaction [17]. It can be either passive, such as television viewing, or active, such as computer games or online chatting, and usually comprises inducing and reinforcing features that may contribute to the promotion of addictive tendencies [17]. It also features the core components of addiction, including salience, mood modification, tolerance, withdrawal, conflict, and relapse [18]. It has been argued by Griffiths that any behavior that fulfills these criteria can be operationally defined as addiction [18]. Some other research also supports the notion that excessive use of technology can be considered problematic [20, 50]. Using pathological gambling as a model, Young proposed that Internet addiction could be defined as an impulse-control disorder, which does not involve an intoxicant [60]. Previous studies examining Internet addiction have found that the use of synchronous communication applications on the Internet, such as instant messaging, by Internet-dependent students is significantly higher than among non-dependent individuals [2, 47, 59, 62]. As instant messaging has become extremely popular in recent years, whether instant messaging addiction exists among teenagers—as well as what symptoms and addict characteristics can be identified—is a research area with significant theoretical and policy implications.

Previous research has also investigated the relationship between psychological variables, such as shyness and alienation, and Internet addiction. For example, Chak and Leung indicated that there is a correlation between shyness and one's tendency to be addicted to the Internet [11]. Jansen and Clafton also reported on the rising phenomenon of Internet addiction in Australia and found that many people are dependent on the Internet for most of their social interaction [25]. As a result, these people are increasingly alienating themselves from the offline community. Other studies also indicated that pathological Internet use is problematic to teenagers' academic performance [37, 47, 48].

Internet and Instant Messaging Penetration in China

According to "The 21st Statistical Survey Report on Internet Development in China", published by the China Internet Network Information Center, there were 210 million Internet users and 170 million instant messaging users in China in 2007 [15]. Among Internet users, 28.8% were students and 19.1% were teenagers under 18 years of age. Of the teenage Internet users, junior high school students (Grades 7–9) spent, on average, about 7.5 h every week on the Internet, whereas senior high school students (Grades 10–12) spent 12.3 h weekly. The report pointed out that 18.2% of senior high school students and 9.6% of junior high school students spent more than 20 h every week on the Internet. These findings suggested that teenagers may be experiencing some degree of Internet dependence. The report further revealed that 85% of teenage Internet users were instant messaging users, whereas 81% of all Internet users used instant messaging. These figures illustrated that instant messaging has become so popular that many teenagers may become easily addicted.

In 2006, the China Internet Network Information Center released "The Survey Report on Chinese Instant Message Market" [14]. The report showed that 73.4% of instant messaging users regarded instant messaging as necessary. Instant messaging tools impacted other communication methods—over 40% of the users regarded instant messaging as their "most frequently used communication channel". Because of its convenience and low cost, over 60% of the instant messaging users reduced their use of e-mail, and over 70% of MSN users and nearly two-thirds of QQ users reduced their telephone use. QQ dominated 84.4% of the instant messaging market in 2006, and MSN ranked second, accounting for 13.9% of the market. These figures indicated that instant messaging is prevalent among Internet users in China, especially teenagers.

Internet Addiction

Derived from the substance-dependence criteria of the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) [1], Internet addiction disorder, the first listed Internet-related disorder, is defined as a behavioral addiction consisting of six core components: salience, mood modification, tolerance, withdrawal symptoms, conflict, and relapse [18]. Griffiths has suggested that the source of this addiction can originate from one or more aspects of Internet use including the process of typing, the medium of communication, the lack of face-to-face contact, Internet content, or online social activities. Young characterized Internet addiction as staying online, for pleasure, largely in chat rooms, for an average of 38 h or more per week, and concluded that Internet addiction can shatter families, relationships, and careers. Utilizing an adapted version of the criteria for pathological gambling defined by the DSM-IV, Young developed eight criteria to provide a screening instrument for addictive Internet use. Individuals have to meet five of eight criteria for Internet addiction to be considered an addict. The criteria are: (1) preoccupation with the Internet; (2) a need for longer amounts of time online; (3) repeated attempts to reduce Internet use; (4) mood modification from Internet use; (5) staying online longer than intended; (6) loss of a significant relationship, job, or educational or career opportunity; (7) deception about the time spent online; and (8) use of the Internet as a way of escaping from problems [14]. Several other studies on Internet addiction have been conducted during the past decade [5, 6, 11, 19, 34, 47, 61].

Instant Messaging Addiction

Instant messaging has penetrated young people's lives, and its use continues to grow. As early as 20 years ago, Shotton suggested that people might experience computer-mediated communication dependence [50]. Scherer's research indicated that Internet-dependent students are almost three times more likely than non-dependent students to use synchronous-communication Internet applications [47]. According to Young, 63% of "avid Internet users" are more likely to use synchronous Internet applications as compared with 12% for non-dependent users [59]. Similarly, Anderson reported that the daily use of synchronous-communication Internet applications among Internet-dependent students is nearly 10 times that of non-dependent students [2]. Yuen and Lavin's research also showed that Internet-dependent individuals spend twice as much time on instant messaging as non-dependent individuals [62]. According to Leung, college students indicated that relaxation, entertainment, and fashion are instrumental motives for ICQ use, while inclusion, affection, sociability, and escape are the intrinsic motives [32]. Students who are heavy users of ICQ are motivated by affection and sociability. The lonelier, more dishonest, and more negative students are, the less truthful they are in self-disclosure concerning their ICQ interactions [33]. Leung also found that being emotionally open on the Net and heavy use of ICQ are the most influential criteria in predicting abuse of the Internet among the "Net generation" [34]. This finding reinforces Wellman's research that Internet-dependent individuals spend most of their time in the synchronous-communication environment engaging in interactive activities, including ICQ, for pleasure-seeking or escape [57]. What's more, research conducted by the organization known as "Breakthrough" found that about 5% of the respondents, who were secondary school students, were addicted to ICQ [7]. These students showed low self-esteem and had less parental and peer support than non-ICQ addicts. They were also weaker in self-expression, listening, and a willingness to express their viewpoints. However, most of these studies conceptualized Internet addiction as a unidimensional construct; almost no research has been conducted on instant messaging addiction from a multidimensional symptomatic perspective.

Shyness and Internet Use

Shyness is a form of social anxiety that interferes with a person's ability to participate in social situations. It is a fear of meeting people and a discomfort in the presence of others [42, 63]. At its core is the anxiety of being evaluated by others and consequently rejected [43]. Shyness can lead to a range of social problems, including self-consciousness, poor self-projection, and deficient communication [29]. Compared with others, shy people are more likely to regard their offline networks as unsupportive and unsatisfying and are happy to be by themselves or to participate minimally in social encounters [40]. What's more, shy people have less social support, smaller friendship networks, and less friendship satisfaction, are more passive, and have fewer interactions in their offline lives than people who are not shy [26].

Recent research has shown that the unique attributes of computer-mediated communication—i.e., it is mediated, low in social cues, and sometimes anonymous—may provide new ways for shy people to communicate with the outside world with less risk of being embarrassed. One study showed that correlations of shyness with aspects of involvement in online relationships are greater than those with involvement in face-to-face relationships [56]. Another study investigated whether the Internet promotes or impedes social interactions and found that shy people feel much less inhibited in social interaction online compared with offline, and consequently they are able to form a number of online relationships [45]. Stritzke and colleagues suggested that some individuals, particularly shy people, prefer to interact in an online environment as opposed to traditional face-to-face interactions [53]. Similarly, McKenna and colleagues pointed out that the Internet helps those people who are shy, lack social skills, or have social anxieties in forming relationships [36]. These people can enjoy aspects of the Internet that allow them to meet, socialize, and exchange ideas through the use of e-mail, ICQ, chat rooms, and newsgroups, which in turn allows them to fulfill unmet emotional and psychological needs that are more intimate and less threatening than real-life relationships [21]. In line with these findings, Caplan confirmed that people who have higher levels of depression, shyness, and loneliness and lower self-esteem have a greater preference for online conversation [10].

Furthermore, Yuen and Lavin studied the role of shyness in Internet dependence and found that Internet-dependent individuals' shyness is greater in face-to-face interactions relative to online interpersonal exchanges, and they discussed how instant messaging can be used to ameliorate shyness and how such reinforced behavior could foster dependence [62]. People who are addicted to the Internet make intense and frequent use of the Internet, especially for online communication via e-mail, ICQ, chat rooms, newsgroups, and online games [11].

Alienation and Internet Use

Alienation refers to a sense of social estrangement, an absence of the support of meaningful social connection, lacking a sense of belonging, and feeling cut off from family, schools, and friends [9, 35]. It directly represents social dysfunction and a failure to bond effectively with prosocial institutions such as the family and school, or even with individuals such as one's peers [38].

No previous studies have examined alienation and instant messaging use, but some studies have explored alienation and Internet use. One study found that Internet sites have the potential to create a sense of community in cyberspace, which could be attractive for alienated youth seeking alternative socialization sources [55]. In a study of alienation and the use of violent Internet sites, it was revealed that alienation from both family and school can predict the use of violent Web sites [51, 52], suggesting that youth who feel disconnected from family or school would be likely to turn to antisocial media content,

particularly on Web sites. These findings demonstrate the attraction of the Internet as an interactive medium for alienated youth.

Furthermore, the Internet itself may "reproduce" alienation. Despite the fact that most Internet use is devoted to active social communication, researchers discovered that such use counter-intuitively takes time away from face-to-face contacts and replaces stronger ties with weaker ones [27]. As a result, interaction quality decreases, resulting in feelings of loneliness, depression, and a lowered sense of belonging, especially for those who are new to the Internet.

Along this line of research, other researchers have found that ostracism (the act of ignoring and exclusion) is as powerful on the Internet as it is in a physical presence [58]. When participants in the research were cyber-ostracized, their sense of belonging and inclusionary status was reduced significantly, which in turn worsened their mood and increased their feelings of exclusion.

In instant messaging, people can talk not only to friends but also to strangers. People can also make new friends through instant messaging. Thus, teenagers who feel alienated from family, friends, and school might tend to seek social support or friendship online through instant messaging.

Internet Use and Academic Performance

Whether academic performance and use of the Internet are interrelated has long been of interest to researchers. A 16-month field study conducted by Jackson and colleagues discovered that children from low-income families who used the Internet more had higher scores on reading achievement tests and obtained higher overall grades than children from low-income families who did not use the Internet very much [24]. Interestingly, a follow-up study based on these findings concluded that academic performance predicts subsequent Internet activities, whereas Internet activities predict subsequent academic performance [23]. However, Barber reported that 86% of teachers responding to a survey believed that Internet use by children does not improve performance, probably due to the fact that the information that the Internet contains is highly disorganized and unrelated to school curricula [4].

Previous researches have studied the relationship between Internet abuse or Internet dependence and academic performance. Scherer and Bost surveyed 531 students about their Internet use, using a checklist of ten clinical symptoms to parallel the symptoms of substance abuse and dependence. Results indicated that 13% of the sample reported that Internet use interfered with their academic work, professional performance, or social lives [48]. An online survey and two campus-wide surveys conducted at the University of Texas at Austin and Bryant College further documented that Internet abuse is problematic for academic performance [8, 37, 47]. Scherer concluded: "Excessive Internet use is problematic when it results in impaired functioning such as compromised grades or failure to fulfill responsibilities [47]."

Studies also have been done to evaluate the relationship between the use of instant messaging (or similar applications) and academic performance. Kubey and colleagues revealed that heavy leisure Internet use is highly correlated with impaired academic performance, particularly when the use is with synchronous-communication applications such as chat rooms and Multiple User Dungeons [28]. The researchers proposed that the unique social qualities of such applications represent a most significant utility for lonely individuals who can be with friends at any time, resulting in many users staying up late at night and feeling tired the next day, which in turn affects their academic performance.

Another study on ICQ (a specific medium of instant messaging) was conducted in Hong Kong to examine the effects that it has on adolescents [12]. The study reported that 38% of the respondents indicated that using ICQ has an effect on their academic performance. However, whether such effects were positive or negative, as stated

by the researchers, could not be determined through the self-report questionnaires. Cheuk and Chan remained optimistic by concluding that if the participants used ICQ for academic issues such as a discussion of homework, then ICQ's effect would be positive.

Studies also have been conducted on the relationship between teenage alienation problems and their effects on academic performance. Coleman discovered that intellectualism is not the sole determining variable in the academic performance of students. The rewards from their social systems, including their achievements in other areas such as sports, and how well they get along with each other are also very important in affecting their performance in school [16]. In the study on Swedish teenagers by Roe, it was discovered that those who feel alienated from classmates and the school subsequently achieve lower levels of academic results [46]. The research conducted by Sugarman yielded a similar outcome. He stated that students having a lower commitment to their "pupil role" achieve less academically than those who are more committed to the role of student [54].

An Empirical Study of Instant Messaging Addiction in China

To continue this line of research, this chapter reports a questionnaire survey research conducted in November 2007 in a middle school in Xiamen, China. A stratified random sampling method was used to select 330 students in Grades 7–12 (aged 12–19) to participate. The aims of the study were to examine: (1) whether instant messaging addiction exists among Chinese teenagers, and, if so, who the addicts are, what their symptoms are, and to what extent they are addicted; (2) whether psychological variables such as shyness and alienation can predict instant messaging use or addiction, among teenagers, and (3) whether instant messaging use and addiction can impair the academic performance of teenagers in China.

The majority of the participants (95.8%; $n = 316$) indicated that they use instant messaging. Only 4.2% of the participants indicated that they had never used instant messaging before. Of the 316 instant messaging users, 70.6% of them indicated that they always or often log onto instant messaging software once they go online. Over 86% of instant messaging users reported that their most frequently used instant messaging function is text chatting, while 89.9% said that they almost always chat with friends as opposed to relatives, teachers, or strangers.

Instant Messaging Addiction and Addiction Symptoms Among Teenagers

Using the classic definition of Internet addiction by Young, 9.7% of the teenagers in our sample could be classified as instant messaging addicts. The results show that instant messaging addicts spend more hours every week on instant messaging and spend significantly longer hours each time they use it.

The study in China also yielded four instant messaging addiction symptoms among teenagers: (1) *Preoccupation with instant messaging* (alpha = 0.82) revealed whether the lives of the teenagers were preoccupied by instant messaging; the teenagers act annoyed when they are interrupted during online chats; they feel preoccupied by online chatting and fantasize about chatting online when offline; they feel depressed and moody when they cannot chat online; they sacrifice sleep to chat online; and they need to increase instant messaging time to achieve satisfaction. (2) *The loss of relationships* due to overuse of instant messaging (alpha = 0.77) reflected that addicted teenagers hide their time spent on online chatting; try to cut down their use but fail; choose to spend more time chatting online rather than going out with friends; and

jeopardize friendships or educational opportunities because of online chatting. (3) *The loss of control* (alpha = 0.73) illustrated that teenagers cannot control the time they spend on instant messaging. This shows that they always spend more time on instant messaging than they intend; they neglect other things they have to do because they are chatting online, and their relatives and friends complain about this. (4) *Escape* (alpha = 0.68) indicated that teenagers use instant messaging as an alternative way to escape from responsibilities; they chat online when they are in a dysphoric mood, and they always anticipate chatting online again. These four symptoms are consistent with most of the "substance dependence" symptoms proposed by the American Psychiatric Association, which include "withdrawal, tolerance, preoccupation with the substance, loss of control over the substance, more use of the substance than intended, continued consumption of the substance despite adverse consequences, and loss of interest in other social, occupational, and recreational activities" [1].

Among the four symptoms, "loss of control" was a significant factor to predict level of instant messaging use and was the most powerful variable to predict academic performance decrement. This indicates that teenage addicts were relatively young and less self-disciplined, and it was not easy for them to control the time spent on instant messaging when they used it to chat online and neglected their homework or daily life duties, thus resulting in academic performance decrement. The four addiction symptoms formed the most powerful group in hierarchical regression to predict teenagers' academic performance decrement; all four were significant predictors. This indicates that teenagers, who showed more severe symptoms in instant messaging addiction, were more likely to suffer from academic performance decrement. This result underscores the harmful effects of instant messaging addiction on teenagers' academic performance and suggests that if teenagers exhibit any of the above instant messaging addiction symptoms, teachers and parents should pay attention to their academic performance.

Effects of Shyness and Alienation on Instant Messaging Addiction and Academic Performance

The study in China also revealed that the shyer the teenager, the higher his or her level of instant messaging addiction. Teenagers who are more alienated from family, peers, and school are more likely to suffer from a higher level of instant messaging addiction. To differentiate between addicts and non-addicts, discriminant analysis found that the instant messaging addicts were heavy users of instant messaging and had more years of online experience; they tended to be shyer and more alienated from peers, school, and family. Teenagers who are heavy users of instant messaging and who suffer from higher level of instant messaging addiction are more likely to have academic performance decrement. These findings are consistent with and reinforce previous research that the higher the tendency for a person to be addicted to the Internet, the shyer the person is; people who are addicted to the Internet make intense and frequent use of it especially for online communication via ICQ [11].

Alienation also showed significant and positive correlations with level of instant messaging addiction and all three alienation dimensions were significant predictors to discriminate instant messaging addicts and non-addicts. That is, teenagers who were more alienated from family, peers, and school were more likely to become instant messaging addicts. Such a result indicates that teenagers who suffered alienation from family, peers, and school tended to seek care, friendship and social support through instant messaging.

Instant Messaging Use and Academic Performance Decrement

Both the level of instant messaging use and level of instant messaging addiction have

significant and positive bivariate correlations with academic performance decrement. This finding suggests that teenagers' instant messaging use did impact their academic performance. The more they used it, the more they would be dependent on instant messaging, and the more they might experience a decrease in academic performance. These findings were in agreement with Cheuk and Chan's study that using ICQ had an effect on adolescents' academic performance in Hong Kong [12]. Therefore, parents and teachers should pay close attention and provide proper guidance or mediation for teenagers' instant messaging use.

Demographics and Instant Messaging Use

Age was a significant negative predictor for level of instant messaging use and a significant positive predictor for level of addiction and academic performance decrement. These findings are interesting, and they suggest that the younger the teenagers, the less self-disciplined they were, and the more they would use instant messaging. At the same time, older teenagers were more mature and have more things to share with friends, such as relationships, affairs, gossips, and issues that are difficult to talk about face-to-face, so they might have been more addicted to instant messaging. This might, therefore, have had a negative impact on academic performance decrement. Older teenagers might have been more rebellious. Teachers and parents might have thought that they were grown-ups and had less control over them. As expected, these results suggest that teachers and parents should pay more attention to older teenagers as they may be most vulnerable to instant messaging addiction.

Gender was not a significant predictor of the level of instant messaging use and addiction. This indicates that gender difference in computer-mediated communication use is narrowing. Years of instant messaging use was significant in predicting level of instant messaging addiction, which indicates that those who have been using instant messaging for a longer time might find more advantages of instant messaging, and thus may become addicted more easily.

Conclusions

Teenagers today are immersed in interactive media. Their lives are dedicated to many of the emerging communication technologies—the Internet, interactive games, mobile phones, SMS, MP3, iPods, and conversing in instant messaging services such as MSN, QQ, ICQ, and Yahoo!Messenger. Many policymakers and critics have voiced fears about what these personal communication technologies are doing to teenagers, especially those consumed in their own privacy. This chapter examined the multidimensional addiction symptoms of instant messaging, together with shyness and alienation, to explore their relationships with instant messaging behavioral patterns. Furthermore, it also investigated the consequences of instant messaging use as related to academic performance among teenagers in a middle school in China. Instant messaging can have a positive, as well as negative, influence on social behaviors and intellectual development. The use of instant messaging is not necessarily an isolating event for young people. For many, it has become an important social activity. In their own space, they appropriate their private time to help them make sense of their lives. However, few parents know for sure what their children are doing with the Internet in their bedroom or private space—often because young people know more than their parents about the Internet. With whom are they chatting using instant messaging, and with what consequences? How can teenagers, along with parents, prevent excessive use and abuse? This research in China provides an additional perspective. In fact, knowing how instant messaging addiction affects academic performance among teenagers in these fundamental ways will help

parents, educators, technology designers, and policymakers to set priorities and effective decisions about mediating teenagers' use of instant messaging services.

Hoarding as a Behavioral Addiction

Jessica R. Grisham, Alishia D. Williams, and Raja Kadib

Contents

Overview

Compulsive hoarding is defined as the acquisition of—and inability to discard—possessions of limited value, to a degree that precludes appropriate use of living spaces and creates significant distress or impairment in functioning [23, 24]. Hoarding can interfere with an individual's ability to work, interact with others, and perform basic activities, such as eating or sleeping. In severe cases, it may lead to dangerous, even life-threatening living conditions. Hoarding also is associated with a profound public health burden. In a survey of local health departments, 64% of health officers reported receiving hoarding complaints, some of which resulted in a significant cost to the community [32]. More recently, a large Internet survey of self-identified hoarding participants ($N = 864$) and family members ($N = 655$) revealed that compulsive hoarding is related to poor physical health, social service involvement, and significant occupational impairment [89].

Hoarding has been linked to anxiety disorders, specifically obsessive-compulsive disorder, although its diagnostic status is plagued with controversy [95]. Consistent with prominent models of anxiety disorders [4], individuals who compulsively hoard frequently report feelings of anxiety when they are asked to discard or organize their possessions. They also may demonstrate avoidance and safety behaviors connected to their hoarding-related beliefs and fears [82]. There is, however, a pleasurable or gratifying component associated with acquiring, collecting, and saving possessions that distinguishes hoarding from other anxiety-related problems.

This appetitive aspect of hoarding suggests that there are similarities between hoarding and behavioral addictions, which include several impulse control disorders (pathological gambling, pyromania, and kleptomania).

In behavioral addictions, individuals experience pleasurable or gratifying feelings while engaging in the target behavior, followed by a decrease in arousal and feelings of guilt and remorse [52]. An individual who compulsively collects items from yard sales and thrift stores may similarly feel a rush of positive emotion upon finding an item that she feels is unique or valuable, followed by feelings of regret when she reflects upon how much the clutter is overtaking her home and negatively impacting her life. While the anxiety-related aspects of hoarding have been the subject of several investigations [24], the appetitive nature of this syndrome has been relatively understudied. Although hoarding behavior is sometimes motivated by a desire to reduce anxiety, there are cases in which hoarding appears to be driven by anticipation of pleasure and impaired self-regulation [44]. There also may be cases in which both anxiety and approach behaviors play a role. From a clinical perspective, this underscores the importance of functional analysis in determining motivation for hoarding and, more specifically, acquisition behaviors.

Classification and Comorbidity

As previously noted, hoarding has been considered to be a dimension or subtype of obsessive-compulsive disorder in much of the recent research [82]. Findings of moderate frequencies of hoarding behavior in obsessive-compulsive disorder populations, ranging from 18 to 33%, support this association [29, 73]. Moreover, several studies have found that individuals who hoard report more obsessive-compulsive disorder symptoms than non-hoarding individuals [23, 29]. Frost and colleagues [31] compared individuals with obsessive-compulsive disorder who exhibited compulsive hoarding symptoms versus those who did not, and found that the two groups did not differ on the number of obsessive-compulsive disorder symptoms displayed, although they both reported more obsessive-compulsive disorder symptoms than did anxious and nonclinical control participants.

Despite this association, there is mounting evidence that hoarding is distinct from other obsessive-compulsive disorder symptom dimensions. Most factor analyses of obsessive-compulsive disorder symptoms have found that hoarding constitutes a separate factor from other obsessions and compulsions [10, 44, 58, 63, 73]. Furthermore, hoarding behavior has been reported in a variety of psychiatric disorders besides obsessive-compulsive disorder, including schizophrenia [62], organic mental disorders [43], eating disorders [22], brain injury [16], and dementia [18]. Finally, hoarding is typically a poor predictor of treatment outcome in both psychological and pharmacological treatments for obsessive-compulsive disorder [11], although several recent studies have not confirmed this association [2, 15, 77, 81]. In light of the conflicting evidence regarding the diagnostic status of hoarding, Wu and Watson [95] examined the relationship between obsessive-compulsive disorder and hoarding in two large samples. They found that hoarding correlated only modestly with other obsessive-compulsive disorder symptoms, which reliably correlated with each other. Further, hoarding was no more strongly associated with obsessive-compulsive disorder symptoms than other dimensions of psychopathology, such as depression.

It is significant that not all individuals who hoard have comorbid symptoms reflective of typical obsessive-compulsive disorder [44]. In addition, hoarding beliefs and behaviors do not always fit the obsessive-compulsive disorder model. Steketee and Frost [82] noted that hoarding thoughts may not always impel the associated compulsive behaviors, may not be as intrusive as typical obsessions, and are not always viewed as ego-dystonic by the individual. Additionally, many hoarders lack insight into the severity of the consequences of their behaviors and experience attenuated levels of distress compared with obsessive-compulsive disorder clients [82]. The ego-syntonic nature of hoarding is similar to that observed in some addictive and impulse control disorders.

Hoarding and Impulse Control Disorders

Most relevant to the current chapter is the association between hoarding and the spectrum of impulse control disorders. Impulse control disorders are positively reinforcing to the individual and are associated with a wide variety of emotional states, including pleasure or gratification. They are characterized by repetitive behaviors and impaired inhibition of these behaviors and include pathological gambling, skin picking, and trichotillomania. Researchers have suggested that impulse control disorders may best be conceptualized as part of an obsessive compulsive spectrum [51, 65] as the urges and subsequent behavioral responses observed in impulse control disorders appear, at least superficially, similar to the excessive rituals observed in obsessive-compulsive disorder [8]. Problems removing unwanted thoughts and deficits in decision making may also represent commonalities between obsessive-compulsive disorder and impulse control disorders.

A key difference between impulse control disorders and obsessive-compulsive disorder, however, is that an individual with an impulse control disorder experiences feelings of pleasure and gratification while engaging in the target behavior, in contrast to the anxiety experienced when individuals with obsessive-compulsive disorder engage in a compulsion [39]. For example, the repetitive and often harmful rituals performed in obsessive-compulsive disorder may appear similar to the wagering behaviors of compulsive gamblers. When significant monetary losses fuel chasing behavior, a compulsive gambler may feel compelled to gamble to avoid negative consequences in much the same way that rituals in obsessive-compulsive disorder are performed in an effort to alleviate negative emotional states such as anxiety, shame, and guilt [87]. However, gambling behaviors are clearly pleasurable and reinforcing [40]. Individuals who hoard also derive a sense of pleasure and gratification from their acquisition behaviors, which may suggest that hoarding fits better among the impulse control disorders than its common conceptualization as a subtype of obsessive-compulsive disorder.

Compulsive hoarding has been linked to impulse control disorders in a variety of studies, suggesting the possibility of a common diathesis underlying both hoarding and certain impulse control disorders. Samuels et al. [73] reported a greater frequency of trichotillomania and skin picking among hoarding compared with non-hoarding individuals with obsessive-compulsive disorder. In addition, Frost et al. [33] found that pathological gamblers reported significantly more hoarding symptoms than light gamblers and speculated that both hoarders and gamblers may share similar concerns about the loss of potential opportunities. Compulsive hoarders believe that items may be needed for some future use and, therefore, fear discarding items as this would represent a lost opportunity for the item's use [33], with some research suggesting that even the sight of a possession can trigger this fear [26]. Frost and colleagues [33] have suggested that pathological gamblers may have difficulty refraining from purchasing chances because of similar beliefs and fears about losing an opportunity to gain financial benefit. Although Grant et al. [41] found a low prevalence of impulse control disorders overall among individuals with obsessive-compulsive disorder, obsessive-compulsive disorder participants with a lifetime and current impulse control disorder were more likely to report hoarding symptoms. In addition, some research suggests that beliefs about possession and about buying are similar to the beliefs of those with compulsive hoarding [55]. The association between hoarding and impulse control disorders is consistent with McElroy and colleagues' conceptualization of a compulsive-impulsive spectrum [66] but requires further exploration.

Hoarding and Compulsive Acquisition

Compulsive acquisition is a central component of compulsive hoarding [23, 24] that is of particular significance when considering hoarding as

a behavioral addiction. The compulsive acquisition component of hoarding consists, in part, of compulsive buying, which is classified as an impulse control disorder [66]. Compulsive buying has been defined as chronic, repetitive purchasing behavior in response to negative events and or/feelings that is difficult to stop and results in harmful consequences [17]. Similar to other impulse control disorders, compulsive buying is associated with a pattern of tension, pleasure, and subsequent feelings of guilt and remorse [12].

A high level of compulsive buying has been found among individuals who hoard [30], and, conversely, a high level of hoarding symptoms have been found in compulsive buyers [34]. A study comparing compulsive buyers with non-compulsive buyers found that compulsive buyers scored higher on both obsessive-compulsive disorder and hoarding symptoms, but the relationship between buying and obsessive-compulsive disorder was mainly mediated by hoarding [34]. Interestingly, this study found that while not all compulsive buyers suffer from compulsive hoarding, nearly all hoarding participants suffer from compulsive acquisition. Compulsive acquisition in hoarders, however, is not limited to buying, but includes collecting free things that are being given away or have been discarded by others. However, Frost et al. [30] found that these behaviors were related; a measure of compulsive buying behavior was associated with a compulsive acquisition of free items.

The relationship between compulsive hoarding and buying may be accounted for by shared cognitive deficits and biases. Both hoarding and compulsive buying appear to be closely related to impaired mental control [30] and fears about decision making [55]. Additionally, evidence suggests that similar cognitive biases about the meaning of possessions exist in both hoarders and compulsive buyers [56]. Although O'Guinn and Faber [68] suggested that compulsive buyers may derive more emotional pleasure from the process of acquiring items, in contrast to hoarders, who retain a sense of satisfaction from items even once ownership has been established, Kyrios et al. [56] found that compulsive buyers did hold beliefs about possession similar to those reported by hoarding participants. These beliefs included fears over lost opportunities to obtain objects, erroneous beliefs about the inherent value of possessions, and beliefs about personal responsibility for objects [55]. Research on compulsive hoarding has suggested that the sight of a possession activates the fear of losing an opportunity [26]. Collectively, these findings suggest a diagnostic overlap between compulsive hoarding, obsessive-compulsive disorder, and impulse control disorders. Steketee and Frost [82], however, in a review of these findings, concluded that limitations such as selection of appropriately defined samples, methodological concerns, the absence of formal diagnostic interviews, and inadequate measurement of hoarding constrain conclusions about whether hoarding is best conceptualized as a sub-syndrome of obsessive-compulsive disorder, as an impulse control disorder, or as a separate clinical construct.

Etiology/Biobehavioral Underpinnings of Hoarding

In the last 5 years, much new evidence has emerged regarding the biological/neural underpinnings of compulsive hoarding. Several case reports have described cases of pathological collecting and saving that began after a brain injury, typically along with other changes in personality and social functioning [16, 46]. These cases suggest that hoarding may be related to frontal lobe dysfunction. Other evidence for the biological correlates of hoarding has come from two sources: neuroimaging studies and genetic research.

Neuroimaging Research

Several recent studies have investigated a possible neural basis of compulsive hoarding. Anderson et al. [3] conducted a study in which

13 of 86 individuals with focal lesions exhibited abnormal collecting behavior. All 13 of these individuals had damage to the mesial frontal region of the brain, including the anterior cingulate region. Further, in the first study using positron emission tomography to examine compulsive hoarding, Saxena et al. [76] found that compared with non-hoarders who had obsessive-compulsive disorder, individuals with both compulsive hoarding and obsessive-compulsive disorder had significantly lower glucose metabolism in the anterior and posterior regions of the cingulate gyrus. The authors posited that lower activity in these regions may mediate the deficits in motivation, attention, memory, and decision making that are associated with compulsive hoarding. Underactivity in these regions also has been observed in cocaine addicts and alcoholics regardless of whether they were continued users or had abstained for a lengthy period [90–92].

Finally, Mataix-Cols et al. [64] conducted a functional magnetic resonance imaging study in which individuals with obsessive-compulsive disorder were presented with pictures containing various types of obsessive-compulsive disorder-related stimuli, including hoarding-related images (old newspapers, clothes, etc.). Participants were told to imagine that the items belonged to them and that they would have to discard them later. During this provocation, participants demonstrated greater activation than controls in the left precentral/superior frontal gyrus, left fusiform gyrus, and right orbitofrontal cortex. Collectively, results of these studies provide evidence that the hoarding symptom dimension may reflect the dysregulation of a specific neural system.

Genetic Research

Findings of several recent genetic studies also support the notion that hoarding represents a unique symptom subtype in obsessive-compulsive disorder with a distinctive psychobiological profile. Lochner et al. [59] genotyped individuals with obsessive-compulsive disorder and control participants of Afrikaner descent to investigate certain polymorphisms in genes hypothesized to be relevant to obsessive-compulsive disorder. They reported that there may be a relationship between variation in the Catechol-*O*-methyltransferase gene and compulsive hoarding. (Catechol-*O*-methyltransferase is an enzyme involved in the degradation of dopamine, a neurotransmitter with increased activity in obsessive-compulsive disorder.) In another genetic study, Samuels et al. [74] treated compulsive hoarding as the phenotype of interest and stratified families with obsessive-compulsive disorder into those with and without two or more relatives affected with compulsive hoarding. Results of the study suggested that a region on chromosome 14 was linked with compulsive hoarding behavior in families with obsessive-compulsive disorder. Finally, Zhang et al. [96] conducted a genome scan of the hoarding phenotype on 77 sibling pairs who were concordant for a diagnosis of Gilles de la Tourette syndrome. Results of this study suggested joint effects for the hoarding phenotype of specific loci on 5q and 4q. While the findings of these studies have not been conclusive, collectively they highlight possible regions of interest with respect to genetic correlates of compulsive hoarding.

Cognitive-Behavioral Theory and Evidence

Current cognitive-behavioral conceptualizations [24, 26] specify a multidimensional model to explain the core manifestations of compulsive hoarding. Hoarding is posited to develop as a result of conditioned emotional responses associated with certain thoughts and beliefs concerning items or possessions. Acquisition and failure to discard possessions represent avoidance of the anxiety associated with discarding and decision making. In addition, similar to other behavioral addictions, excessive saving behavior

is positively reinforced because the possessions attain a pleasurable or comforting quality. The prominent model of compulsive hoarding proposed by Frost and Steketee [26] consists of four main components: information-processing deficits, beliefs about and emotional attachments to possessions, and emotional distress and avoidance behaviors that develop as a result.

Information-Processing Deficits

The cognitive-behavioral model of hoarding suggests that individuals who hoard may possess information-processing deficits that result in confusion or misinterpretation about the value of possessions and difficulty organizing and discarding. Several neuropsychological studies of compulsive hoarding support the notion that there are cognitive deficits associated with this syndrome.

Grisham et al. [45] compared a compulsive hoarding group with a mixed clinical group and a community control group on a number of measures for attention, working memory, and verbal and nonverbal intelligence. They found that those in the hoarding group had intact verbal intelligence and working memory but were impaired on measures of attention and nonverbal intelligence. They also were slow to initiate responses and had difficulty inhibiting impulsive responses. Similarly, Hartl and colleagues [50] found that hoarding adults displayed symptoms consistent with attention-deficit/hyperactivity disorder on a self-report measure. Weaknesses in these neuropsychological domains of attention and nonverbal intelligence may, therefore, limit hoarders' ability to sustain attention during a task (e.g., when deciding what possessions to save or discard) and to organize their possessions and reduce clutter. Other studies have found evidence for indecisiveness [25] and deficits in verbal and nonverbal memory [49].

Hoarding behavior also appears to be associated with specific deficits in organizing and categorizing common objects [61, 93]. Wincze et al. [93] compared the performance of hoarders with the performances of non-hoarders who had obsessive-compulsive disorder and control participants on a sorting task. They found that participants in the hoarding group were under-inclusive (i.e., they sorted the objects into a larger number of categories) compared with control participants. They also took a longer time than the controls to decide in what category the objects belonged, and they reported more distress during the sorting task. This was only true, however, when they were sorting personally relevant objects. These results suggest that the information-processing deficits due to an under-inclusive categorization style are not global but are specific to relevant objects. Wincze at al. [93] suggested that hoarders' difficulty categorizing objects may be due to the meaning attached to objects, which influences what features of the object are attended to during a sorting task. Luchian et al. [61] replicated this study with nonclinical hoarding and control participants and found similar results.

There are some inconsistencies in the research on hoarding and associated neuropsychological deficits. While Grisham et al. [45] found that hoarders displayed relatively intact decision making on a gambling task, Lawrence and colleagues [57] found that hoarding symptoms were associated with specific decision-making impairments on the same gambling task, in addition to poor set shifting on a sorting task. Lawrence et al. [57] suggested that hoarders have difficulty deciding whether to save or discard a possession due to these difficulties in decision making. Additionally, the risky behaviors exhibited by hoarding participants suggest that problems with impulse control may contribute to difficulties in decision making. Grisham et al. [45] did observe greater impulsivity in the hoarding group on measures of attention. The discrepancies between these studies are likely due to differences in the samples selected. In the Grisham et al. [45] study, the hoarding group consisted of participants who met the criteria for compulsive hoarding, regardless of whether they had obsessive-compulsive disorder, while the hoarding group in Lawrence et al. [57] comprised

individuals with obsessive-compulsive disorder who also displayed hoarding behaviors.

The recent findings on specific neuropsychological characteristics associated with hoarding may elucidate the relationship between hoarding and addictions. Addictive disorders are characterized by repeated behaviors that are pleasurable to perform. Hoarding may similarly be associated with a pleasurable state upon acquisition of new items, but hoarding behaviors are also viewed as an attempt to avoid the emotional distress associated with discarding [24]. Although the motivations behind the behaviors (pleasure seeking vs. distress avoiding) may vary, there is a degree of overlap that may be accounted for by similar neuropsychological deficits. Lubman et al. [60] argued that problematic drug use is associated with decreased inhibitory control, thus compromising decision-making ability. The poor inhibition and decision making are also evident in compulsive hoarding [45]. The deficits observed in hoarding participants on the gambling task [57] have also been found with drug-addicted individuals. Furthermore, these individuals show behavioral responses similar to the hoarders observed by Lawrence et al. [57] and individuals with lesions to the orbitofrontal cortex [5], the same region implicated in positron emission tomographic studies of hoarders. Drug-addicted individuals also show deficits in response inhibition [37] similar to those observed by Grisham et al. [45] with compulsive hoarding participants.

Emotional Attachment to Possessions

Maladaptive beliefs and excessive emotional attachment to possessions are also posited to play a central role in the maintenance of compulsive hoarding [26, 86]. The beliefs and cognitions associated with excessive saving range from exaggerations of common beliefs, e.g., "I need these sentimental possessions to remind me of important events in my life" to more idiosyncratic reasons for saving, e.g., "These used Band-Aids® are a part of me because they contain my blood." The individual's unrealistic beliefs about possessions are associated with excessive emotional attachment to objects, which leads to delaying or avoiding the process of making decisions and discarding [23]. Research suggests that these beliefs cluster into four basic types: emotional attachment to possessions, memory-related concerns, responsibility for possessions, and control over possessions [86].

Excessive attachment to possessions can lead to a sense of grief and loss when individuals with compulsive hoarding are forced to discard items [13]. These reactions can even be comparable to the grief experienced due to the death of a loved one [24], a finding that accords with a tendency for hoarders to imbue their possessions with human qualities, thereby anthropomorphizing them [42]. As these reactions can inevitably provoke anxiety, avoidance of discarding is negatively reinforced because it prevents the experience of these emotions. Anxiety can also arise when others attempt to arrange or utilize a hoarder's possessions. Control over possessions appears to be partly related to a heightened sense of responsibility for keeping objects intact and to a sense of personal responsibility for being prepared in the event that an object is required at some point in the future [28].

Assessment of Compulsive Hoarding

Despite growing interest and research in the area, there is still a paucity of measures specifically designed to assess compulsive hoarding. Several measures of obsessive-compulsive disorder include hoarding subscales, such as the Yale-Brown Obsessive Compulsive Scale [38], the Obsessive Compulsive Inventory [20], and the Obsessive Compulsive Inventory-Revised [21]. Many studies of hoarding have used the two Yale-Brown Obsessive Compulsive Scale items assessing hoarding obsessions and compulsions. Some researchers have raised concerns about using these items [82] due to questions about

the definition of a hoarding obsession and the inability of these two items to assess many crucial aspects of hoarding behavior. One recent study of hoarding [70] used the Dimensional version of the Yale-Brown Obsessive Compulsive Scale [71]. This version was designed to assess obsessive-compulsive disorder dimensions (contamination, cleaning, harm, hoarding, symmetry, sexual/religious, and miscellaneous obsessions and compulsions). The Dimensional version of the Yale-Brown Obsessive Compulsive Scale includes a series of clinician-administered scales that can be used to assess the presence and severity of each symptom dimension.

The Obsessive Compulsive Inventory and Obsessive Compulsive Inventory-Revised include several symptom subscales including Washing, Checking/Doubting, Obsessing, Mental Neutralizing, Ordering, and Hoarding. Both measures are somewhat better than the Yale-Brown Obsessive Compulsive Scale at assessing hoarding; however, the Hoarding subscales of both the original Obsessive Compulsive Inventory and the revised inventory are still problematic. This subscale failed to distinguish clinical from non-anxious controls adequately in the original Obsessive Compulsive Inventory [20], and the revised inventory has demonstrated weak internal consistency [47]. Additionally, Abramowitz and Deacon [1] found that the Obsessive Compulsive Inventory-Revised hoarding subscale correlated only weakly with the other Obsessive Compulsive Inventory-Revised subscales and did not correlate with the Yale-Brown Obsessive Compulsive Scale in a clinical sample of anxious participants. These findings raise concerns about the appropriateness of utilizing obsessive-compulsive disorder measures to index hoarding thoughts and behaviors.

The first systematic attempt to design a scale solely to measure hoarding symptoms was the Hoarding Scale [23], a 22-item self-report questionnaire that assessed discarding behaviors, emotional reactions to discarding, problems with decisions regarding discarding, concerns over future use of discarded items, and sentimental attachment to possessions. The Hoarding Scale was found to be both reliable and valid in college, clinical, and community samples. In addition, it was able to discriminate between individuals who reported experiencing hoarding tendencies and community controls [23]. Although it possessed sound psychometric properties, the Hoarding Scale had inherent limitations as subsequently identified by the primary author [35]. Given the limited information about hoarding behaviors at the time of its development, the Hoarding Scale did not assess all of the components that are now known to be important facets of hoarding, such as excessive acquisition. The scale also confounded beliefs about possessions with behavioral symptoms and included items about specific types of possessions that were not applicable to every individual with hoarding tendencies [35]. In addition, the Hoarding Scale did not adequately assess distress or impairment at the clinical/severe level [82].

The recognition of the Hoarding Scale's limitations led to the development of a revised measure to address these concerns, the Saving Inventory-Revised [35]—a 23-item self-report questionnaire with three subscales assessing: (1) excessive acquisition of purchased and free items, (2) saving and discarding behaviors, and (3) excessive clutter as a result of these behaviors. The Saving Inventory-Revised has been shown to discriminate between identified hoarders and both non-hoarding controls and non-hoarding obsessive-compulsive disorder cases [35]. The subscales have been shown to correlate with additional indices of hoarding interference, such as activity dysfunction and both self- and observer ratings of clutter in the home [13, 35, 88].

There are several other self-report measures of hoarding. One commonly used measure, the Saving Cognitions Inventory [86], is a 24-item self-report inventory that assesses beliefs and attitudes experienced when trying to discard possessions. Participants rate the extent to which a thought influences their decision about whether to discard a possession on a 7-point Likert scale. The four subscales assess emotional attachment to objects, beliefs about objects as memory aids, responsibility for not wasting possessions, and

the need for control over possessions, respectively. In addition, a few studies have employed the Yale-Brown Obsessive Compulsive Scale: Acquisition and Saving Version [84], a 10-item self-report measure that is modeled on the Yale-Brown Obsessive Compulsive Scale. The Acquisition and Saving Version indexes the severity of hoarding thoughts and behaviors and the subsequent interference and avoidance. Questions address time spent, distress, interference, and effort and success in resisting thoughts and hoarding behaviors. Finally, the Activities of Daily Living-Hoarding Subscale [83] is a 16-item inventory designed to assess interference in daily activities such as bathing, dressing, and preparing and cooking food due to clutter within the home. Items also assess general conditions within the home such as the presence of rotten food and associated safety/health issues (fire hazard, unsanitary conditions). The Activities of Daily Living-Hoarding Subscale is particularly useful when completed by two raters (e.g., by the hoarder and family member or clinician) as discrepancies between the two ratings can be indicative of poor insight.

Poor insight poses a problem for the assessment of hoarding when using measures that rely on self-disclosure of beliefs and behaviors. As noted previously, individuals with compulsive hoarding demonstrate limited recognition of the problem [11, 14, 19, 42, 80], with as many as 50% failing to recognize their behaviors as being problematic [31, 85]. The validity of self-report inventories may, therefore, be compromised. In an effort to address this concern, Frost et al. [36] developed a pictorial measure to index the extent of clutter within the home. The Clutter Image Rating [36] includes nine pictures that vary in rating from 1 (no clutter) to 9 (severe clutter) for a kitchen, a living room, and a bedroom, with a mean composite score calculated across the three rooms (range 1–9). Respondents select the picture that most closely matches each room to provide a rating of the amount of clutter associated with that room.

In addition to the measures described here, many studies have also used their own clinician-administered interviews to assess the presence and severity of hoarding (cf. [45, 77, 79]). The lack of uniformity across studies underscores the need for the development of a standardized structured interview to aid in future investigations of the parameters associated with compulsive hoarding, particularly one that can be used as a treatment outcome index.

Treatment of Compulsive Hoarding

The presence of hoarding symptoms is often a negative predictor of treatment outcome for current treatments that are effective in treating obsessive-compulsive disorder [11]. This is true for both pharmacological and psychological treatments [7]. It has been suggested that this is because those with hoarding problems often refuse treatment and/or are less motivated to engage due to poor insight. It is usually a family member or spouse that pressures the hoarder to seek treatment. Kozak and Foa [54] suggested that traditional treatments for obsessive-compulsive disorder may be less effective because hoarders often display perfectionistic thinking and magical ideas that interfere with the treatment components.

Biological Treatments

Most biological treatments have examined the effect of serotonergic medications on symptoms of compulsive hoarding. In a study by Mataix-Cols et al. [63], 150 individuals with obsessive-compulsive disorder were treated with serotonergic reuptake inhibitors across six placebo-controlled medication trials. The authors examined whether different factor structures on the Yale-Brown Obsessive Compulsive Scale checklist predicted treatment response after controlling for baseline severity of symptoms. Only the hoarding dimension of the Yale-Brown Obsessive Compulsive Scale was associated with poorer outcomes on obsessive-compulsive disorder symptom

measures, suggesting that hoarding symptoms predict poor treatment outcome.

Winsberg et al. [94] investigated treatment outcome following treatment with serotonergic reuptake inhibitors in a sample of 20 compulsive hoarders. Of the 18 participants who received an adequate trial, half showed an improvement by at least 25% on the Yale-Brown Obsessive Compulsive Scale, with one showing a marked response. It is unclear, however, whether these changes occurred in hoarding symptoms. All participants in the trials had other obsessive-compulsive disorder symptoms, and the improvement in Yale-Brown Obsessive Compulsive Scale scores may have been due to changes in these symptoms. The nine individuals in the study who received cognitive behavioral therapy intervention for hoarding based on the treatment outline provided by Hartl and Frost [48] appeared to show somewhat greater improvements than those treated with medication alone. In another treatment study by Black et al. [7], medication and cognitive behavioral treatments were compared with placebo. In a sample of 38 non-depressed individuals with obsessive-compulsive disorder, approximately 18% of those who reported hoarding symptoms responded to treatment, compared with 40% of treatment responders in the non-hoarding group. These results are in accord with the suggestion that hoarding symptoms negatively predict treatment response.

Nevertheless, there is some promise for biological treatments for hoarding as recent studies [15, 77] have found that hoarders do respond, at least to some degree, to medication. Saxena et al. [77] found that hoarders with obsessive-compulsive disorder responded as well to the serotonergic reuptake inhibitor medication paroxetine as did those with obsessive-compulsive disorder but no hoarding symptoms, although the treatment response of both groups was not optimal. Other studies have found that early onset, poor insight, somatic obsessions [15], sexual obsessions [2], and comorbidity [81] are predictors of poor treatment response to medications and not hoarding symptoms. One of these studies [15], however, did find a statistical trend suggesting that hoarding may have been a negative predictor of treatment response.

Psychological Treatments

Current cognitive-behavioral techniques have had some success for the treatment of compulsive hoarding (e.g., [84]). This treatment approach is largely based on the model of compulsive hoarding described by Frost and Hartl [24]. The treatment usually comprises a group program with additional individual sessions that involve therapists visiting clients' homes to complete exposure and discarding exercises. Treatment usually lasts from 6 months to a year.

Cognitive behavioral therapy for hoarding covers five general themes: education about hoarding, improving decision-making capacity, development of an organizational system for possession, graded exposure to avoidance behaviors, and cognitive restructuring around beliefs about possessions [27]. The exposure sessions are conducted both during sessions, with clients bringing in a selection of possessions, and within the home. Clients are expected to practice making decisions about the category to which possessions belong (i.e., discard, save, or retain for sorting later) and to follow through with these decisions. This exposes them to the emotional distress of discarding and challenges fears about making a mistake, missing information, and being responsible for discarded items. Therapists never touch clients' possessions without permission so that the client is entirely responsible for the decision-making process. Clients are taught to challenge their beliefs about the emotional significance of their possessions, the cost of making a mistake, the need for perfectionism, and the importance of remembering/having access to information. They are also required to create an organizational system and to categorize possessions that they decide to save based on this system in order to reduce clutter.

There is some evidence indicating that treatments based on the cognitive-behavioral model are effective for compulsive hoarding. Hartl and

Frost [48] conducted a multiple baseline experimental case study involving an individual with a long-standing hoarding problem. Therapy consisted of the strategies outlined above delivered in weekly 2-h sessions combined with regular homework tasks. After 9 months, there was a reduction in hoarding symptoms, indecisiveness, and non-hoarding obsessive-compulsive disorder symptoms. After 18 months, the targeted living spaces were almost completely free of clutter. Steketee et al. [84] conducted a larger-scale study for seven individuals over 20 weeks. Six of them attended group therapy and had individual home visits, while the seventh received individual home visits using a similar individual treatment applied by Hartl and Frost [48]. Scores on the Yale-Brown Obsessive Compulsive Scale showed some improvement after 15 sessions of treatment. Self-report ratings also improved on recognition of irrational reasons for saving, organization, and decision making, although clutter was slow to improve. Scores on the Yale-Brown Obsessive Compulsive Scale and self-report measures improved further for participants who continued fortnightly treatment for a year.

Saxena et al. [75] reported similar improvement in a group of 20 compulsive hoarders with obsessive-compulsive disorder. A large group of individuals with non-hoarding obsessive-compulsive disorder symptoms also received treatment. This included 6-week daily multimodal therapy involving cognitive behavioral therapy, selective serotonin reuptake inhibitor medications, and psychosocial rehabilitation. Scores on the Yale-Brown Obsessive Compulsive Scale following treatment showed improvement for both the hoarding and non-hoarding groups, although the improvement was less marked for the hoarding group. Importantly, improvements in mood and psychosocial functioning were similar for both groups.

Overall, research findings indicate that compulsive hoarders do respond to cognitive behavioral therapy, although improvements are moderate in comparison with gains observed in non-hoarders with obsessive-compulsive disorder. There are a number of methodological limitations, however, that temper these findings. First, there is a lack of properly controlled treatment studies that involve allocation to treatment (cognitive behavioral therapy or medication) and a placebo group. Also, the lack of specificity of the measures used to index symptoms makes it difficult to determine whether improvements are due to changes in hoarding symptoms or other non-hoarding obsessive-compulsive disorder symptoms. Reliable measures of symptoms specific to hoarding need to be used to determine whether treatment is actually targeting hoarding.

Compulsive hoarders may be responding relatively poorly to treatment due to a lack of insight and motivation to engage in treatment [24]. It may, therefore be advantageous to incorporate a motivational interviewing component into treatment to increase individuals' insight into their hoarding problems. Tolin et al. [88] reported that homework adherence was a positive predictor of treatment outcome, highlighting the importance of insight and motivation to overcome hoarding problems. Motivational interviewing [67] is often used in the treatment of addictions to resolve ambivalence about change and to help individuals identify the discrepancy between their current behavior and their goals for the future. A meta-analysis of randomized controlled trials examining the efficacy of motivational interviewing [9] found that this technique alone was as effective as other active treatments for problems involving drugs and alcohol, diet, and exercise. Tolin et al. [88] suggested that a motivational interviewing component could be integrated into treatment for compulsive hoarders when motivation wanes.

Future Directions in Hoarding Treatment Research

In a large survey, Kessler et al. [53] found that adult attention-deficit/hyperactivity disorder was highly comorbid with other mental disorders and substance use problems. They suggested

that treating attention-deficit/hyperactivity disorder successfully may have an impact on the development of other comorbid disorders. Indeed, there is evidence that adult attention-deficit/hyperactivity disorder is a risk factor for substance use disorders [6]. Among other neuropsychological deficits, individuals with hoarding display a deficit in sustaining attention. Hartl et al. [50] found that hoarding participants displayed symptoms consistent with attention-deficit/ hyperactivity disorder in adults on a self-report measure. Weaknesses in attention may limit hoarders' ability to sustain attention during a task (e.g., when deciding what possessions to save or discard), organize their possessions, and reduce clutter.

Treatment for attention-deficit/hyperactivity disorder is usually stimulant medication [69]. Cognitive behavioral treatment for attention-deficit/hyperactivity disorder may augment stimulant medication and improve engagement with specific treatment strategies and homework tasks involving decision making, categorization, and discarding [78]. Psychological treatments for attention-deficit/hyperactivity disorder involve direct education and the implementation of compensatory strategies and some cognitive restructuring for unhelpful beliefs about coping with stress. The compensatory strategies may include better planning and organization, removal of distractions, memory aids, and breaking up complex tasks into simpler, manageable chunks [72]. Treatment for compulsive hoarders with symptoms of adult attention-deficit/hyperactivity disorder may thus incorporate such strategies and modify delivery of treatment.

Conclusions

In summary, it is useful to view hoarding from an addictions perspective in order to gain new insight into this complex phenomenon. First, this framework encourages us to shift our focus to the positively reinforcing aspects of hoarding behavior, rather than focusing solely on its anxiety-related features. Second, comparing hoarding with other types of behavioral addictions may shed light on some of the underlying neural mechanisms of hoarding, as well some of the cognitive and self-regulation deficits that may be associated with this disorder. Third, some of the challenges encountered in the treatment of hoarding, such as lack of insight or motivation, are common in substance abuse and behavioral addictions. We may be able to turn to this empirical literature for specific clinical strategies, such as motivational interviewing, that have been efficacious in treating addictive disorders.

What Is Motivational Interviewing?

Motivational Interviewing is a counseling approach used to explore and resolve ambivalence about behavior change. There is a strong evidence base that it reduces substance use problems and a growing evidence base for other problems. It has been defined as "a client-centered, directive method for enhancing intrinsic motivation to change by exploring and resolving ambivalence" [25]. The directive aspect of the approach refers to the therapist's intentional pursuit of the resolution of ambivalence and initiation of positive change as central goals. The client-centered aspect of the approach refers to the consistent focus on the client's concerns, perceptions, hopes, and goals rather than those of the therapist. It also refers to Motivational Interviewing's reliance on client-centered techniques such as reflective listening and client-centered attitudes such as unconditional positive regard and accurate empathy. Thus, while focusing on and eliciting the client's perceptions, the Motivational Interviewing therapist explores areas of unresolved ambivalence and guides the client to resolve them to improve the client's life.

Motivational Interviewing was first described as a way to work with people having problems with drinking [19]. People with substance use problems and disorders often have mixed feelings and thoughts about their drug and alcohol use. While they may perceive some negative consequences of drinking or using, they also enjoy positive experiences such as intoxication,

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_35,

disinhibition, socialization, and pleasure. They may remain in a conflicted or ambivalent state about changing unless their perception shifts about the balance of these costs and benefits. Understanding and resolving this ambivalence is a central goal of Motivational Interviewing, and is accomplished through elicitation rather than persuasion. Therapists elicit the client's ideas and feelings about the current behavior, how the behavior fits in with hopes and values, and whether there might be more optimal choices from the client's perspective [43]. The therapist elicits the client's own reasons and rationale for possible change, referred to in Motivational Interviewing research as "change talk." In essence, Motivational Interviewing is focused more on the *whether* and *why* to change than on the *how*.

The counseling style used in Motivational Interviewing is "quiet and eliciting" and the "therapeutic relationship is more like a partnership. . .than expert/recipient roles" [36]. The spirit of Motivational Interviewing may be more important than techniques per se. The Motivational Interviewing spirit is one of collaboration between two experts, one with intimate knowledge of the self (the client) and one with skill in managing a constructive conversation about change (the therapist). The spirit of Motivational Interviewing is based on a respect and admiration for the client's autonomy, which is manifested as direct and indirect support for the client's ability and authority to make choices, consider options, and take actions. Finally, the spirit of Motivational Interviewing is evocative. Therapists ask questions and reflect the client's perceptions in such a way that a new understanding or commitment is evoked through the conversation. The therapist elicits the client's perspective on defining which behaviors might be problems, explores the client's own concerns, and elicits from the client intention to change or optimism about change.

Although the therapist has a goal of facilitating the exploration and resolution of ambivalence, the therapist is not attached to any particular outcome. By remaining focused on the client's concerns and ideas about change, therapists can assess the client's current readiness to change, and tailor the strategies they use. A growth metaphor has been used to describe readiness for change [41]. For a client not ready to make a change, the Motivational Interviewing therapist prepares the ground for planting by exploring the client's own perspectives, values, and hopes for the future. When a client is unsure about making a change, the Motivational Interviewing therapist plants seeds but understands that the soil has not been watered, maintaining a neutral but helpful stance. When a client is ready to make changes, the Motivational Interviewing therapist witnesses the plant breaking through the soil and reflects these observations. When the client is actively making changes, the Motivational Interviewing therapist understands that the plant may soon be ready for harvesting and provides support as needed.

The relational stance in Motivational Interviewing is one of respect and collaboration. Motivational Interviewing therapists believe that clients have expertise on themselves that can be used to make healthy changes. Using this approach, therapists elicit more information than they provide. The client may do more of the talking, explaining, exploring, and considering. Complementing the client's effort, the therapist offers reflections, questions, and summaries, while affirming the client's work. Therapists using the Motivational Interviewing approach tend to ask rather than tell, and to listen rather than advise. Motivational Interviewing therapists show curiosity rather than content expertise, even when they have substantial expertise in the area of the client's concern. It is more important that the Motivational Interviewing therapist develops an understanding of the client instead of providing information, education, or persuasion, all of which may provoke resistance or reluctance. This style can be seen as guiding rather than using a directing style, in which a therapist directs a client to absorb information, take advice, or follow instructions. Additionally, the eliciting, guiding, collaborative style in Motivational Interviewing tracks the client's experiences and perceptions, but differs from following in that the therapist maintains a

deliberate focus on the goal of exploring and resolving ambivalence.

Motivational Interviewing practice builds upon this collaborative relationship with a basic communication style that is used throughout consultation or counseling sessions. The style is summarized with the acronym OARS—*O*pen questions that encourage further elaboration and consideration, *A*ffirmations that foster positive feelings in the consultation, *R*eflections that indicate that the therapist has heard and accurately understood the client, and *S*ummaries that extend the basic reflections to include a sense of momentum or build interest in changing direction. These techniques are used to build rapport and gain understanding of a client's issues, to mend rifts in the treatment relationship, to redirect clients to more useful areas of consideration, and to solidify commitment to change in an established relationship where therapeutic alliance is strongly present.

In addition to the emphasis on using OARS as a basic communication style, the Motivational Interviewing therapist uses broader strategies that are consistent with the four principles of Motivational Interviewing. The four principles are Expressing Empathy, Developing Discrepancy, Rolling with Resistance, and Supporting Self-Efficacy [25]. Expressing Empathy is a principle that guides the therapist to seek understanding of the client, and to make comments that convey the accuracy and depth of this understanding. Developing Discrepancy is a principle that reminds the therapist that change is not typically sought or made until a person is at least somewhat uncomfortable with the status quo, or can envision a better, brighter opportunity sufficient to overcome the entropy of the familiar. Rolling with Resistance is a principle that reminds the therapist to avoid arguing for change when the client argues in favor of the status quo, and to acknowledge then sidestep resistance rather than identifying it as a problem, making it the focus of therapy, or confronting it in any way. Supporting Self-Efficacy is a principle that reminds the therapist to elicit client confidence about accomplishing tasks involved in making major lifestyle change. These principles lead naturally to specific strategies that are often used in Motivational Interviewing to achieve therapeutic gains.

Common Motivational Interviewing strategies and some *examples* of how the therapist might begin to use them include:

1. *Agenda setting*. How would you like to spend our time together today? Or Which of these issues would you like to discuss first? Or What's your top priority right now?
2. *Negotiation of focus*. Given your diagnosis with asthma and your doctor's advice to quit smoking, there may be a number of concerns you have. Which is most pressing to you now? Or It sounds like alcohol and drugs have been causing you some difficulties. What other issues should we put on the table for consideration? Or Of the three areas you just discussed, drinking, arguing with your wife, and spending too much money, which is the one you'd like to start with today?
3. *Scaling importance, confidence, and readiness*. I'd like to understand more about how you view your drinking. On a scale of 0–10, with 0 being not at all important, and 10 being extremely important, how important is it for you to change your drinking now? Or Given that you'd like to make these changes to your cocaine use, how confident do you feel that you can do it? Or While you believe it is quite important to quit smoking, and you feel a bit of confidence you could do it, how ready are you to quit smoking now?
4. *Providing information*. I have some information about maintaining a healthy weight while quitting smoking if you are interested. Or You talked about wanting to get some more information about managing your drinking We offer several options here including meeting with a therapist to do a kind of "check up" about drinking, enrolling in our drinkers' support group, or discussing your health further with the nurse or with me. There are additional resources I can point you to, including written materials and interactive programs on the internet. What would you like to try?

5. *Exploring strengths*. What are some personal qualities that you are proud of? OR Which strengths did you use when you overcame that challenge?
6. *Looking backward*. Let's talk about a time before you started using. What were you doing then? And then, when you began using? And later, as time went on? What do you notice, thinking about the time since you started using?
7. *Looking forward*. Where do you think you're going with this eating and exercise pattern if you look ahead a few years? What will likely happen if you maintain your current habits? What might happen if you made some small changes?
8. *Remembering successes*. You were successful in changing your heroin use. Tell me more about how you were able to stay quit. . .what parts of that change might be relevant now, as you consider quitting smoking weed?
9. *Considering hypothetical changes*. If you were to make a commitment to begin writing down what you are drinking each day, how might you remind yourself to do it? What would be challenging? What would be rewarding?

In addition to defining what Motivational Interviewing includes, it is also useful to define what it does not include. For example, while occasional advice may be given to clients who are seeking it, unsolicited advice is not offered without first securing client permission. Similarly, therapists do not confront or warn clients, engage in domineering or controlling interactions, or express their own concerns about clients or client choices (except in extenuating circumstances where clients may be in immediate danger). Motivational Interviewing strategies or techniques are not simply added into interactions that are hierarchical in nature; rather, the Motivational Interviewing style prescribes that the therapist-client relationship is inherently non-hierarchical.

In summary, Motivational Interviewing is a counseling approach in which therapists use a client-centered stance paired with eliciting techniques to help clients explore and resolve their ambivalences about changing behaviors that are not optimally healthy. It is characterized by a collaborative, autonomy-supporting, and evocative style in which therapists seek to understand clients' perspectives, while directing clients towards considering changing one or more behaviors by building a sense of discrepancy between the current and hoped-for self, avoiding confrontation, and supporting clients' optimism about the possibility and methods for change. Table 1 summarizes common characteristics of Motivational Interviewing and shows their relationships to Motivational Interviewing principles.

A Brief History of Motivational Interviewing

Although it has strong roots in client-centered counseling, Motivational Interviewing developed more out of practical experience than theoretical conviction, and can be considered atheoretical or theoretically eclectic. Bill Miller's exploration with Norwegian colleagues of his intuitive practice guided him to elucidate the principles underpinning his approach, which integrated cognitive and behavioral elements into a broadly client-centered style. Miller's original principles were supplemented by collaborator Steve Rollnick's observation that ambivalence was a central aspect of change, and that Motivational Interviewing specifically targeted ambivalence. Working together, Miller and Rollnick developed the clinical methods and described them in their 1991 book [24]. They anchored their discussion of the rationale for elements of the clinical methods on discussion of the theories to which the elements were logically linked. The first related theory was Carl Rogers' theory of the necessary and sufficient conditions for therapeutic change, such as genuineness, congruence, and accurate empathy [35]. A second related theory was cognitive dissonance theory, in which Festinger posited that people would work to reduce thoughts that were strongly

Table 1 Principles of Motivational Interviewing and relationships to common techniques and strategies

	Principles			
Techniques and strategies	Express empathy	Develop discrepancy	Roll with resistance	Support self-efficacy
Seek and accept the client's perspectives	x		x	x
Listen more than speak	x		x	
Ask open questions	x	x	x	
Set agenda collaboratively				x
Reflect your understanding	x		x	
Affirm the client's efforts				x
Summarize your understanding	x		x	
Ask key questions that build momentum		x	x	x
Explore ambivalence by examining pros and cons of changing	x	x	x

Envision a different way		x		
Consider values		x		
Elicit and reflect change talk		x		x
Set goals collaboratively				x
Recall successes	x	x		x
Encourage small steps toward change	x			x
Ask for commitment or emphasize it when it emerges	x		x	x

Note: We show here a list of common Motivational Interviewing techniques and strategies, rather than a comprehensive list, and show the most likely relationship to each principle. In any particular clinical situation, it is possible that a specific technique may relate to more than one principle

dissonant with their behaviors by altering either their attitudes/thoughts or their behaviors [9]. While cognitive dissonance theory as a whole is no longer part of the model of Motivational Interviewing, recent versions of Motivational Interviewing have retained the idea of the related concept of discrepancy). A third related theory was Bem's self-perception theory, in which people observed themselves, their behaviors, and their statements, and inferred from those actions what they believed and valued [3].

Studies of Motivational Interviewing and Miller's Drinker's Check-up showed early positive findings in that brief 1–4 session interventions had a clear impact on drinking behaviors up to a year later. A four-session adaptation of Motivational Interviewing that included personalized feedback, Motivational Enhancement Therapy, demonstrated its efficacy as a treatment approach for problem drinking in the large U.S. clinical trial, Project MATCH. Interest grew in using Motivational Interviewing, originally conceptualized as preparing people for changing addictive behaviors, with problems beyond substance abuse. It is fair to say that there has been an explosion of interest and studies of Motivational Interviewing in the past 15 years, including approximately 200 clinical trials.

While the scientific literature on Motivational Interviewing helped to increase its popularity, a significant factor in its dissemination was the development of a network of skilled trainers who trained therapists in Motivational Interviewing across settings and in many countries across the globe. Rather than disseminating Motivational Interviewing through writing only, Bill Miller and Steve Rollnick personally trained the first generation of Motivational Interviewing Trainers. This group began meeting regularly at the time of the (then annual) Training of New Trainers conducted by Miller and Rollnick and was initially a loose collaboration of volunteers. As new trainers were trained, the group outgrew its original small format and added online support for its growing community. With technical assistance from the Mid-Atlantic Addiction Technology Transfer Center, the Motivational Interviewing Network of Trainers has grown into

an active international community of many hundred trainers who interact via listservs, annual meetings, an online journal, and collaborative commercial and charitable training projects around the world. The Motivational Interviewing Network of Trainers is now an independent entity that counts many of the most active Motivational Interviewing researchers among its members, thus developing a strong communication loop between researchers, practitioners, administrators in a wide variety of cultures and professional settings.

Theoretical Concepts and Emerging Models of Motivational Interviewing

Although Motivational Interviewing was derived from practice-based evidence, there are ongoing attempts to understand it theoretically. Currently, there is no comprehensive theory of Motivational Interviewing that explains its actions or drives its development, although there are several threads. In this section, we consider how an emerging model of Motivational Interviewing might be woven from the threads of self-determination theory, the transtheoretical model of behavior change, emotions theory, interpersonal theory and psychotherapy, and data on Motivational Interviewing and some of its potential mechanisms.

Motivational Interviewing as an Activator of Intrinsic Motivations and Growth

Motivational Interviewing seeks to build internal motivation to change, even in the context of clients seeking to change due to some duress or external situation. Individuals with higher levels of internal motivation for change may be more likely to succeed in achieving and maintaining the desired change. Motivational Interviewing seeks to elicit the person's healthy aspirations and propensity for positive growth. These aspirations and growth experiences are often internally motivating, rather than resulting from external reinforcement alone. These goals of activating intrinsic motivations overlap somewhat with self-determination theory. Self-determination theory posits an alternative to some views of human motivation as originating in physiological needs, or as a drive state seeking to amend deficits. Instead, self-determination theory proposes that growth-oriented activity is the central source of motivation [6]. Self-determination theory states that people have innate needs for competence, relatedness, and autonomy, and that these needs can explain intrinsic motivation. Self-determination theory proposes that motivation becomes internalized naturally because humans are ready to internalize ambient values and regulations. Individuals come to grasp the importance of social values as children. Over time, they transform observed social mores into personal values and self-regulation. Self-determination theory proposes that internal motivation is most likely when a person has a sense of efficacy, control, or self-regulation about the required behavior. Self-determination theory outlines a continuum of motivations ranging from externally regulated to truly intrinsic. Markland and colleagues propose that Motivational Interviewing is not focused on truly intrinsic motivations (defined by self-determination theory as engaging in behaviors because they are inherently interesting or enjoyable) [16]. Rather, Motivational Interviewing focuses on a broader range of autonomous motivations regarding behaviors that lead toward desired outcomes for the person. These outcomes may involve extrinsic gain or increased coordination with one's values and self-identity.

Motivational Interviewing as a Method to Move People Through Stages of Change

Motivational Interviewing is a counseling style concerned with encouraging behavior change. The transtheoretical model [7, 34] is a model

of how people make deliberate changes, especially eliminating problem behaviors and beginning new, healthier behaviors. The most well-known aspect of the transtheoretical model is the "Stages of Change" model, in which behavior change is seen as a process that progresses from low awareness and no intention to change through high awareness and active efforts to initiate or maintain change. The five stages of change are pre-contemplation, in which people may not recognize their behavior as problematic and are not planning to change; contemplation, in which people are considering change but remain ambivalent because there are also benefits resulting from their current behavior; preparation, in which people have decided to make a change and are making plans to change; action, in which people are actively taking steps to change, and maintenance, in which people are integrating the new behaviors into their ongoing lifestyle.

While distinct, the transtheoretical model and model of stages of change and Motivational Interviewing "grew up together" and complement one another [8]. Specifically, Motivational Interviewing is a valuable approach to use when people are in the early stages of change, to build interest and motivation for change. The concept of stages may be better as a heuristic than as a reflection of reality. In clinical encounters, readiness for change can fluctuate within a single discussion about change. By maintaining a client-centered perspective and eliciting client readiness to change rather than attempting to use pressure to motivate change, the therapist using Motivational Interviewing can avoid evoking resistance by "getting ahead" of the client.

Motivational Interviewing as an Activator of Emotions and Openness

Most descriptions of Motivational Interviewing and its work with ambivalence have focused on cognitive rather than emotional elements. The resolution of ambivalence is seen as a cognitive task, as in reaching a decision about which choice to make. Motivational Interviewing techniques have been described in cognitive and behavioral terms, as means to positively resolve tension created by unresolved ambivalence about change. Wagner and Ingersoll presented an alternative conceptualization of Motivational Interviewing [42]. Elicitation of negative emotions (e.g., by developing discrepancy) helps clients by narrowing their focus to areas in which they feel discontent, which leads toward them wanting to escape from the current unsatisfactory situation or avoid a future unsatisfactory situation. In contrast, the concept of positive reinforcement involves seeking positive states through behaviors that lead toward more satisfying conditions. From this perspective, motivation involves a desire to experience positive emotions. A positive emotions model encourages a view of motivation that emphasizes opening up to new experiences and actively seeking to build resources to support change and is consistent with the Broaden and Build model of positive emotions in motivation [10, 11]. Elicitation of the positive emotion of interest may lead to greater openness to experiencing. When a client experiences interest (or related emotions such as wonder or curiosity), his or her cognitive focus broadens to consider options that previously had been overlooked or rejected. This increased flexibility in conceptualizing situations may then facilitate resolution of ambivalence and increased openness to engage in activities that lead toward change. As the person acts in the newly considered direction, he or she may improve certain skills and increase the likelihood of achieving a desired outcome. Movement in this positive direction may increase confidence, sense of accomplishment, self-esteem and mood, thus establishing these increased resources for the person to draw upon in service of even more profound changes. After analyzing common Motivational Interviewing techniques and strategies through the lens of the broaden-and-build model, Wagner and Ingersoll concluded that Motivational Interviewing elicits positive emotions of interest, hope, contentment

and inspiration by inviting clients to envision a better future, to remember past successes, and to gain confidence in their abilities to improve their lives.

Motivational Interviewing as an Interpersonal Intervention

Interpersonal theory and research suggest that interpersonal interactions can be represented by two orthogonal dimensions: control and affiliation [15]. The control dimension ranges from Dominance to Submission, while the affiliation dimension ranges from Warmth/Friendliness to Coldness/Hostility. When plotted, they form a circle that represents how controlling and affiliative a person is in interactions with others. Considerable evidence exists that a friendly interpersonal style elicits reciprocal friendly responses from others and a hostile interpersonal style also elicits a reciprocal, hostile response [14]. Interpersonal theory also suggests that a dominant interpersonal style pulls for complementary submissive behavior, while submission pulls for complementary dominant behavior. However, although dominant behavior may pull for submissive behavior, it often elicits reciprocal dominant behavior as interactants struggle for the upper hand in a relationship.

Interpersonal theory has psychotherapeutic implications. While submissive and friendly-submissive clients may pull for and respond well to dominant and friendly-dominant therapists, clients having other baseline styles may not react as well to such a therapeutic stance. Clients presenting with hostile-dominance, who may be angry and lashing out, are unlikely to respond well to a therapist who attempts to assert control or dominance over the interactions even in a friendly-dominant manner, even though this is a logical stance to take if the therapist believes that the client's aggression must stop. Although being friendly and easy-going may be difficult to do in this situation, it is more likely to pull the client toward a friendly stance himself, which is likely to be more productive in moving forward. In contrast, with a client who is clinging and submissive, therapists may be pulled to provide reassurance, structure and direction, yet this is likely to reinforce the client's needy behavior. Instead, a therapist may take an interpersonal stance that pulls for the client to become more assertive and assume greater ownership of his life, even though the client may be pulling for the therapist to take a dominant stance. Figure 1 shows an interpersonal circumplex with hypothetical Motivational Interviewing-congruent therapist behavior and client responsive behavior.

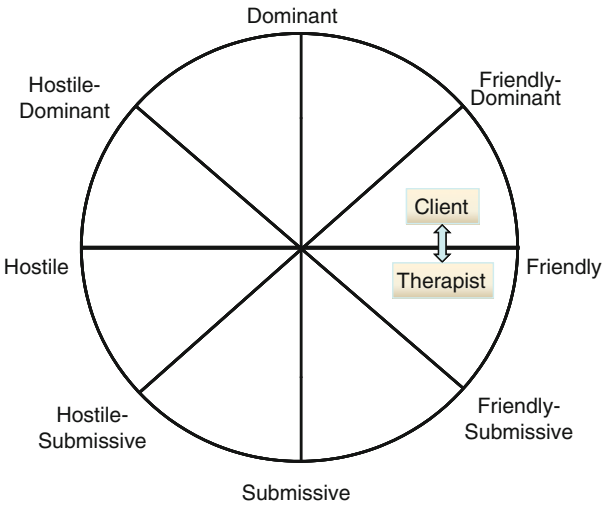

Fig. 1 Interpersonal circumplex with hypothesized Motivational Interviewing-consistent therapist characteristics and responsive client characteristics

By definition, Motivational Interviewing therapists attempt to be both client-centered and directive. Regarding the client-centered aspect, it is useful to consider a continuum of therapist centered and client centered responses. We first present the continuum in a linear fashion, with therapist-centered behaviors that are hostile and controlling on the left and friendly but controlling to the right. Client-centered responses are in the center, ranging from deflecting on the hostile side to affirming on the warm side (see Fig. 2).

On both ends of the continuum is the behavior "direct," because directing can be done in a hostile or warm manner. In our view, this behavior anchors the continuum up and around to the interpersonal circle to the top, which is dominance on the control dimension. Dominance is associated with being right, with being in authority, and with exerting authority or attempts to control others. These behaviors reflect the therapist's perceptions and needs in a moment, and tend to indicate that the therapist has moved away from being client-centered. Such therapist-centered responses are more likely to elicit reactance, whether negative or positive, because they encroach upon the client's being by establishing a hierarchy in which the therapist is above the client.

How might we classify particular therapist statements to better understand how interpersonal interactions work in Motivational Interviewing? A therapist responding to a client's reduction in drinking may say "I am proud of you." Upon first consideration, this appears to be a positive response, falling on the warm side of the affiliation dimension. However, this kind of statement is more likely to be perceived as approval, specifically praise, because it contains a dominant, judgmental element. Another example is "You worked really hard on that," which would be considered an affirmation, because it is an observation that notices the client's effort, rather than evaluating or praising the outcome. Motivational Interviewing primarily uses the middle range of responses from deflection (occasionally, shifting focus) to affirmation. Responses near to these are also used in Motivational Interviewing, but less often. On one demonstration video, Bill Miller agrees with a client angered by previous treatment staff telling him he must accept a label: "It doesn't make any sense to me! It's natural to push back when people push against you." Considering this continuum of possible therapist statements, it appears that Motivational Interviewing draws nearly exclusively from the client-centered range of responses.

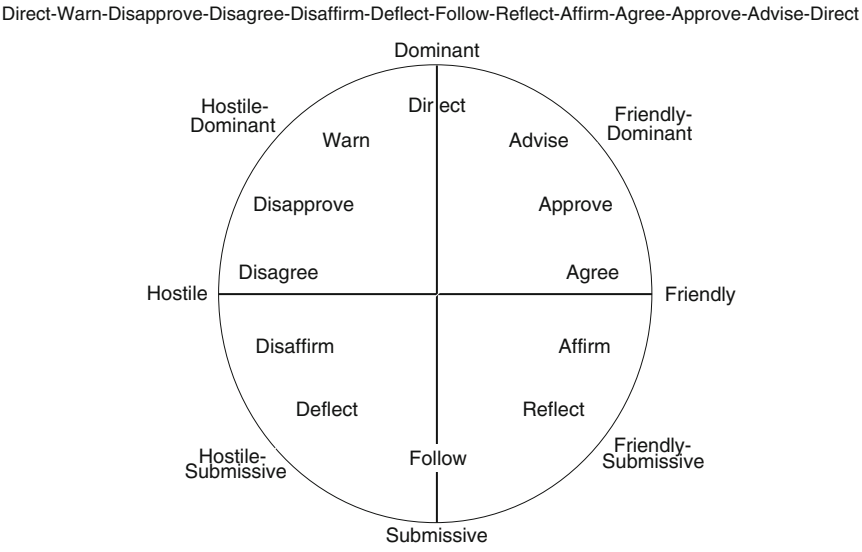

Fig. 2 Linear and circumplex depictions of therapist-centered and client-centered therapist behaviors in Motivational Interviewing

Interpersonal theory has the potential to explain some mechanisms of action in Motivational Interviewing. Interpersonally, Motivational Interviewing therapists tend to be friendly, which elicits a friendly, cooperative stance from most clients. While Motivational Interviewing has a directive component, in that the therapist leads the client to explore and resolve ambivalence and initiate change, this directive process is not necessarily dominant interpersonally. For many people in a leadership role, it is natural to default to a more dominant style to lead, using either warm dominance by being outgoing, encouraging, praising, suggesting, etc., or cold-dominance by directing, warning, confronting, or disapproving. Rather, the Motivational Interviewing therapist leads through affirmation, reflection, listening, and deflecting, all considered submissive behaviors. From the framework of interpersonal theory, these behaviors are less likely to elicit reactance, and are predicted instead to elicit reactions of more outgoing, spontaneous, confident and self-reliant behaviors from clients. Thus, clients take responsibility for deciding on and enacting steps toward change, increase their self-efficacy for specific challenging behaviors, and build momentum and excitement about change. Motivational Interviewing is thus almost entirely anchored in a friendly to friendly-submissive therapist stance. This interpersonal stance in Motivational Interviewing is paired with a leading/guiding/directing intent, and this unusual combination may contribute to the success of the Motivational Interviewing approach.

Motivational Interviewing as a Method to Reduce Resistance and Increase Change Talk

Miller discussed the evidence for different hypotheses about Motivational Interviewing and their possible implications and later elaborated these ideas [21, 26]. In his earlier presentation, he posited a model of Motivational Interviewing in which four hypotheses were considered as potential explanations for the behavior change observed following Motivational Interviewing treatment. Specifically, he hypothesized that Motivational Interviewing would increase client change talk, that Motivational Interviewing would reduce client resistance, that defense of the status quo by clients would relate negatively to change, and that change talk would relate positively to change. Using data from a previous study comparing Motivational Interviewing to a confrontational approach, he found that Motivational Interviewing yielded 111% more change talk and that therapist confront responses predicted client resistance in the form of arguing, interrupting, negative responses, or off-task responses [22]. A psycholinguistic analysis of Motivational Interviewing showed increases in change talk, especially related to therapist listening and reframing behavior and decreases in commitment to drug use [1]. He argued that these data support the hypothesis that Motivational Interviewing increases client change talk and reduces resistance talk. Resistance during counseling was correlated with no change in drinking [1] and commitment to continued drug use during Motivational Interviewing predicted continued drug use [1]; thus, he argued that the hypothesis that client resistance predicts lack of change was supported. Additionally, he concluded while there is some evidence that an increasing slope of change talk in sessions is related to positive outcomes, there is not yet evidence that this is a causal relationship. He also drew from counseling studies with some conceptual or technique similarities to Motivational Interviewing and posited that the resolution of ambivalence is promoted by accurate empathy. Therefore, Miller's model of how Motivational Interviewing may be working is that in an empathic relationship, where there is low confrontational behavior by the therapist, listening and reframing relate to more change talk, which related to better outcomes. Additionally, he asserted that as change talk is observed by the client, the client takes action, consistent with the assertion in self-perception

theory that people observing their own speech draw conclusions about their interest or motivation to take actions based on their speech. That is, they infer motivation to change and a desire to take action when they hear themselves speak in favor of changing. Alternatively, change talk could be interpreted as *implementation intentions*, which have been shown to relate to initiation of action across behavioral domains [12] and specifically, to reduction of substance abuse behavior following verbal commitments to change [1, 17]. In essence, many models using different terms assert that when a client talks about doing something, or making a specific change, they are more likely to do so.

Summary: Emerging Components in a Model or Theory of Motivational Interviewing

In a more recent elaboration, Miller and Rose summarize Miller's early work, and propose that two active components in combination lead to the efficacy of Motivational Interviewing: a relational component that includes empathizing, collaborating, evoking client talk about their perspectives, and supporting client autonomy, and a technical component that includes evoking and reinforcing change talk [26]. Miller's emerging model presents some pieces of the puzzle, but these pieces may or may not be unique to Motivational Interviewing and might be common factors, shared by other psychotherapies. Further, while Miller's recent work may provide a working model of Motivational Interviewing in describing what happens, it is not an encompassing theory that attempts to explain why clients make changes after such interactions. An eventual model of Motivational Interviewing would elucidate elements unique to Motivational Interviewing and elements shared with other psychotherapies, and would demonstrate how the relational, technical, and interpersonal components work to produce client changes in beliefs, perspectives, emotions and actions.

Evidence About Motivational Interviewing

Evidence About Efficacy

What is the evidence base for Motivational Interviewing? The literature on Motivational Interviewing has been on an exponential growth curve. There were 161 grants funded by the U.S. National Institutes of Health that test some aspect of Motivational Interviewing active as of June 2009. Motivational Interviewing and its most common adaptation, motivational enhancement therapy, have been listed as an evidence-based practice in two prominent compendia of evidence-based treatments for substance use disorders [31, 32]. There have been three meta-analyses of Motivational Interviewing since the 2002 book was published. Because Motivational Interviewing is a general counseling approach of unspecified duration, researchers are required to make specific adaptations to individual populations and settings. Thirty randomized controlled trials of adaptations of Motivational Interviewing were subjected to meta-analysis [5]. Most commonly, adaptations of Motivational Interviewing targeted drinking ($n = 15$, 50%), while 2 targeted smoking cessation, 5 targeted drug use, 4 targeted diet and/or exercise, 1 targeted psychiatric treatment adherence, and 1 targeted disordered eating. These studies were conducted in a variety of settings, with the most common setting a substance abuse treatment center ($n = 11$), while 9 were in hospitals. The mean dose of the intervention ranged from 15 to 240 min, and averaged 99 min. The authors found variable effect sizes depending on the target behavior. There were medium effects in drug use and diet/exercise areas, small to medium effects in drinking, and no effects on smoking cessation or HIV risk behaviors. Adaptations of Motivational Interviewing improved client success rates, with one-third making the desired change without the adaptation of Motivational Interviewing and one-half making the desired change with the adaptation of Motivational Interviewing.

In the substance use areas, adaptations of Motivational Interviewing doubled abstinence rates from 1 in 5 to 2 in 5. The observed effects were durable, diminishing only slightly from 20 to 67 weeks of follow-up. In addition to effects on a single target behavior, adaptations of Motivational Interviewing also demonstrated medium social impact effect sizes that were not correlated with the target symptom. In a test of the "file drawer problem," in which insignificant results are unlikely to be published, the authors found that 1181 unpublished studies finding a null result would be needed to reduce the effect size of the published studies to non-significant. There is an investigator effect, with Miller's studies yielding a 0.51 (moderate) effect size, compared to studies conducted elsewhere, 0.21 (small). Adaptations of Motivational Interviewing are efficient; they produce similar results in 2 sessions that are achieved by other psychotherapy studies in 8 sessions for a variety of target behaviors.

The next meta-analysis of extant studies of Motivational Interviewing included a variety of target behaviors [13]. These investigators included studies with at least a pre-post design as well as randomized controlled trials, so included a broader spectrum of designs. They rated the methodological quality of the 72 studies and found that their characteristics did not differ from the larger literature on alcohol treatment outcome studies. The target behaviors included: alcohol (31), drug abuse (14), smoking (6), HIV risk (5), treatment compliance (5), water purification (4), diet and exercise (4), and one each on gambling, relationships, and eating disorders. Across all studies, the total n of participants was 14,267, while the n of each study ranged from 21 to 952, with a mean of 198. Men represented 54.8% of the total sample, with a mean age of 34. 43% of participants in the studies were ethnic minorities. The number of Motivational Interviewing characteristics ascribed to the treatment by study authors showed no relationship to effects, but those studies using a treatment manual showed lower effects than those without. Hettema and colleagues found that similar to other behavioral treatments, effects of Motivational Interviewing appear early and tend to diminish somewhat over time, except in additive studies, where they remain stable. They found that the average effect size of Motivational Interviewing was $d = 0.77$ at post-treatment, $d = 0.31$ at 4–6 months, and $d = 0.30$ at 6–12 months. They concluded that Motivational Interviewing is effective but that a number of process variables may affect outcomes, including therapist behaviors.

Another meta-analysis of Motivational Interviewing evaluated its impact on a number of health behaviors compared to the impact of brief advice [37]. Seventy-two trials published from 1991 to 2004 were found that compared Motivational Interviewing to brief advice across medical and psychological settings. There was a significant effect of Motivational Interviewing on a number of diverse target behavior indicators including body mass index, total blood cholesterol, systolic blood pressure, blood alcohol concentration, and standard ethanol content, but not on cigarettes per day or hemoglobin A1C. Motivational Interviewing demonstrated an effect in 74% of the randomized controlled trials assessed regardless of the interventionist's profession (psychologist, physician, nurse, etc.), and likelihood of an effect increased with increases in the number of minutes per session and the number of encounters per client. The authors concluded that Motivational Interviewing is more beneficial than brief advice for a broad range of target behaviors.

Evidence About Motivational Interviewing Processes and Their Relationships with Outcomes

The connection between process and outcome has not been established in Motivational Interviewing. However, there are therapist and client processes that are presumed to relate to change in Motivational Interviewing based on Miller and Rollnick's description of Motivational Interviewing. Motivational Interviewing therapists maintain the collaborative,

evocative, autonomy-supporting stance known as Motivational Interviewing spirit across sessions, and demonstrate empathy for the client. Therefore, it is hypothesized that when Motivational Interviewing therapists display Motivational Interviewing spirit and empathy, clients will show higher engagement and lower resistance. A corollary hypothesis is that clients with lower resistance and higher change talk in Motivational Interviewing sessions should have better outcomes. Additionally, Motivational Interviewing therapists use open questions, reflections, affirmations, and summaries as primary techniques, while employing strategies such as emphasizing choice and control, reframing, and rolling with resistance. Therefore, it is hypothesized that Motivational Interviewing performed with more open than closed questions, more reflections than questions, and more Motivational Interviewing-consistent strategies should result in better client outcomes. While the literature addressing this area is limited, it is growing and is providing some consistent answers about how Motivational Interviewing may be working.

Therapist interpersonal skills include acceptance, egalitarianism, empathy, warmth, and spirit. When therapists display a high degree of these qualities, they may facilitate the formation of a helpful therapeutic alliance and the engagement of clients in the process. This hypothesis was tested in a secondary analysis of therapists undergoing training to refine their Motivational Interviewing skills, in which therapists generated audiotapes of themselves working with a client with a substance abuse problem [30]. Tapes were rated with the Motivational Interviewing Skill Code to assess therapist global characteristics and provide frequency counts of therapist Motivational Interviewing consistent and Motivational Interviewing-inconsistent behaviors. Client affect, cooperation, engagement and disclosure were also rated using the Motivational Interviewing Skill Code. Using a structural equation model, they found that the latent construct of therapist interpersonal skills composed of acceptance, egalitarianism, empathy, warmth, and spirit were positively related to client involvement and that the correlation between therapist interpersonal skills and Motivational Interviewing-inconsistent behaviors was negative. They concluded that therapist interpersonal skills directly facilitated client collaboration, and that therapists with these skills did not undermine client engagement even when they displayed some Motivational Interviewing-inconsistent behaviors.

In a study of Motivational Interviewing treatment fidelity to a semi-structured, scripted Motivational Interviewing intervention targeting HIV medication adherence, investigators rated audiotaped sessions of about 30 min in length using the Motivational Interviewing Skill Code [20], a 3-pass system that generates global scores, behavior counts, and client global scores [39]. They found that interviewers achieved behavior counts consistent with the Motivational Interviewing style, while their global scores did not quite reach the benchmark. They found that a higher ratio of reflections to questions and the number of affirmations were associated with higher antiretroviral therapy adherence at study exit, while closed-ended questions were negatively associated with better adherence.

Similarly, Boardman et al. [4] assessed initial counseling sessions targeting smoking among inner-city African-Americans using the Motivational Interviewing Skill Code. They used a mixed linear models approach to control for therapist effects in all models, and found that an averaged Motivational Interviewing global score composed of acceptance, egalitarianism, warmth, genuineness, empathy, and Motivational Interviewing spirit and behavior counts of higher Motivational Interviewing consistency (including advice with permission, affirming, emphasizing choice and control, reframing, supporting, and using open questions and reflections), were related to greater frequency of client change talk (statements about recognizing problems, expressing concern, desire, intention, or optimism for change) and to a higher averaged global score of client expression of affect, cooperation, self-disclosure, and engagement. Behavior counts indicating Motivational Interviewing-inconsistent behaviors (giving advice without permission, confronting, directing, raising

concern without permission, and warning) were unrelated to client change talk or global scores. However, specific behaviors were related to some outcomes. Behavior counts of affirm, open questions, reflect, and support were positively related to a therapist-client interaction global score composed of averaged ratings of collaboration and benefit. Behavior counts of advice without permission showed a negative correlation with change talk. They found no predictors of client resistance statements.

In a study of Motivational Interviewing skills of peers conducting Brief Alcohol Screening and Intervention for College Students sessions targeting college drinking, investigators used the Motivational Interviewing Treatment Integrity scale [29] to assess the relationship between facilitator skills and drinking-related outcomes [40]. Participants in Brief Alcohol Screening and Intervention for College Students sessions showed increases in contemplation and decreases in drinking from baseline to 3-month follow-up. Peer therapists providing the Brief Alcohol Screening and Intervention for College Students intervention achieved beginning proficiency levels on global ratings of Empathy, percent Motivational Interviewing-adherent behaviors, and percent open questions, while they fell below beginning proficiency on Motivational Interviewing Spirit, reflections to questions ratio, and percent complex reflections. Regression analyses showed that closed questions were associated with decreased contemplation and open questions were associated with increased contemplation. More simple reflections were associated with increased drinking, but this relationship was attenuated when therapists attained a greater proportion of complex reflections.

Several studies have assessed client resistance and its relationships to therapist behaviors and to outcome. Although not directly examining Motivational Interviewing, an early study exploring the relationship of therapist behavior to client resistance found that resistance varied depending on therapist behaviors, with educational or confrontational behaviors eliciting more resistance, and client-centered behaviors eliciting less resistance [33]. The more time the client showed resistance in the session, the poorer the drinking outcome [22]. The reverse was also true; clients who showed little resistance manifested improved drinking outcomes up to 12 months later.

Amrhein and colleagues rated client speech across deciles of Motivational Interviewing sessions in a single-session intervention and examined the relationships of client change talk and commitment talk to outcomes [1]. They found that those who changed and maintained change in drug use evidenced increasing commitment language across a Motivational Interviewing session. In contrast, those who were categorized as strugglers showed decreasing change talk and a reduction in commitment language by the end of the session, and had poorer drug use outcomes. Further, Strang and McCambridge rated client speech for change talk and found that action-oriented change talk, presumably representing either commitment or a stronger implementation intention, was related to subsequent marijuana use at three month follow-up [18].

The association between client speech, therapist behaviors, and outcomes has been investigated in a line of ongoing research with one unpublished and three published studies to date. Moyers and colleagues found that client change talk and counter-change talk were related to substance abuse outcomes in the expected directions [18]. They found that the more the therapist affirmed, emphasized control, asked permission before raising concerns, and made reflections, the more clients engaged in total change talk in the session [27]. Going beyond simple correlational analysis, Moyers further studied the conditional probabilities of certain classes of client speech following various forms of therapist speech in Project MATCH's motivational enhancement therapy sessions [27]. They used an instrument designed for the study, the Sequential Code for Observing Process Exchanges, which consisted of 46 behavior counts (30 therapist and 16 client) derived from the Motivational Interviewing Skill Code. They combined client speech about the target behavior into positive (indicating change talk),

negative (indicating counter change talk) or other. Therapist behaviors were combined into Motivational Interviewing-inconsistent, Motivational Interviewing-consistent, or other categories. Motivational Interviewing-consistent behaviors included specific strategies such as emphasizing choice and control. They found that when therapists performed in a Motivational Interviewing-consistent manner, there was an immediate increase in the probability that clients would produce change talk in the next utterance. In contrast, therapists displaying Motivational Interviewing-inconsistent behaviors (such as warning or advising without permission) increased the immediate probability of clients producing counter change talk. Additionally, change talk sometimes followed "other" therapist behaviors that are part of the basic Motivational Interviewing style such as questions, and reflections, as well as other strategies such as giving information, providing feedback, providing opinions, and conversational fillers.

Lastly, these investigators investigated whether client change talk during three types of substance abuse treatment sessions predicted drinking outcomes [28]. They rated sessions from 12-step facilitation, cognitive-behavioral therapy, and motivational enhancement therapy from Project MATCH using the Motivational Interviewing Skill Code. Using the outcome definitions from Project MATCH, they considered the impact of client change talk and counter change talk on percent days abstinent and drinks per drinking day, taking into account baseline values on both these drinking variables. They found that adding change talk and counter change talk improved the model of outcome percent days abstinent, with counter change talk being a significant predictor. Adding change talk and counter change talk also improved the model of outcome drinks per drinking day, with both change talk and counter change talk acting as significant predictors in the expected directions. They concluded that the causal chain tested in their series of studies demonstrate that therapist behaviors evoke change talk, that counter change talk and change talk are different constructs, and that both are simultaneous predictors of outcome.

While the literature on how Motivational Interviewing works is still small, there are some common findings emerging from the studies to date. Empathy and Motivational Interviewing Spirit (collaboration, evocation, autonomy-support) both relate to engaging clients and building therapeutic alliances. Several studies found that open questions, reflections, and affirmations encouraged change talk, while closed questions did not. In addition, those behaviors considered to be Motivational Interviewing-consistent, such as asking permission to give advice, affirming, emphasizing client choice and control, and support, have been related to more change talk, as well as to more positive substance abuse outcomes in several studies. Some aspects of a model of how Motivational Interviewing works are emerging already, although many questions remain about the directionality and causality of current hypotheses. Table 2 presents a summary of tests of mechanisms of action of Motivational Interviewing published to date.

The evidence base and the summary from these meta-analytic and process-outcome studies indicate a number of important findings. First, nearly all studies have been adaptations of Motivational Interviewing, with most including both the counseling style and some form of personalized feedback rather than tests of it as a "pure" clinical method. Second, Motivational Interviewing is superior to no treatment and is equivalent to other active treatments despite its relative brevity, thus there may be cost effectiveness advantages to Motivational Interviewing. Third, the measurement of intervention fidelity needs to be expanded among clinical trials, many of which claim to use Motivational Interviewing but do not present evidence of its competent use or fidelity to its spirit and methods. Fourth, the study of process-outcome relationships in Motivational Interviewing is in early stages, and will require time to demonstrate which components of Motivational Interviewing are necessary and sufficient, and whether these are unique to Motivational Interviewing or might occur in

other psychotherapy approaches as in a common factors model. As more information about process-outcome relationships in Motivational Interviewing accumulates, it will inform the development of an empirically based model of Motivational Interviewing, and perhaps, of related psychotherapies.

Populations, Settings, and Applications of Motivational Interviewing

When Miller and Rollnick first described a complete version of Motivational Interviewing, its basis was work with drinkers. The current status of Motivational Interviewing is vastly different. There are at least six broad domains of concern that have been addressed by Motivational Interviewing, but within these domains, there are many potential populations of people and even more potential behavioral targets that could be addressed by Motivational Interviewing. We will review some of these briefly (see www.motivationalinterviewing.org for an expansive bibliography).

In the domain of substance abuse, common populations treated with Motivational Interviewing in clinical and research settings have included people with symptoms of problem drinking or drug use, ranging from youth experimenting with drinking for whom drinking is a statutory offense, through adolescents and adults with alcohol abuse disorders, through adults with severe alcohol and drug dependence problems, including those whose addiction problems have resulted in involvement in the criminal justice system. Studies have been published showing the efficacy of Motivational Interviewing to reduce drinking, increase abstinence from drinking, reduce heavy drinking days, reduce smoking, increase abstinence from tobacco, reduce gambling problems, facilitate harm reduction as in using needle exchange programs, and reduce drug use.

In the domain of medical disorders, Motivational Interviewing has been used to help patients with a number of medical diagnoses and related health conditions, some of which have obvious or less obvious relationships with substance abuse. At the high end of the severity of illness spectrum, some Motivational Interviewing practitioners and researchers have explored helping people with traumatic brain injury to increase healthy habits to assist in their brain injury rehabilitation, and increasing motivation among patients with heart disease to undergo cardiac rehabilitation including making changes in diet, exercise, and medication use. At the moderate level of medical acuity, Motivational Interviewing has addressed chronic pain management as well as diabetes risk reduction and diabetes management. Others have used Motivational Interviewing for prevention of disease or illness, for example, by targeting obesity before medical consequences develop. Consistent with prevention are a number of Motivational Interviewing applications toward health promotion that seek to increase healthy eating habits, physical activity, safer sexual practices, mammography screening, medication adherence, oral health care, and osteoporosis prevention and treatment.

In the domain of mental health, there is much growth in applications of Motivational Interviewing, resulting recently in a book with chapters ranging the gamut of psychological problems [2]. Relating to substance use problems, Motivational Interviewing has been used clinically and tested in research as a dual disorder intervention, targeting both substance use and mental illness. It has also been adapted to target behaviors that are often problematic in mental health treatment for anxiety, bipolar disorder, depression, post traumatic stress disorder, and schizophrenia, such as keeping appointments, taking psychoactive medications, and attending support groups. Motivational Interviewing methods have also been adapted in marital counseling for problems that may be related to substance abuse, including dysfunctional relationships.

The United States Department of Justice has adopted Motivational Interviewing as a preferred best practice in the area of criminal justice, including imprisoned inmates and those supervised in community correctional settings. Many

of those who are in criminal justice settings have substance abuse issues. Related to these settings are child protective services and domestic violence prevention and treatment services, which provide care to those involved in the legal system.

A domain that is just beginning to use Motivational Interviewing is education. So far, efforts to use or test Motivational Interviewing have focused on literacy acquisition and employment readiness, which are often found to be life problems among those with a significant substance abuse history.

Lastly, there is another domain that overlaps but does not neatly fit into any of the others. Motivational Interviewing is being used increasingly to target simultaneous health risk behaviors across a number of settings beyond the typical medical consultation room, including public health and media-accessed settings. Promising projects have shown the benefit of Motivational Interviewing to reduce the risk of alcohol-exposed pregnancy by targeting both drinking and contraception, sexual behavior-change including safer sex behaviors often in the context of drug or alcohol use as an additional target, and drug and alcohol use that overlap with criminal behavior.

The list of possible applications and behavioral targets of Motivational Interviewing is dauntingly long, and there is also increasing diversity in the settings in which Motivational Interviewing is delivered. Motivational Interviewing began as an outpatient psychotherapy for alcohol problems, with the model of an individual person seeking counseling coming in to a therapist's office and sitting for 45 min or an hour to discuss a troubling issue. It then expanded into medical consultation, where brief versions of Motivational Interviewing were developed and tested that could be managed in the much shorter visit times expected in the setting. Common practices include using Motivational Interviewing for all individual substance abuse treatment sessions, or adding Motivational Interviewing as a prelude to treatment entry where treatment follows a different model. Some therapists combine Motivational Interviewing with personalized feedback, employing a strategy based on motivational enhancement therapy, to begin considering the issue of change with a client. Other therapists combine Motivational Interviewing spirit, techniques, or strategies with other clinical methods, such as cognitive-behavioral therapy or values clarification methods. In the public sector, both in the community mental health system in the U.S. and the criminal justice system, Motivational Interviewing is commonly provided in a group format, because these services often offer groups as the primary treatment modality.

New Directions in Motivational Interviewing

Studying Motivational Interviewing

Most of the research on Motivational Interviewing to date has shown that Motivational Interviewing has strong main effects. There are now enough studies showing that Motivational Interviewing is efficacious in research settings applied to many challenging behavior change situations. An understanding of Motivational Interviewing should now progress toward identifying how Motivational Interviewing can be made effective in routine clinical care across a number of settings. This will require not only research on the dissemination process itself, but consistent evaluation of the fidelity of various Motivational Interviewing-informed interventions. The field has produced nearly a dozen instruments to measure Motivational Interviewing behaviors and processes that could be used to demonstrate whether and when Motivational Interviewing was delivered competently. Identifying the key components of Motivational Interviewing and how it works will allow it to be transformed into new methods of service delivery. Several teams are already working on computerized or web-based delivery of Motivational Interviewing that could allow the method to be delivered independent of the

availability of a competent Motivational Interviewing therapist. Identifying salient components of Motivational Interviewing will also inform efforts to disseminate it and make it work in various settings outside of the tight control of a research study.

Preparing Therapists to Use Motivational Interviewing

Therapists prepare themselves to use Motivational Interviewing by diverse methods. A decade ago, therapists may have read the original Miller and Rollnick book, and possibly attended a workshop offering a one or two-day introduction to Motivational Interviewing practice, and began to use Motivational Interviewing in their practice. With the emergence of studies showing that workshops often do not produce many competent Motivational Interviewing therapists in the absence of additional training, supervision, and coaching about specific Motivational Interviewing behaviors, the expectations for training have changed. Reading and introductory workshops are ways to increase interest in learning Motivational Interviewing. Monitoring or coding sessions provides additional data for therapists to use to improve practice by identifying areas of competence and areas that need attention to achieve competence. It is unclear whether therapists can do this themselves and achieve competence, or whether additional supervision and coaching of Motivational Interviewing practice is needed. Many therapists now enroll in introductory, intermediate, and advanced clinical workshops, while others seek supervision or evaluation of practice samples to improve their competence in Motivational Interviewing.

In addition to individual therapists becoming trained in Motivational Interviewing, it is now common for agencies to request training for many of their staff in Motivational Interviewing, or to seek to become a Motivational Interviewing-competent organization. This goal would seem to require several steps, such as exploring therapist and management perspectives about current services and competencies, broadening perspectives to build curiosity or interest in adding skills to the therapists' and agency's repertoires, and taking action to procure training, supervision, and organizational consultation. It is still relatively rare for an agency to take all of these steps, and to evaluate progress in a systematic way.

Some therapists and teachers provide training for others in Motivational Interviewing. Some of them are self-trained and others undergo a series of training experiences intended to increase their competency in training others in Motivational Interviewing. These experiences may include learning Motivational Interviewing and providing it clinically, seeking consultation on Motivational Interviewing practice, providing basic training on Motivational Interviewing, seeking consultation on Motivational Interviewing training skills or co-training with a more experienced trainer, obtaining training on the various methods to code Motivational Interviewing practice and/or to provide supervision using various systems, training agency-based supervisors or trainers on how to provide Motivational Interviewing supervision or training within an agency, and participating in a formal training for trainers such as that offered by the Motivational Interviewing Network of Trainers.

Improving the competence of Motivational Interviewing therapists, organizations, and trainers is an emerging area. Miller has compared learning Motivational Interviewing to learning to play the piano. While a brief workshop to teach fingering methods or specific compositions may help, more is needed to create a competent pianist. Similarly, a Motivational Interviewing workshop may pique the interest and increase some skills of a therapist, but training in theory, specific methods, timing, self-monitoring, and much actual practice may be required to achieve competence, and later, fluency in Motivational Interviewing. How to train or produce Motivational Interviewing-skillful organizations is a challenge already being addressed in some large scale projects, especially in the area of criminal justice. However, there is

little current evidence about preferred methods in this area, and similarly, little evidence about best practices in training trainers. All of these areas await further development as the demand for training therapists and organizations continues.

Defining Motivational Interviewing

As practice evolves and new evidence about effectiveness and process-outcome relationships emerges, it is likely that definitions of Motivational Interviewing will change. In some ways, this has already happened. There are at least four perspectives on defining Motivational Interviewing. One is that Motivational Interviewing *is a creation of and defined by its original developers*. Motivational Interviewing was described initially by Miller [19, 23] and then by Miller and Rollnick [24, 25] and these founders of the approach may continually revise and update it as their own experiences and thoughts develop. Therefore principles, goals, techniques, strategies, and terms of Motivational Interviewing follow from the founders' decisions, which may be influenced by data or practice or even whim. If the founders are the sole arbiters in defining Motivational Interviewing, it is whatever they say it is, and elements may be added or deleted based on their preferences.

From the clinical research perspective, Motivational Interviewing may be viewed instead as *a set of attitudes, techniques, and strategies that can be described in a manual and can be evaluated with measures of treatment fidelity*. This clinical research perspective focuses on sharp boundaries, specified timeframes, clearly defined strategies and techniques to address specific target behaviors, and attempts to isolate the unique elements of Motivational Interviewing. The clinical research definition of Motivational Interviewing results in a binary decision in that either Motivational Interviewing is being done or Motivational Interviewing is not being done. From this perspective, that Motivational Interviewing is a specific definable intervention, a therapist could be seen as "doing Motivational Interviewing" in some sessions and not others, or possibly during some moments and not others.

Yet another perspective is the practitioner's angle. Practitioners might view Motivational Interviewing *as an overarching counseling style*, a general way of working with clients. The practitioner using this style weaves whatever strands are most useful in the moment, no matter where those elements might have originated (in Motivational Interviewing, in adaptations of Motivational Interviewing, or in similar or complementary therapeutic approaches, disciplines, or experiences). From this perspective, practitioners may see themselves as doing Motivational Interviewing even when a video sample of a discrete moment in therapy might show them to be providing a cognitive-behavioral therapy-derived intervention, albeit in a Motivational Interviewing-consistent style. In such practice, a decision rule might be "can one smoothly transition in and out of elements borrowed from elsewhere?" The therapist may be exploring ambivalence with a client and notice a bit of distorted thinking, slip unnoticed into working with the client on exploring the background of that thinking, or its fit with reality or rationality, then slip back out and back to exploring ambivalence again. To the practitioner, this whole session may be defined as Motivational Interviewing if Motivational Interviewing spirit and techniques are present, and if the client's responses indicate that the therapeutic alliance is steady.

A fourth perspective is that Motivational Interviewing is a set of ideas or concepts that originated with Miller and Rollnick, but are now independent from them. A conceptual perspective might define Motivational Interviewing as *a set of specific ideas that fit into a nomological net, a framework of logically coherent and connected constructs into which empirical and practice findings are placed and interrelated*. A conceptual perspective on defining Motivational Interviewing may be based less on either need for clear definition and fidelity to that definition

as in the clinical research perspective, or need for pragmatism and devotion to doing what works best in the moment as in the practice perspective.

In summary, Motivational Interviewing is an efficacious method to facilitate behavior change that has strong evidence for its positive impact on addictive behavior. It often achieves good outcomes with fewer sessions and less time than other substance abuse treatment methods. It has become a popular approach and is utilized around the world for the treatment of substance abuse as well as other behavior change challenges. While the clinical methods have been detailed thoroughly, assessing practice and exploring process-outcome relationships are areas getting more attention recently. Additionally, models of Motivational Interviewing are being proposed and tested using old and new data. As Motivational Interviewing expands into new areas of application beyond its individual substance abuse counseling roots, there is a need to develop innovative methods of delivery, and to provide effective training for therapists, agencies, and trainers. Lastly, the very definition of Motivational Interviewing may be changing. It could become a clinical method that retains a distinct identity and is used in specific situations. Alternatively, Motivational Interviewing may become incorporated into practice and eventually lose its individual identity or become one of several specific approaches that focus on client motivation as a central component in fostering behavior change.

Introduction

Cognitive behavioral therapy has proven to be an effective psychotherapeutic treatment for psychiatric disorders such as mood and anxiety spectrum disorders, as well as substance use disorders, including abuse and dependence. It is an individualized, collaborative approach to psychotherapy that emphasizes the importance of thoughts, feelings, and expectancies and also incorporates more traditional behavioral approaches that utilize counter-conditioning and contingency management in addressing the problem of addiction. Cognitive behavioral therapy is based, in part, on social learning theory. Thus, an underlying assumption of cognitive behavioral therapy is that learning processes play an important role in the development and continuation of substance abuse and dependence. These same learning processes can be used to help individuals reduce their drug and alcohol use through modification and substitution of existing patterns. Cognitive behavioral therapy also is based on stress and coping theory. These theories promote that life stressors are likely to trigger the use of avoidance or emotion-focused coping strategies such as substance use among individuals who have low self-efficacy and poor problem-solving coping skills in an attempt to avoid experiencing distress. As such, cognitive behavioral therapy focuses on challenging individuals' positive expectancies about substance use, enhancing their self-confidence and self-efficacy to resist substance misuse, and

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_36,

improving their overall and specific skills for coping with life stress.

When applied to the addicted population, cognitive behavioral therapy helps a client change his/her drug or alcohol use as well as risky attitudes and beliefs. Cognitive behavioral therapy combines two very effective kinds of psychotherapy—cognitive therapy and behavioral therapy. Cognitive behavioral therapy for substance use disorders focuses on helping clients in two major behavioral ways. The first is to help reduce the intensity and frequency of their urges to use, by undermining their underlying beliefs or cognitions about using. The second is to teach the clients specific techniques for controlling or managing their urges to use or drink. In other words, the basic goals are to reduce the pressure to use and increase control. When a client's addiction is determined to be related to a co-occurring disorder, the psychiatric disorder also needs to be addressed by the mental health care provider.

Cognitive therapy focuses on how certain thinking patterns or beliefs cause symptoms. Distorted or unproductive thoughts or cognitions can produce negative moods such as anxiety and depression, which can ultimately provoke more maladaptive thinking and/or behaviors that do not help facilitate positive change or affect. Cognitive therapy strategies focus on thought processes, recognizing that emotions and behaviors are best addressed by considering the faulty thought processes that precede such feelings and acts. Specifically, cognitive therapists collaborate with clients to define problems, explore beliefs, re-examine appraisals and thoughts about their use of substances, and modify these thoughts to promote more favorable and adaptive cognitions, which, in turn, impact positively both behaviors and mood. In addition, coping skills training expands this emphasis on thought processes by focusing clients on accepting stressors in their lives and constructively pursuing strategies to change their valence and tendency to pursue substances to escape and/or avoid situations [3]. While researchers/clinicians affirm the practicality of this approach as well, cognitive therapy cannot comprehensively address all aspects of substance abuse without addressing the destructive behavioral inclinations common to substance users.

Behavioral therapy focuses on weakening the connections between troublesome situations and habitual behavioral reactions to them. Strategies included in behavioral therapy include repeated behavioral practice of techniques such as distraction and relaxation, and exploring consequences and reinforcement. A major goal of the behavioral component is to weaken the learned association between triggers such as the environment, situation, people, or moods and the response of drug or alcohol use and replace it with a more appropriate response. In time, the healthy response will become more familiar and replace the old response of using. Thus, in many ways, the behavioral strategies employed are similar to those used for habit reversal or compulsive behaviors. These include teaching relaxation strategies such as deep breathing and progressive muscle relaxation, learning alternative responses such as drinking juice instead of alcohol, employing behavioral distraction, and avoiding triggers or risky situations. Two subtypes of this approach include contingency management (a positive-reinforcement treatment method in which clients are given rewards for constructive actions taken toward their recovery) and community reinforcement (a set of procedures that systematically reinforce treatment retention and substance reduction/abstinence). Clients may be rewarded for specific positive behaviors, such as producing drug-negative urine, returning to therapy, specific lifestyle changes, etc. [1]. These effective behavioral strategies frequently are incorporated into cognitive behavioral therapy for substance use disorders.

Cognitive behavioral therapy integrates both methods into a logical series of cognitive and behavioral strategies that can identify maladaptive thoughts and resultant actions (via decisional matrix and functional analysis), disrupt automatic patterns of functioning (through coping skills training and practice), reduce the impact of—and harmful response to—stress, and adopt more pro-social learning and interactions.

The goal of cognitive behavioral therapy can be either abstinence or moderate/controlled drinking or drug use (i.e., harm reduction), and is employed routinely for relapse prevention in abstinent individuals. Cognitive behavioral therapy helps the client identify his/her own unique high-risk situations for use. Then, the client may develop plans and skills that are alternatives to using in these situations. Cognitive behavioral therapy also increases the client's confidence about his/her ability to resist using. Because substance use disorders have high rates of return to using, cognitive behavioral therapy includes effective relapse-prevention components of treatment.

Overview of Cognitive Behavioral Therapy

Cognitive behavioral therapy combines two effective kinds of psychotherapy—cognitive therapy and behavior therapy—to help clients change their drinking or drug use behavior and related risky attitudes and beliefs. Cognitive therapy teaches individuals how certain thinking patterns contribute to their symptoms—by giving them a distorted picture of events and interpersonal interactions in their lives, thus directly contributing to feelings of anxiety, depression, or anger that may provoke them into ill-chosen actions. Behavior therapy helps individuals weaken the learned connections between troublesome situations and their habitual behavioral reactions to them.

Following the work of the more radical behaviorists (i.e., Skinner, Watson), Albert Ellis applied behavioral concepts to his work on human emotions. Ellis drew attention to the relationship between events (the "activating event"), personal beliefs, and resultant emotional responses. This model (a main component of rational emotive therapy) came to be known as ABC (A: activating event, B: beliefs, and C: emotional response), highlighting how a personal belief (B) about an activating event (A) could impact emotions (C). Ellis demonstrated that changing maladaptive beliefs (termed "irrational beliefs") regarding a client's perceptions of activating events to more rational and practical personal beliefs would lead to more desired emotional self-management. This model is used frequently in cognitive behavioral therapy and has been shown to be very effective in altering negative emotional states that predispose a person to seek unhealthy substances [12].

Similarly, Aaron Beck extended Ellis's work to address irrational beliefs in primarily depressed clients. Since negative mood states have a high concordance rate with substance abuse and dependence (13–30%), Beck's strategies can be very helpful in addressing the myriad of irrational beliefs held by individuals with substance abuse or dependence disorders [4]. Specifically, Beck identified several common irrational beliefs held by these individuals that serve to reinforce their desires to use substances. These thought patterns include thoughts of helplessness, ideas that drugs improve their functioning, all-or-none thinking, self-criticism, assuming need for perfection, and mind reading. Failure to question the rationality of these thoughts relegates substance-abusing clients to repeat continuously the ABC cycle with the addition of behaviorally acting on "C" in a way that further discourages the clients and reinforces the hopelessness that they feel through substance use. Through cognitive behavioral therapy, however, these irrational thoughts are explored extensively while supplanting drug behavior with healthy coping strategies. The goal of cognitive behavioral therapy can be to attain either no drinking/drug use (abstinence) or moderate/controlled drinking/use (i.e., harm reduction).

When utilizing cognitive behavioral therapy, the client identifies his/her own unique high-risk situations for heavy drinking or drug use with the help of the therapist. Then, using cognitive behavioral therapy techniques, the therapist helps the client to develop plans and skills that are alternatives to using alcohol or drugs in these situations. Thus, using cognitive behavioral therapy also increases the client's confidence about

his/her ability to resist using alcohol or drugs. As people who are addicted typically demonstrate high rates of return to using, cognitive behavioral therapy also includes relapse-prevention training and strategies to employ when lapses occur.

Therapists who provide cognitive behavioral therapy typically possess at least a master's-level degree plus specific training in this area, and more typically possess a Ph.D. in clinical or counseling psychology or an M.D. and advanced training in psychotherapy. Cognitive behavioral therapy has been used within both inpatient and outpatient settings. Longabaugh and Morgenstern [23] recommended at least 12 sessions for substance abuse clients. In this way, cognitive behavioral therapy not only is clinically effective for substance abuse treatment, but it is also efficient, time-limited, and cost-effective. Prior to initiating a cognitive behavioral therapy course of treatment, however, it is helpful for the therapist to assess the client across a number of functional areas in order to customize therapy to the client's specific needs. Specifically, a thorough evaluation of readiness to change, mood, anxiety, and other emotional difficulties can be very helpful in defining the content of therapy. Information regarding the most recent negative consequences precipitated by substance abuse and the client's current stage of change can be particularly helpful in determining how the therapist should interact with the client initially.

Prochaska et al.'s transtheoretical model is a useful conceptualization of a client's stage of change that can be used to motivate a client and better inform subsequent psychotherapy [34]. The transtheoretical model of behavior change, or stages of change model, describes a series of six behavioral stages that an individual experiences in modifying a negative behavior in his/her life. These stages include precontemplation, contemplation, preparation, action, and maintenance. Precontemplation is the first stage in this model and refers to individuals who do not consider their current behavior to be problematic and have not thought about stopping/changing their behavior within the past 6 months. As individuals begin to recognize the negative consequences of their behaviors, they move into the contemplation stage, where they begin to think about changing their behavior over the next 1–6 months. In the preparation stage, the individual begins to implement changes in drinking or drug use behaviors. In this stage, the individual is attempting changes and practicing new behaviors. In the action stage, the individual has successfully changed his/her behavior and has been able to sustain these changes for up to 6 months. In the maintenance stage, the individual has successfully changed his/her behavior and maintained these behavioral changes for 6 months or longer. By identifying a client's current stage of change, the cognitive behavioral therapist can better tailor the initial dialog of therapy to address related barriers to the client's desire to change and level of progress with respect to making changes. Clients at less advanced stages of change (precontemplation, contemplation, and preparation) have been known to express more resistance to change or deny the impact of substance abuse [34].

Using the collaborative encouragement of motivational interviewing in conjunction with cognitive behavioral therapy, clients can begin to resolve feelings of ambivalence that interfere with their desire to change. Motivational enhancement can begin to reveal a client's maladaptive thought patterns that can be explored in more detail as the cognitive behavioral therapy sessions progress. Strategies such as using open-ended questions, affirming client thoughts, reflecting client statements, and summarizing client messages can be helpful in resolving clients' confusion and resistance to change.

Clients in more advanced stages of change (action and maintenance) can begin cognitive behavioral therapy immediately. In such cases, exercises such as the decisional matrix, which involves having the client list the pros and cons of using and not using substances, can be employed to clarify further any remaining ambivalence and reinforce motivation to change.

Cognitive Model of Addiction

Multiple interrelated cognitive models of addiction have been developed and evaluated since Bandura's classic presentations of social learning theory in the late 1960s and 1970s [2]. For example, Marlatt [25] described four cognitive processes related to addictions that reflect the cognitive models: self-efficacy, outcome expectancies, attributions of causality, and decision-making processes. According to Beck et al. [4], people try drugs initially to get pleasure, to experience the exhilaration of being high, and to share the excitement of using with others. In addition, often additional positive expectations are associated with use of the drug. For example, with cocaine, individuals expect greater energy, fluency, and creativity. They might desire reduced appetite that can lead to weight loss and greater productivity. For alcohol abusers, greater sociability, reduced anxiety, and relief from boredom are often prime motivations for early use. These positive consequences often mask the negative consequences of drug use. While these desired states may be based partly on real drug effects, substance users begin to distort the valence and importance of these effects over time. Cognitive distortions, in combination with life stressors (which ultimately increase as the person begins to neglect or avoid problems or responsibilities), lead to increased drug and alcohol use in pursuit of greater relief and/or pleasure, or a desire just to feel "normal." Such problem-distracting behaviors have been described as self-medicating, whereby the person seeks to reduce the distress and problems associated with using through avoidance behavior and by increasing the use. This increased drug and alcohol use leads to greater problems in the person's life and greater problem avoidance through greater and/or more frequent substance use.

In addition to the distorted thoughts that substances users hold regarding the positive effects of using, users have been found to have a significantly greater tendency to ruminate on irrational or automatic cognitive thoughts. These thoughts include beliefs such as: "I can't settle down without a few drinks," "I can't stand this feeling," and "people don't like me unless I am intoxicated." Such thoughts often relate to feelings of depression and anxiety, and the substance users seek the substance to reduce the distress of such thoughts. Drugs initially act as a distraction against these automatic and distressing thoughts and allow the person to forget the unpleasant ruminations. In this way, drugs appear to serve an adaptive function by allowing the person to "turn off" the ruminations temporarily. Unfortunately, this distraction is maladaptive over the long term, in that it prevents the individual from facing and dealing with problems in a healthy manner and creates more functional life problems. As the person becomes physiologically and psychologically dependent (addicted) upon the substance, the ability to change cognitive distortions without assistance becomes less and less likely. The goal of the cognitive therapist, then, becomes helping the client to recognize these distortions and to develop self-efficacy to actively address such thoughts in a more adaptive manner.

In Beck et al.'s [4] words, "self-efficacy refers to one's judgment about one's ability to deal competently with challenging or high-risk situations." Marlatt [25] explained that low levels of self-efficacy are associated with relapse, and high levels are associated with abstinence, with levels of self-efficacy increasing as a function of success. Outcome expectancies refer to an individual's anticipation about the effects of an addictive substance or activity. To the extent that a person expects a greater positive than negative outcome from drinking or using drugs, the person is likely to continue using. Attributions of causality refer to an individual's belief that drug use is attributable to internal or external factors. External attributions typically result in continued substance use since the individual perceives his/her use to be predestined and out of his/her control [25]. Finally, Marlatt [25] described the process of alcohol abuse, dependence, and relapse as a cognitive decision-making process, and proposed that substance use is a result of multiple decisions,

which may or may not lead to further substance use. He explained that although some decisions initially appear to be irrelevant to substance use, they nonetheless may result ultimately in an increased likelihood of relapse because of their incremental push toward higher-risk situations.

Persons with substance abuse problems remain very vulnerable to high-risk stimuli for a variety of reasons. Specifically, as people accommodate their drinking and drug habits, they begin to establish behavioral patterns in a variety of environmental contexts, which reinforce their intention to use as well as their experiential expectations. These environmental contexts become associated with the positive experiences of the drug over time and evolve into "triggers" that stimulate the user's desire for the drug. These triggers include both internal and external cues. Internal cues may include positive or negative emotions, pain, and/or frustration. External cues can include time of day (evening, night, etc.), place (at a friend's house, at a bar, etc.), or even other persons (friend, family, etc.). External cues also can include situations such as getting paid or working in an environment where alcohol is served (waitresses, bartenders, etc.). These triggers often activate clients' erroneous or irrational beliefs and lead them to make risky decisions that bring them closer to using. Such triggers must be identified and explored for underlying beliefs that shape physiological sensations linked to craving.

Beck found that underlying addictive beliefs result from dysfunctional core schemas in three areas: personal survival, autonomy, and freedom [4]. These addictive and dysfunctional thought patterns are experienced as taking over the individual's life, goals, and values, thereby leaving one's job and families as secondary priorities. The short-term gain of a "high" or reduction of internal tension is followed by long-term negative consequences and problems [4]. To break this pattern, clients need to learn to cope directly with problems associated with substance dependence, as well as to confront problems of everyday life in a more active and problem-solving manner.

The obstacle, unfortunately, in eliminating the substance use is the dysfunctional beliefs that the individual holds about the substance [4]. These beliefs range from the fear of the side effects of withdrawal to the belief that he/she cannot function without the substance. In addition, permission beliefs are common in addicted individuals. These are conceptualized as thoughts that allow or give permission to the individual to go ahead and use. These thoughts include such self-statements as "Just one drink won't hurt anything. Go ahead and have one." Changing these schemas, maladaptive beliefs, thought patterns, and associations with common triggers is at the core of the cognitive approach. Thoughts must be altered to achieve long-term behavioral change.

From this perspective, the primary tasks of treatment are to identify and challenge the maladaptive cognitions surrounding alcohol and drug use and replace them with more realistic and adaptive thoughts and beliefs in order to facilitate more adaptive behaviors of reduced use or abstinence. When more adaptive cognitive thinking has been restored, behavioral changes consistent with constructive thinking will follow. Figure 1 portrays the cognitive behavioral conceptualization of addiction.

Behavioral Model of Addiction

From the perspective of cognitive behavior theory, alcohol and drug dependence is viewed as learned behavior that is modeled, acquired, and reinforced through experience and learning. If alcohol or drugs provide or are perceived to provide certain desired results (e.g., good feelings, reduced tension, etc.) on repeated occasions, the person may learn that the substance leads to the desired outcome. In other words, the substances and positive feelings become strongly associated with each other. People typically begin using drugs or alcohol as a positive reinforcer in their lives—to celebrate a special occasion, as a reward, to reduce inhibitions, and/or to promote relaxation. In other words, initial use of drugs

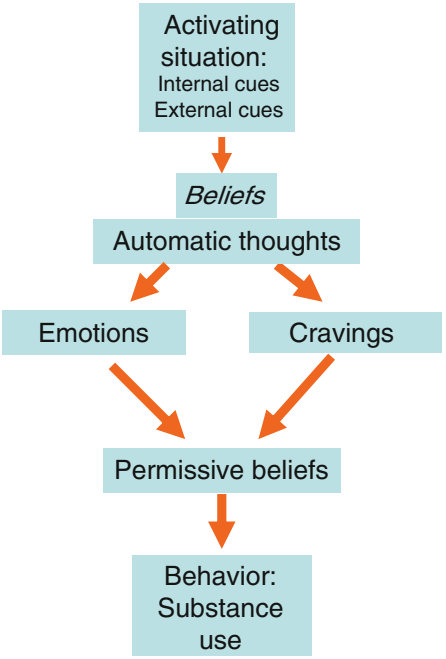

Fig. 1 Cognitive behavioral conceptualization of addiction

or alcohol is associated with its positive consequences, becoming the preferred way of achieving those results, particularly in the absence of other ways of meeting those desired ends. For some individuals, chronic use of drugs or alcohol can become a problem in cases where the substance is no longer used to feel good, but to avoid negative thoughts/feelings or to "feel normal" by reducing withdrawal symptoms. When this happens, substance use becomes a negative reinforcer instead of a positive reinforcer. From this perspective, the primary tasks of treatment are to: (1) identify the specific needs that alcohol and drugs are being used to meet, and (2) develop skills that provide alternative ways of meeting those needs. In so doing, this breaks the learned associations between using drugs and alcohol and both the positive and negative reinforcers.

Case Conceptualization

As is the case in the treatment of other disorders, cognitive behavioral therapy for substance use disorders involves a unique case conceptualization for each individual. This forms the basis for a strong collaborative relationship between client and therapist and effectively guides the content of the sessions. Through such collaboration, the client and therapist proceed to utilize specific, goal-oriented techniques tailored to the client's individualized needs and goals [15] while simultaneously enhancing the therapeutic alliance and collaborative nature of the work. Individuals also are taught to address and resolve naturally arising ambivalence about treatment to develop their motivation and progress toward their treatment goals. During therapy sessions, as well as through the use of self-help homework assignments, clients pursue solution-focused strategies that address the realities of recovery from addictive disorders. Psychotherapeutic innovations in relapse prevention often are implemented over the course of cognitive behavioral therapy for alcohol and other drug use disorders through identifying and reducing or learning to cope with high-risk use situations.

Case Example

> Jared is a 47-year-old man with a history of using alcohol since adolescence. He initially began using alcohol to reduce anxiety and facilitate dating experiences after he divorced his wife in his thirties. He began using alcohol as a way to enhance his ability to generate conversations in social situations. He works as an accountant and believes that others are very critical of him and see him as "stuffy" and "boring". He uses the alcohol mainly in the evenings when he goes out with business associates after work, although on weekends he has noticed that his drinking often starts early and continues all day long when he is visiting with friends or family.

When Jared first divorced, he was quite anxious about becoming more social and going out with peers again. He started consuming a few alcoholic beverages as a way to reduce his anxiety and lower his inhibitions about making interesting conversation. In this way, Jared's behavior was positively reinforced and he would later remember the situation as enjoyable and without anxiety. Over time, however, his

tolerance for alcohol increased and he required more drinks to achieve his perceived degree of calmness required to make good conversation. He started feeling more anxious, and even depressed, if he could not consume alcohol, particularly when meeting with others.

Figure 2 shows a cognitive behavioral case conceptualization of Jared's alcohol use.

Fig. 2 Cognitive behavioral conceptualization of Jared's case presentation

By understanding the relationships between Jared's dysfunctional thoughts and behavioral patterns, insight regarding the nature of his alcohol problems can be gained and an individualized treatment program can be developed to address his unique needs. Since cognitive behavioral therapy has evidence-based techniques as its foundation, techniques such as recognizing and challenging maladaptive automatic thoughts, cue exposure, drug refusal training, and methods for coping with craving are used to help an individual break his/her pattern of addiction. Furthermore, as addictive disorders often involve deficits in areas such as social skills, management of emotions, and tolerance of difficult emotions, individuals often pursue progress in these areas within cognitive behavioral therapy. For example:

> Jared was encouraged to keep a diary of his thoughts and behaviors to help him understand and recognize the connection between his maladaptive thoughts and subsequent emotions and behaviors. With this information, Jared and his therapist were able to challenge the veracity of his anxiety-provoking thoughts and substitute his critical interpretations with more rational views of his reality. In addition, Jared was taught relaxation techniques (progressive muscle relaxation and imagery) to help manage his anxiety, as well as learning to tolerate some anxiety in his interactions with others. Finally, Jared learned social skills regarding interactions with others, particularly in regard to his unrealistic expectation that he should always be the entertainer in a conversation. Through these interventions, Jared began to expose himself to social situations without reaching for a drink.

The rationale of cognitive behavioral therapy holds that substance abuse is learned and, therefore, it can be unlearned over time through the use of cognitive behavioral techniques. Understandably, a person with a substance use disorder faces many challenges and, potentially, many serious consequences. However, through cognitive behavioral therapy, such individuals can take part in an effective, flexible, and evidence-based therapy specifically tailored to the challenges involved in overcoming substance abuse or dependence and their individual needs. In doing so, they can avail themselves of a solution-focused approach to treatment embedded within a respectful and collaborative therapeutic relationship to facilitate recovery from addiction and the overall lifestyle change that they need.

Application of Cognitive Behavioral Therapy for Addiction

Understanding the theoretical underpinnings of cognitive and behavioral conceptualizations of addiction helps the therapist identify logical cognitive and behavioral targets for therapeutic intervention. This allows the therapist to individualize treatment for each client while remaining consistent with the general theoretical approach.

Therapy typically begins with an introduction to cognitive behavioral therapy and an opportunity for the client to disclose information about himself/herself. This is an important time for

self-disclosure and building of the therapeutic alliance, as well as the beginning of the process of case conceptualization of the client and his/her presenting issues. During these early meetings, initial treatment goals are discussed. These goals are set collaboratively, with the client having the final say in the establishment of his/her goals. Abstinence is encouraged but may not be an absolute requirement. Treatment goals may involve substance use behaviors as well as other aspects of clients' lives, such as improved relationships, mood states, and level of functioning. Therapists work with clients to ensure that these goals are attainable (the client can produce them), realistic (the environment can produce them), and appropriate (they are related to the designated work to be done in therapy). Goals are revisited and revised as needed throughout treatment, based primarily upon the client's progress, which is assessed regularly.

The therapeutic process itself includes meeting regularly (usually for an hour weekly) for at least 3–6 months or longer if necessitated by continuation of symptoms or development of additional problems. Within each session, material is presented and reviewed regarding specific areas of concentration that relate to substance use disorders as well as more general issues related to emotional dysfunction. Session material may be presented orally and in writing (e.g., using written materials, flip charts, or a wipe-off board), and clients are encouraged to take notes, as visual learning significantly augments oral presentation of material and helps clients retain more information and stay involved in the session. There are issues that must be covered for the majority of clients receiving cognitive behavioral therapy, including: coping with cravings, thinking about using, problem solving, refusal skills, dealing with lapses, and relapse prevention. In addition, there often are additional issues that need to be addressed, such as assertiveness training, anger management, and recognizing and managing negative moods. These issues are addressed on an individual basis, but in a standardized cognitive behavioral conceptualization. Thus, evidence-based treatment is tailored to the individual and provided in a consistent manner.

Weekly assignments or "homework" are assigned at each session and reviewed at the following session. The homework is a major part of cognitive behavioral therapy and ensures that clients are actively incorporating skills and techniques presented and reviewed in sessions in real life. Clients are encouraged to complete the homework, preferably in writing, and always through real-world practice. Research demonstrates that those who complete homework assignments more regularly and consistently attain a better outcome from therapy, particularly for those higher in readiness to change [7, 11]. Therefore, homework completion is strongly encouraged. Compliance with homework can be increased in many ways: (1) through explaining the reasoning for the assignment and why and how it is theorized to help the client; (2) reviewing in session how to complete the homework; (3) assessing the client's motivation and ability to complete the homework by asking the client how likely he/she is to complete it and identifying any potential obstacles for completion, and then (4) clarifying ambivalence about homework and planning for obstacles, as well as (5) setting realistic expectations for the length of time and level of difficulty of the homework.

If a client is regularly non-compliant with homework, efforts are made to explore and change this therapy-interfering behavior. Specific techniques are employed to improve homework compliance, including making homework assignments specific and clear and explaining the rationale of the homework as well as the potential benefits of completing the assignment. As stated, setting realistic expectations for the homework is also important. Most assignments take less than 15 min to complete, and this needs to be made explicit to the client or else the client may overestimate the time needed to complete the assignment and may not even attempt it. Behavioral experiments need to be clearly defined and a rationale provided for their use, along with expected benefits. In addition, the client's level of motivation and commitment

to completing the assignments can be assessed prior to the end of the session, so that realistic expectations are made regarding the homework. For instance, if a client understands the rationale of the homework and knows how to complete it and how long it will take, but still states that he/she does not want to do it and does not think that he/she is likely to complete it, then both the therapist and client understand that the homework will most likely not be completed unless the client's motivation changes. Some authors argue that homework non-compliance, to some degree, is an inevitable feature of cognitive behavioral therapy and, when effectively addressed, can yield some of the greatest opportunities for therapeutic change [18]. To that end, it is an expected and important component of cognitive behavioral therapy, and both clients and clinicians are wise to anticipate and prepare effectively for non-compliance issues.

General Components of Manualized Cognitive Behavioral Therapy for Addiction

Cognitive behavioral therapy is often provided in a standard, manualized format for conceptualizing drinking and drug abuse problems and designing interventions that focus on developing healthier coping skills. It is delivered in a collaborative motivational interviewing style, which facilitates the individual's progress through stages of change and therapeutic recovery. Manualized cognitive behavioral therapy is based on the early works of Beck et al. [4], Ellis and Velten [10], and the later works of Marlatt et al. [25, 26]. These works eventually were condensed into the National Institute on Alcohol Abuse and Alcoholism's treatment protocol used in multi-site national addiction studies, including MATCH and COMBINE [16]. While there have been many variations and therapy subtypes that fall under the collective umbrella of cognitive behavioral therapy, this protocol specifically outlines standardized session themes and activities that have been shown to bring about positive outcomes (reductions in drinking or drug use) and ensures systematic, effective, reliable, and replicable administration of treatment to individuals. The structure of cognitive behavioral therapy discussion topics and session activities for substance abuse has been useful in promoting effective management of session time, focus on client thoughts, and development of more effective coping strategies [44]. It should be noted, however, that while this manualized approach has proven helpful and represents one of the most common cognitive behavioral frameworks for treating substance abuse and dependence, therapists have considerable flexibility in matching unique client strengths and weaknesses to specific cognitive behavioral interventions within the weekly theme (such as role plays, review of take-home assignments, construction of agenda, etc.). As such, the session is approached in a collaborative manner that tolerates modifications to planned activities as necessary. Yet, even with these potential changes and exploration of therapy-related themes, an overall commitment to therapeutic setting and following a set agenda is recommended to provide useful structure to the client problem-solving and coping resolution process [44].

The following recommendations are based on results from the University of Virginia Center for Addiction Research and Education clinic, which is part of the Department of Psychiatry and Neurobehavioral Sciences. Like the National Institute on Alcohol Abuse and Alcoholism's cognitive behavioral therapy manual, our clinic also administers cognitive behavioral therapy over 12 sessions in either group or individual format. There are seven core sessions, four elective sessions, and a termination session. Specific material is covered in each session as tolerated and has been designed and studied for optimum effectiveness.

Contraindications

There are some contraindications for use of cognitive behavioral therapy in populations

with substance use disorders. First of all, this approach requires a minimum level of cognitive functioning. Specifically, abstract reasoning is deemed necessary for clients to understand and process session material and apply this knowledge to changing their behavior patterns and coping skills. Clients with serious psychopathology (such as manic episodes, psychosis, or acute intoxication) or low IQ/cognitive impairment [28] are likely to have great difficulty understanding concepts such as cues or automatic thoughts and/or systematically adopting new coping skills. Furthermore, clients with a diffuse set of maladaptive thoughts and behaviors may require a greater number of sessions to achieve abstinence in comparison with those with specific, more circumscribed maladaptive symptoms. Finally, cognitive behavioral therapy, although person-centered, is also directive in nature, with the therapist playing a major role in directing the focus and content of each session. As such, some clients may respond with resistance to this approach or demonstrate slow progress in therapy. Thus, it is important to be aware of the stage of change for your client and consider integrating a motivational interviewing style into your work if it is clear that the client is unwilling to admit that they have an addiction problem or if your client loses motivation at any time during treatment. If clients report that they do not wish to change their behavior, cognitive behavioral strategies, such as listing the pros and cons of using and quitting in the form of a decisional matrix (see Fig. 3), clarifying values, examining consequences of use, and challenging expectancy beliefs about use can successfully be utilized to clarify ambivalence and help refocus the therapeutic work on change.

BOX 1: Good things about drinking:	BOX 4: Good things about changing my drinking:
BOX 2: Bad things about drinking:	BOX 3: Bad things about changing my drinking:

Fig. 3 Decisional matrix or advantages-disadvantages analysis

Format/Length/Setting

Clients are seen either one-on-one or in a small group setting (2–5 individuals per group) in a private, confidential clinic for 12 sessions. Each individual session lasts approximately 60 min, and group sessions last approximately 90 min, although some sessions can be extended or reduced based on client needs. During the first session, the therapist devotes the time to develop a strong therapeutic alliance with the client, approaching the client in a friendly and neutral (i.e., not extremely dominant, not extremely submissive) interpersonal manner. In our clinic, clients are given a questionnaire every three sessions that assesses their interpersonal impression of the therapist and their working relationship. Research has shown that therapists who are able to maintain friendly and neutral interactions best facilitate client outcomes [16]. During each session, the therapist checks in with the client and reviews his/her progress over the preceding week. Then, the therapist reviews the take-home assignment from the previous week, highlights achievements, and determines the cause of skill failures. Next, the therapist and the client create an agenda for the session duration that includes exploration of the weekly theme (see list of themes below). The remainder of the session explores new skill acquisition, and, together, the therapist and the client determine new practice activities and goals for the subsequent week.

Expectations of Therapist for Client

It is important for the therapist to discuss treatment expectations on the first day of therapy.

Clients are expected to attend therapy regularly, on time, and sober. They are expected to report about their addiction honestly and to complete practice assignments before returning to therapy.

Functional Analysis

At the beginning, as well as throughout addiction treatment, clients and therapists should use monitoring records and functional analysis tools as a way to conceptualize clients' use and problems. In Table 1, clients are asked to notice and record the situations in which they crave alcohol or drugs and record the severity of the craving and their subsequent behavior. By doing so, people increasingly become aware of the specific triggers in their environment and the variations in their cravings, as well as when they give in to their cravings. In Table 2, a functional analysis table, clients are asked to track the triggers (What set me up to use?), thoughts and feelings (What was I thinking and feeling?), behavior (What did I do?), and positive (What positive thing happened?) and negative (What negative thing happened?) consequences of their substance use. Clients should be instructed to write down every time they think about drinking or using a drug. It is important that clients record the time and day whenever they record an entry in this log to help with understanding behavioral patterns. In the "Triggers" column, clients should record who they are with, what they are doing, details about the situation, etc., to give a full picture of what was happening at the time a craving or urge to use or drink began. In the next column, they are to record specific thoughts and feelings that provoked the urge to use. In the middle "Behavior" column, clients should record how they were responding to the situations. Did they call a friend? Watch TV? Or pop open a can of beer? They should record all of this information here. In the last two columns, they should record the consequences, both positive and negative, of their behavior. Clients should bring this record with them to their next appointment for further review. These exercises should continue throughout treatment, particularly as clients become more skilled at choosing more adaptive coping strategies.

Table 1 Self-monitoring of cravings

Event/situation	Intensity of cravings (0–100)	Behavior

Skills Training

Clients also are taught pro-social adaptive coping skills to substitute maladaptive ways of coping. Specifically, clients are taught to set realistic self-goals, self-monitor thoughts and behaviors, challenge irrational thoughts, delay reacting to cravings, pursue distractions, confront problems directly, problem-solve actively, talk to others, avoid triggers, and reduce stress. These skills are assessed at baseline and tracked throughout treatment. Clients are taught to practice strategies between therapy sessions and to treat drinking opportunities as "experiments" for learning to implement new skills in the face of triggers to use.

Manualized Sessions—Sequence of Therapy Topics

Session 1: Introduction—Set goals, review therapy expectations, and teach self-monitoring of triggers, thoughts, feelings, behaviors, and positive and negative consequences; also determine clients' drinking/using patterns. Clients are given a manual to reinforce weekly topics.

Session 2: Coping with Cravings—Explore a variety of active coping strategies to reduce cravings, such as: distraction, delaying use, pursuing social support, avoiding triggers, deep breathing/progressive muscle relaxation, imagery/urge surfing, and recalling negative consequences/planning ahead.

Session 3: Thinking about Using—Review thoughts common to persons with addiction

Table 2 Functional analysis: self-monitoring record

Event/ Situation (Day & time) –What was I doing? –Who was I with? –Where was I?	*TRIGGERS (antecedents) What set me up to drink/use?*			*STOP for a second!!!!*		*(Consequences of behavior)*	
	Thoughts/images	*Feelings*	*Intensity of cravings, desire to drink/use (0–100)*	*Alternative thoughts* (try to challenge your automatic thoughts about drinking)	*Behavior*	*Positive consequences (short-term)*	*Negative consequences (long-term)*
3/3/08, 9 P.M. At home with girlfriend, arguing	I can't stand this; I need a drink	Frustrated, upset, angry	95	I might want a drink, but I do not really need it; drinking is not really going to make any difference	Got away, drank 4 beers	Calmed down	Girlfriend got even more mad

problems, such as: nostalgia, disillusionment, frustration, all-or-none thinking, self-doubt, feeling uncomfortable, helplessness, wanting to escape, crisis response, and testing control. Also consider how clients' expectations regarding how substance impacts thoughts/feelings affect behavior.

Session 4: Problem Solving—Present a model for solving problems in an active way that considers generating a list of alternatives and evaluating pros and cons and the likelihood of positive outcomes, given the potential to resolve.

Session 5: Drink Refusal Skills—Consider ways to avoid giving in to requests by peers to use. Teach client to avoid these high-risk situations to the extent possible and, when unexpectedly exposed to triggers, to rely upon a predetermined plan to avoid use.

Session 6: Dealing with a Lapse—Describe how clients can lapse from time to time and how such lapses need not derail progress. Give strategies to help client return to recovery and refocus on treatment goals.

Session 7: Seemingly Irrelevant Decisions—Examine how small, seemingly irrelevant decisions that do not appear to affect drinking/use decisions can put a person at risk for relapse. Examine ways to prevent relapse through the deliberate choice of low-risk behavioral choices.

Termination/Maintenance/Relapse Prevention—Review client progress over the course of therapy, re-examine client goals, review briefly all material, determine client skill achievements, recommend further practice with some skills, and make recommendations for follow-up.

Example of Skill Acquisition

Jared completed a coping strategy questionnaire at baseline, indicating that he was relatively passive in dealing with his stress and anxiety and that he generally gave in to cravings when they developed. To collect more information about Jared's coping skills and to help Jared see a connection between his coping strategies and behaviors, he was assigned to complete a functional analysis diary. Jared was initially reluctant to keep a diary regarding his daily drinking habits because he felt that he did not have any triggers and that he "just liked the taste" and "enjoyed a few drinks" with others. However, after reviewing his first week with his therapist and attempting to complete the diary retrospectively, Jared became aware that much of his drinking related to feelings of inadequacy and loneliness. Jared found that these feelings were reinforced each night with different people in that he was able to stop his feelings of anxiety by drinking "a few" beers. Unfortunately, the next day Jared would always feel tired and disappointed by how many beers he had in fact drunk. He also worried about what he may have said in his "entertaining" conversations, as he often could not even remember much of the night beyond his second drink. In this way, the therapist was able to challenge his expectation that drinking made him entertaining and also help him to realize that drinking did not cure his anxiety over the long term; it only served to blunt temporarily all feelings. It also was determined by reviewing the diary that Jared was going to nightly events that all involved opportunities to consume alcohol. With his therapist, he was able to recall healthier activities such as playing tennis or volunteering with a local charity. These activities helped to remove some of Jared's temptation to drink, as well as distracting him for several hours in the evening, a time when his cravings were the most intense. Through the activities, Jared learned how to cultivate a few new friendships without alcohol, which helped provide support for Jared when he was feeling stressed. Over time, Jared was able to look forward to not going to the bars with his old friends; he then felt encouraged that he could tolerate some anxiety around others and developed pride that he did not need alcohol to endure his stress. Jared continued to keep a journal of his thoughts and behaviors throughout therapy and became more aware of the great importance of monitoring his triggers, particularly when his problem seemed too overwhelming to overcome. Jared completed a post-therapy coping skills questionnaire and was able to identify several strategies that he found to be helpful and effective for dealing with his cravings.

Research Support for Cognitive Behavioral Therapy in Addiction Literature

Cognitive behavioral therapy has been demonstrated to facilitate effectively improvement for

a number of mainstream substance abuse disorders. Reductions in drinking and drug use were seen mostly when clients were motivated to change and possessed at least a low average intelligence level needed to process and relate thought patterns with behavioral reactions [27]. Treatment gains with respect to stimulant use have been well established, with evidence that gains persist and grow over periods of 6–12 months [5, 37].

Review of Cognitive Behavioral Therapy for Stimulant Drugs

Cocaine

Approximately 1.5 million adults use cocaine in the United States, often leading to problems in daily functioning and, ultimately, cocaine dependence. Cognitive behavioral therapy has been demonstrated to be useful for managing and resolving the problems associated with drug abuse and dependence. Marlatt and Gordon [26] introduced cognitive behavioral interventions as an effective approach that can alleviate psychological distress associated with repetitive physical and psychological habits arising from specific, reinforcing cognitive and behavioral patterns. Additional work by Carroll et al. [5] extended Marlatt and Gordon's work to include a specific, manualized protocol (see the National Institute on Drug Abuse–endorsed format for cognitive behavioral therapy sessions above) for treating cocaine disorders. Subsequent researchers studying the effectiveness of cognitive behavioral therapy protocols typically have adopted this manual.

A group of clients receiving cognitive behavioral therapy for cocaine dependence was compared with a similar group receiving contingency management treatment (in which the client gets a "reward" contingent on reduced drug use) [37]. Individuals in this study received three sessions of 90-min group cognitive behavioral therapy weekly, or three 2- to 5-min contingency management sessions (including receipt of voucher, if warranted), for a total of 16 weeks. Individuals demonstrated efficacious results 1 year after treatment was terminated, although these differences did not emerge until after treatment had ended [5, 37]. Although contingency management clients reported less use during the study, those who had received cognitive behavioral therapy did significantly better than contingency management clients at distant follow-up (6 months and 1 year later) [37]. In another comparison study of cognitive behavioral therapy versus interpersonal therapy and/or disulfiram administration, cognitive behavioral therapy was found to be at least as effective as these other therapies [6, 7].

Trujols et al. [43] undertook the painstaking task of evaluating specific cognitive behavioral therapy styles and techniques to determine the best practices within this model. These cognitive and/or behavioral therapy interventions included contingency management with vouchers, cue exposure treatment, relapse prevention therapy, and motivational interviewing. This review highlighted several strengths and weaknesses within these interventions. Contingency management interventions were found to present economic limitations, with questionable results regarding the maintenance of drug reduction outcomes. In contrast, cue exposure treatment (exposing individuals to cognitive cues that promoted drug use) resulted in definite treatment gains, including greater client retention and increased negative urine drug screens [7], although Carroll et al. [7] noted that cravings initiated by cues outside the scope of clinical practice tended to perpetuate drug use. Researchers examined the role of at-home practice of cue exposure over 12 weeks of cognitive behavioral therapy and found that these reinforcing assignments resulted in higher program retention rates and thus kept clients committed to treatment [7, 11].

Schneider and Khantzian [39] further evaluated specific beneficial cognitive behavioral therapy mechanisms in an attempt to identify cocaine-dependent populations that could best benefit from cognitive behavioral therapy. They found that individuals' level of readiness for change differentiated treatment outcomes. They cautioned therapists to elicit and consider a

client's stage of change prior to initiating any cognitive behavioral therapy technique, as some techniques can be contraindicated depending on where the client is in the cognitive process of making a change in his/her drug-use behavior [24]. Trujols et al. [43] concluded by noting that careful tailoring of cognitive behavioral therapy to the cocaine-dependent individual's needs in conjunction with other empirically derived biological approaches (i.e., pharmacotherapy) may ultimately equip these individuals with the best tools to overcome their addictive behaviors. The ability to choose appropriate homework tasks, therefore, may represent an important mechanism by which cocaine dependence might be attenuated. Additionally, affective functioning (i.e., history of depression or anxiety) and deficits in abstract reasoning have been cited as important mediators in promoting superior cognitive behavioral therapy outcomes [28].

Knapp et al. [19] evaluated specific components of various substance abuse therapies to identify best-practice strategies in counseling substance-abusing or substance-dependent individuals. They identified five components as integral to the cognitive behavioral therapy process: (1) client-therapist collaboration, (2) case conceptualization, (3) structure, (4) socialization to the cognitive model, and (5) the use of cognitive and behavioral techniques [19]. They also described a number of supplementary methods involved in cognitive behavioral approaches including "Socratic questioning", analysis of advantages and disadvantages of use, monitoring of drug-related beliefs, activity monitoring and scheduling, behavioral experiments, and role playing. When 26 comparison studies (i.e., cognitive behavioral therapy versus another psychosocial modality) were examined, mixed outcomes were reported. Although cognitive behavioral therapy emerged as a better therapy in approximately one-third of these studies, the loose conceptualizations and definitions used to characterize the cognitive behavioral therapy studies in this review likely obscured true differentiation of cognitive behavioral therapy versus other therapy effects. While additional research is warranted to understand better the precise mechanisms of action for effective cognitive behavioral therapy, available research to date confirms its potential value as an effective treatment approach for substance disorders.

Methamphetamines

The National Survey on Drug Use and Health reports that an estimated 10.4 million people are afflicted with problems associated with methamphetamine abuse or dependence. Despite multiple efforts to reduce access and prevent experimentation, methamphetamine abuse and dependence remain increasingly difficult to treat once an individual is introduced to this drug. While several psychosocial approaches have been explored and evaluated, cognitive behavioral therapy has emerged as a superior option in reducing or arresting drug consumption [36].

Specifically, Rawson et al. [36] looked at several components of a "Matrix model" approach that was developed to impact the use of methamphetamines in dependent individuals. These components were derived from the cognitive behavioral therapy literature and included detailed information about the effects of stimulants, family education, 12-step program participation, and positive reinforcement for behavioral change and treatment compliance. Clients received 16 weeks (36 sessions) of cognitive behavioral therapy in a group format along with family education, social support, and individual counseling. While it is difficult to tease out the effect that additional therapies may have had on clients, Rawson et al. [36] concluded that cognitive behavioral therapy techniques produced greater treatment adherence and greater abstinence than did various community treatment protocols.

In a randomized controlled trial of cognitive behavioral therapy for regular amphetamine users, Baker et al. [1] reported on the feasibility of a brief (four-session) dose of cognitive behavioral therapy. They found that cognitive behavioral therapy was moderately effective among regular methamphetamine users in promoting abstinence, but cautioned that their

results were preliminary and more research was needed. Baker et al. replicated these findings by examining the role of motivational interviewing with cognitive behavioral therapy and found that those clients who received at least two treatment sessions were most likely to increase abstinence compared with controls [1]. In addition, reductions in depression also were reported among cognitive behavioral therapy treatment groups. Further, these reductions in methamphetamine use and depression symptomatology extended beyond predicted outcomes and were associated with stage of change, polydrug use, injection use, risk-taking behavior, criminal activity level, and psychiatric distress.

Baker et al. [1] recommended use of a "stepped-care" approach whereby the intervention starts with a structured assessment session and self-help material, followed by regular cognitive behavioral therapy sessions. The amount and dose of cognitive behavioral therapy is commensurate with the presentation of the clients' level of pathology (e.g., two sessions for regular users and additional sessions for those with moderate-to-severe levels of depression). Pharmacotherapy and/or longer-term cognitive behavioral therapy was recommended for non-responders [1]. Lee and Rawson [20], however, emphasized the limited effectiveness of medications for methamphetamine users and acknowledged psychological interventions as the treatment of choice. These researchers reviewed randomized trials of cognitive behavioral therapy and found reductions in methamphetamine abuse, as well as other positive changes, even when treatment was limited to 2–4 sessions. The longevity of these effects, however, is not yet known. As such, cognitive behavioral therapy, even in its briefer adaptations, appears to be effective in reducing methamphetamine use.

Caffeine

Despite the widespread availability and cultural norm for caffeinated beverage consumption, little research exists examining the negative consequences of excessive and harmful caffeine consumption as well as consideration of potential interventions that might reduce these behaviors. Ogawa and Ueki [33] advocated that caffeine manufacturers should clearly indicate caffeine content, specify a low-risk and safe amount of caffeine consumption, and state clearly that large quantities lead to long-term health risks. Through case studies, Ogawa and Ueki [33] revealed the nature of caffeine dependence and requested further study for interventions that can impact the nature of these behaviors. As caffeine dependence resembles other psychostimulant addiction (although it is notably less risky), cognitive behavioral therapy represents a promising psychosocial approach by which to reduce excessive caffeine consumption. More research is needed to confirm this possibility.

Nicotine

Cognitive behavioral therapy has been used to help smokers reduce or quit smoking with mixed success. In a study of outpatient smokers receiving cognitive behavioral therapy plus nicotine replacement therapy or placebo for 2 h weekly for 5 weeks, 28% of those clients receiving cognitive behavioral therapy became abstinent from smoking and maintained that abstinence at 12 months [38]. In a group of cancer patients, although cognitive behavioral therapy reduced smoking behavior, it did no better than a basic health education condition in achieving smoking abstinence [40]. Sykes and Marks [41] developed a self-help cognitive behavioral therapy program for disadvantaged smokers and reported abstinence or reduced consumption in clients who were provided with cognitive behavioral therapy tools.

Recent trends in cognitive behavioral therapy research and smoking have considered the role of depression in maintaining smoking abstinence. Hall et al. [13] randomized individuals in a $2 \times 2 \times 2$ design whereby recently quitting smokers had a chance to receive cognitive behavioral therapy or no cognitive behavioral therapy and an antidepressant (nortriptyline or

placebo). Analysis of the resultant data demonstrated that cognitive behavioral therapy was superior to other treatments for those reporting depressed mood but not for those with normal mood [13]. There was a non-significant trend favoring cognitive behavioral therapy in achieving abstinence, but cognitive behavioral therapy did not enhance smokers' compensatory coping skills. Discussion focuses currently on the need to examine a wide range of possible mediating variables in future research on cognitive behavioral therapy for smoking cessation [42]. Several clinical trials have tested whether cognitive behavioral therapy for smoking cessation would especially benefit depression-vulnerable smokers, with mixed results [12].

Review of Treatment for Depressant Drugs

Alcohol

Cognitive behavioral therapy for the treatment of alcohol dependence likely represents one of the most studied treatments for the reduction or cessation of compulsive alcohol drinking. These cognitive behavioral therapy treatments have varied in length, modality (groups, individuals, or couples), content, treatment setting, and the addition of coping skills training [31]. Despite these differences, all cognitive behavioral therapy approaches focus on deficits in coping with stress and alcohol cues that maintain excessive drinking. Within these approaches, several strategies are explained: identification of situations likely to elicit inadequate coping, the use of instruction, therapist modeling, role playing, and behavioral rehearsal to enhance coping skills. Through repeated instruction and therapist support, clients begin to manage exposure to alcohol-related stimuli and handle stressful situations in more adaptive ways. Across 21 studies using cognitive behavioral therapy as a component of a larger treatment program, Longabaugh and Morgenstern [23] found that this treatment approach was more effective in reducing drinking than comparison treatment 71% of the time. Indeed, Miller and Wilbourne [31] documented significant and maintained improvements for alcohol-dependent individuals receiving cognitive behavioral therapy. Subsequent study replication by Kavanagh et al. [17] that compared additional cue exposure strategies with traditional cognitive behavioral therapy techniques (listed above), while demonstrating efficacy, did not further enhance the strength of these findings. In comparing cognitive behavioral strategies with other treatments with strong theoretical underpinnings, Longabaugh and Morgenstern [23] found equal effectiveness in 80% of cases.

In a more comprehensive review of behavioral and cognitive behavioral treatments for alcoholism, Kadden [15] explored several topics used within a cognitive behavioral therapy framework in an effort to identify inconsistencies in the literature and target research needs. In this paper, Kadden considered cue exposure, contingency management, community reinforcement, coping skills training, behavioral marital therapy, and client-treatment matching. Following an extensive review of the literature, Kadden [15] reported that coping skills training was ranked highest for effectiveness in treating alcoholism. The other approaches revealed mixed evidence in terms of efficacy and clear mechanism of action. Although coping skills training raised some concerns and limitations compared with other treatments, it increased consistently treatment effectiveness when used in conjunction with other cognitive behavioral therapy strategies. Kadden concluded by suggesting that treatment matching to individuals' characteristics may maximize the effectiveness of these interventions despite the lack of robust matching effects (in the absence of severe psychopathology) reported in previous publications of Project MATCH [15, 35].

In an attempt to understand better how mechanisms of action within cognitive behavioral therapy account for favorable outcomes, Long et al. [21] identified five promising variables in predicting treatment success: higher self-efficacy

in positive social situations, greater treatment program involvement, a lower perception of staff control, a greater perception of treatment as helpful, and a reduction in psychological symptoms during treatment. As such, the authors suggested promoting clients' confidence and the perception of helpfulness in conjunction with skill-based relapse prevention strategies [21]. Furthermore, social exchange models of intimate relationships also play a role in recovery, and therapy targeting the social functioning in an alcohol-dependent individual leads to improved relationship satisfaction, marital stability, and decreased domestic violence [32]. These cognitive behavioral therapy strategies promote better drinking outcomes associated with partner reinforcement of abstinence. Longabaugh et al. [22] cautioned, however, that more research is needed to confirm these preliminary findings.

Finally, in a more basic focus on social interactions, Meier et al. [30] considered the role of the therapeutic alliance in treating alcohol dependence. The research thus far has indicated mixed results. While Meier et al. found that early therapeutic alliance predicts engagement and retention in drug treatment, Dundon et al. [9] could only confirm these findings with non-cognitive behavioral therapy interventions. In Dundon et al.'s study, three groups were examined (a medication-only group, a medication plus medication-adherence focus group, and a medication plus cognitive behavioral therapy group); yet only the medication-only and medication plus adherence groups were associated with positive outcomes (number of sessions attended and/or days abstinent). It should be noted, however, that Dundon et al. [9] studied individuals interested in receiving pharmacotherapy, which may select for a different subject population from those who might benefit from the therapeutic alliance developed through psychotherapy alone. Also, Dundon et al. [9] did not follow the role of changes in the therapeutic alliance over time, which can take time to develop and is likely to affect client behavior. More research is needed in this area to better inform cognitive behavioral therapy for alcohol dependence [9].

Benzodiazepines

A paucity of literature exists regarding benzodiazepine abuse or dependence and cognitive behavioral therapy. The majority of publications focus on pharmacotherapeutic dosing or medication changes with close monitoring as a means of reducing benzodiazepine misuse problems. Future research should consider how psychosocial interventions can enhance these efforts. Given the success of cognitive behavioral therapy with similar substances in this class, cognitive behavioral therapy would likely provide additional means by which to ameliorate benzodiazepine dependence.

Barbiturates

The current state of barbiturate dependence and cognitive behavioral therapy has not been studied. Most people with barbiturate abuse or dependence problems are treated with pharmacotherapeutic dosing and medication strategies without psychosocial approaches. Cognitive behavioral therapy would likely add benefits to these treatments.

Hypnotics

A review of hypnotics and cognitive behavioral therapy revealed a lack of cognitive behavioral therapy interventions in altering hypnotic abuse or dependence behaviors. As cognitive behavioral therapy has been found to be efficacious in treating other depressant drug dependence, additional research in this area is warranted.

Future Directions

In our clinic, our primary goals are to keep our clients safe and to keep them returning for therapy. If these goals cannot be met, no other goals can be achieved. As such, there are

times when a cognitive behavioral therapy protocol must be adapted to meet these specific goals. Anecdotally, we have found that some sessions must run longer or shorter than stated in the protocol to maintain these goals. In addition, there are times when one session must be reviewed a second time, or when a scheduled session's content must be truncated to address other issues that are more pressing in the client's life. Further research that tracks these cognitive behavioral therapy modifications and how they impact clients' outcomes is needed.

Additionally, future research needs to focus on the development of an effective working alliance between therapist and client. While past research has considered the working alliance at the first session, more information is needed regarding how the therapist/client relationship changes over time, how to augment these changes, and how best to achieve an effective relationship that promotes changes in clients' substance use.

Another area of research potential is treating substance-abusing individuals with co-occurring disorders (depression, anxiety, etc.). Thus far, cognitive behavioral therapy emerges as an effective adjunct for reducing addictive behaviors in depressed individuals when depression is targeted; yet additional research is needed to apply best these findings to the diverse populations who suffer from drug dependence. To begin with, additional research is needed to determine the specific mechanisms of action at play in cognitive behavioral therapy that best promote the reduction of drug-seeking and drug-using behaviors. With the finding that individuals with substance abuse problems also report high rates of depression, cognitive behavioral therapy strategies that specifically identify and target the unique thought patterns and behaviors of these individuals hold much promise. In fact, research that considers and targets all *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition disorders in substance-abusing individuals should be examined using cognitive behavioral therapy as a potential therapeutic tool that can likely address both disorders in a way that medications and/or educational sessions cannot. Research that considers matching specific cognitive behavioral therapy strategies with specific Axis I disorders will likely prove very promising in addressing the unique experiences of substance abusers and comorbid disorders.

Another area of promising research considers the role of computers and electronic devices in promoting reduced addictive behaviors and/or reinforcing abstinence. Multiple Web sites have emerged that provide education and a chance to network with other addicts or specialists who can provide help during non-work hours when cravings and high-risk behaviors are more likely to take place. Carroll et al. [8] recently explored the use of a computer-assisted delivery of cognitive behavioral therapy for addiction and noted this agent to be an effective adjunct to standardized outpatient treatment for substance dependence. More research is needed to expand on this likely successful variation of traditional cognitive behavioral therapy. Through exploration of these potential adjuncts to traditional cognitive behavioral therapy, treatment of substance dependence will continue to improve and impact the lives of those who struggle with substance dependence.

Despite the demonstrated effectiveness of cognitive behavioral therapy for the treatment of substance abuse or dependence, there is still much about this therapy that remains unknown. Researchers continue to try to define specific dose-effect relationships by condensing treatment durations and identifying clients who are most suitable to benefit from fewer sessions. Research efforts need to compare directly the standard cognitive behavioral therapy with these briefer truncated cognitive behavioral interventions. In addition, the specific therapeutic mechanism(s) of change or action for cognitive behavioral therapy must still be identified [23]. Greater understanding of the impact of therapist variables on identified mechanism(s) of change also may be helpful in facilitating the development of efficacious, condensed forms of cognitive behavioral therapy [14].

Kadden [15] has suggested that the study of cognitive behavioral therapy for relapse prevention may be advanced by identifying the most

efficacious approaches to cognitive behavioral therapy, exploration of mediating factors, and identifying clients who are most likely to benefit from specific cognitive behavioral therapy strategies. Important elements of cognitive behavioral therapy selected for further investigation include cue exposure (i.e., factors that mediate or moderate cue reactivity), contingency management (i.e., optimal schedules for reinforcing abstinence and other supportive behaviors), community reinforcement (i.e., elements that are critical to maintaining outcomes), coping skills training (i.e., relative effectiveness of the various skills-training components, optimal combinations of them for different types of clients, and the optimal number and duration of treatment), the role of personality, interpersonal and environmental factors, and a re-examination of client-treatment matching. McKee et al. [29] has questioned further how future treatment might better motivate clients for successful cognitive behavioral therapy. Through greater understanding of the components of cognitive behavioral therapy and the interactions among client, therapist, and intervention factors in substance abuse treatment, best-practice strategies can be developed to provide briefer, more effective cognitive behavioral therapy to clients with limited resources and/or need, for more immediate outcomes.

Community Reinforcement Approach and Contingency Management Therapies

Nancy M. Petry and Danielle Barry

Contents

Introduction

This chapter first describes the rationale behind and evidence in support of the efficacy of community reinforcement approach therapy. This treatment is most often applied to alcohol-dependent individuals, but there have also been a few studies examining its effects among individuals with illicit drug use disorders. Most typically, when applied to illicit substance abusers, community reinforcement approach therapy is combined with another behavioral therapy—contingency management. The second section of this chapter details the theoretical basis and evidence of efficacy for contingency management interventions. The chapter concludes by discussing issues related to the cost-effectiveness of these interventions and their adoption in practice settings.

Community Reinforcement Approach Therapy

Community reinforcement approach therapy was first developed over 30 years ago by Hunt and Azrin [21]. They described the community reinforcement approach as a comprehensive bio-psychosocial treatment for alcohol dependence. It is based on the theoretical view that individuals use substances for their positive, reinforcing effects and that the relative lack of alternative, non-drug reinforcers maintains dependence. The development of alternative reinforcing activities that are incompatible with drug use is central to the community reinforcement approach.

The community reinforcement approach begins with a detailed functional analysis concerning the triggers and consequences of drug use behaviors. An example of a functional analysis is presented in Table 1. The treatment package itself includes a number of aspects: sobriety sampling, monitored disulfiram consumption (when appropriate), behavioral skills training, social and recreational counseling, behavioral

Table 1 Sample functional analysis form for use in community reinforcement approach therapy

Day/time	Situation	Thoughts/ feelings	Substance use? What and how much?	Positive consequences	Negative consequences
Mon pm	Argument with neighbor	Angry!	Alcohol 9–10 beers	Forgot about neighbor for a while	Neighbor called cops because of noise.
Tues pm	Friend offered me a hit.	Terrible craving, really wanted to use.	Cocaine. 1/2 gram	Fun to be with old friend. Felt good.	Went home and drank more that night, even though I wasn't planning on drinking. Felt guilty next day.

Adapted from Budney and Higgins [5]

marital therapy, problem solving, and drink refusal skills. Thus, some of the components of the community reinforcement approach are similar to cognitive behavioral therapy (see Chapter "Cognitive Behavioral Therapy for Addiction").

The difference between the two types of therapies is that the community reinforcement approach is more directive, community based, and behavioral than cognitive behavioral therapy. In the community reinforcement approach, the therapist places a great deal of emphasis on changing environmental contingencies in the client's life. Employment, recreation, and family systems are all addressed to promote a lifestyle that is more reinforcing than substance use. Rather than being entirely office-based, the community reinforcement approach is typically performed, at least in part, in the community. If clients do not attend treatment or do not follow through with an employment or recreational goal, the therapist may go to their homes, take them to job interviews, or help them try a new recreational activity. The purpose of expanding the treatment beyond the office setting is to increase the positive reinforcing effects of non-substance-using activities by direct exposure.

Initial reports of the efficacy of the community reinforcement approach for the treatment of alcohol dependence were promising. Hunt and Azrin [21] and Azrin [2] described two early studies in which 16 and 18 alcohol-dependent individuals, respectively, were randomized to usual psychosocial therapy plus disulfiram or to the community reinforcement approach plus disulfiram. In both studies, the community reinforcement approach-treated individuals spent significantly fewer days drinking than did those receiving usual care. The latter study had a long-term follow-up, which found that 90% of those who had received the community reinforcement approach remained abstinent up to 2 years later.

Additional studies in alcohol-dependent individuals have found the community reinforcement approach to be of therapeutic benefit to alcohol-dependent individuals. For example, Azrin and colleagues [3] noted a therapeutic benefit of the community reinforcement approach, and Smith et al. [51] also reported that this approach led to greater abstinence during treatment than did usual care plus disulfiram treatment. Miller et al. [28, 29] examined the various components of the community reinforcement approach and likewise found the community reinforcement approach to improve the treatment outcomes of those who received concomitant disulfiram treatment.

Several independent reviews and meta-analyses have concluded that the community reinforcement approach is an important, established, and effective treatment for alcohol use disorders [10, 19, 20, 27]. Furthermore, in a recent review of the community reinforcement approach's effectiveness, Roozen et al. [48] concluded that the community reinforcement approach, alone or with disulfiram, is efficacious for the treatment of alcohol dependence. However, the use of the community reinforcement approach alone in the treatment of other illicit drug use disorders has not been examined

extensively. Most studies that have examined the community reinforcement approach have done so in conjunction with another behavioral therapy, contingency management.

Contingency Management Interventions

Contingency management, similarly to the community reinforcement approach, is based on the principles of behavioral therapy. The primary difference between the two interventions is that contingency management provides *tangible* reinforcers for achieving target behaviors to increase the likelihood of those behaviors reoccurring, while the community reinforcement approach exposes clients to reinforcing activities and experiences. Typically, contingency management interventions identify an appropriate target behavior (e.g., abstinence as verified by a negative urine toxicology test) and provide tangible reinforcers each time the target behavior occurs. The reinforcers are most often monetary-based vouchers exchangeable for retail goods and services or the chance to win prizes of varying magnitudes. If the target behavior does not occur, the reinforcers are removed [13, 33].

Contingency management is generally not provided as a stand-alone treatment for substance use disorders, but instead it is added to another treatment to improve outcomes. Contingency management is often combined with the community reinforcement approach in attempts to improve further the efficacy of the community reinforcement approach alone. An early study of voucher-based contingency management by Higgins et al. [15] offered the community reinforcement approach along with contingency management to 13 consecutively admitted cocaine-dependent outpatients and offered 12-step-based drug counseling to the next 15 consecutively admitted cocaine-dependent outpatients. In the contingency management condition, vouchers worth a specific amount of money were provided whenever individuals submitted cocaine-negative urine samples. Significant group differences emerged in the percentage of participants who remained in treatment for 12 weeks, with 85% in the community reinforcement approach plus contingency management group and 42% in the 12-step group remaining in treatment for the entire period. Participants in the community reinforcement approach plus contingency management group also achieved significantly longer periods of objectively verified continuous cocaine abstinence, with 77% vs. 25%, respectively, achieving a month or more of continuous abstinence.

Higgins et al. [14] next conducted a 24-week randomized study comparing the same two treatments in a sample of 38 individuals, with half of them assigned to community reinforcement approach plus contingency management and the other half assigned to 12-step counseling. Fifty-eight percent of the participants in the community reinforcement approach plus contingency management group completed treatment versus 11% of those in 12-step counseling. The groups also differed significantly on rates of continuous abstinence. Sixty-eight percent of participants receiving community reinforcement approach plus contingency management achieved 8 weeks of continuous abstinence compared with 11% in the 12-step counseling group. Group differences remained at 6-, 9-, and 12-month follow-up interviews [12]. Participants who received community reinforcement approach plus contingency management were more likely to self-report cocaine abstinence over the past 30 days and to submit cocaine-negative urine samples compared with those who received 12-step counseling.

To isolate the specific contribution of contingency management to these beneficial outcomes, Higgins and colleagues [13] next randomized 40 cocaine-dependent individuals to the community reinforcement approach alone or community reinforcement approach plus contingency management. Significantly more participants in the combined condition remained engaged in treatment for 24 weeks (75%) than in the community reinforcement approach-alone condition (40%). Longest duration of continuous abstinence

differed between groups as well. Participants in the community reinforcement approach plus contingency management condition achieved an average of 11.7 (± 2.0) weeks of continuous abstinence from cocaine, while those in the community reinforcement approach-alone condition achieved an average of 6.0 (± 1.5) weeks. These studies demonstrate that community reinforcement approach plus contingency management is more effective than the community reinforcement approach alone for increasing the duration of abstinence. Further, the benefits of community reinforcement approach plus contingency management persist up to a year beyond the end of the period during which vouchers are available [11, 18].

While contingency management adds to the benefits of the community reinforcement approach, the converse is also true: including the community reinforcement approach improves the benefits associated with contingency management alone. Higgins et al. [17] assigned 100 cocaine-dependent individuals in a random fashion to either the combination of contingency management plus the community reinforcement approach or contingency management alone. Participants who received the combined treatment remained in therapy longer, used cocaine less frequently during treatment, and reported a lower frequency of drinking to intoxication than did those who received contingency management alone. Individuals treated with community reinforcement approach plus contingency management also evidenced improvements on other domains relative to those who received contingency management only. These included higher days of employment, reduced depressive symptoms, and fewer hospitalizations and legal problems. Thus, contingency management is an efficacious intervention for cocaine dependence, but it is most effective when administered in conjunction with the community reinforcement approach in this population.

Other studies have extended these benefits of community reinforcement approach plus contingency management to other substance-abusing populations. Bickel et al. [4] randomized 39 opioid-dependent individuals to a usual-care condition or community reinforcement approach plus contingency management. During treatment, abstinence rates were significantly higher among those who received contingency management. Using a non-randomized design, Schottenfeld et al. [49] compared 117 opioid-maintained, cocaine- and opioid-dependent individuals who received either drug counseling or community reinforcement approach plus contingency management. Although retention and drug use did not differ between those receiving different forms of therapy in this report, engagement in community activities unrelated to drug use (e.g., parenting activities, employment, or planned recreational activities) was significantly associated with abstinence.

In the treatment of other drug use disorders such as nicotine, marijuana, or benzodiazepines, contingency management is typically applied as an adjunct to usual-care psychotherapies, rather than in conjunction with the community reinforcement approach. A variety of studies demonstrate that contingency management improves the treatment outcomes of marijuana-dependent individuals when added to motivational enhancement therapy or cognitive behavioral therapy [6, 7, 23]. Contingency management is also efficacious in the treatment of nicotine dependence [9, 16, 46, 47] and benzodiazepine use [54].

Two recent meta-analyses have demonstrated the therapeutic efficacy of contingency management in treating different substance use disorders [26, 44]. Across 30 studies comparing treatments with and without the addition of voucher-based contingency management, Lussier et al. [26] found medium-sized group differences in length of abstinence from cocaine, opiates, tobacco, alcohol, and marijuana, with no significant difference in outcomes across specific drugs. More immediate delivery of reinforcement and higher reinforcement magnitude were associated with greater therapeutic benefit [26]. In an independent analysis of 47 contingency management trials that used vouchers as well as other forms of reinforcement (e.g., cash and privileges such as take-home methadone doses), Prendergast et al. [44] found that contingency management was most effective in reducing cocaine

and opiate use. Smaller effects were noted with respect to reducing tobacco and polydrug abuse. While both of these meta-analyses found benefits of contingency management, they included many studies that did not incorporate appropriate behavioral principles in the design of the reinforcement structure, such as frequent monitoring and reinforcement and escalating reinforcers with sustained behavioral change [33]. The benefits of contingency management are greater in studies that utilize appropriate behavioral principles.

Issues Hindering the Implementation of the Community Reinforcement Approach in Practice

Despite the strong research evidence that supports the efficacy of community reinforcement approach and contingency management in substance-abusing populations, these interventions are rarely implemented in clinical practice. The primary reason for lack of use relates to costs. The community reinforcement approach is labor intensive and difficult to employ in practice settings, most of which are understaffed and underfunded. In its traditional sense, the community reinforcement approach is individually based and quite labor intensive in nature. Typically, one therapist will manage a small caseload of 10 or fewer clients.

In an attempt to make the community reinforcement approach less labor intensive for therapists and more practical to implement in busy clinical practice settings, some studies have examined a modification of the approach by providing contingency management for completing goal-related activities. Rather than the therapist going out into the community with the client to ensure exposure to non-drug-related activities, the therapist will contract with the client each week to complete up to three goal-related activities. If the client engages in the activities and provides objective verification of completion, the client will earn tangible reinforcers such as vouchers. Table 2 provides an example of a typical activity contract.

This approach has been studied in several clinical trials. In a sample of polydrug-using individuals on methadone, Iguchi et al. [22] found that an intervention that provided tangible reinforcers for completion of goal-related activities resulted in lower drug use both during the treatment period and throughout the follow-up period than a usual contingency management approach that only reinforced drug abstinence. However, a subsequent study with cocaine-abusing individuals from psychosocial (non-methadone) clinics failed to show a significant benefit of the contingency management for activity condition relative to usual care [34]. In that study, contingency management for submission of negative urine samples did significantly improve outcomes relative to standard care. Thus, there is inconsistent evidence that this modified contingency management approach is sufficient to improve drug use outcomes in clinical settings.

Importantly, contingent activity contracting is important for engaging individuals in drug-free recreational and other activities. If activity contracting procedures are employed without contingent reinforcement, these activities are completed less than one-third of the time [40]. In contrast, when tangible reinforcers are provided in a contingent manner, these activities are completed about two-thirds of the time [40, 43]. Furthermore, completion of these activities was typically associated with a reduction in drug use and improvements in psychosocial functioning. Individuals who completed family activities compared with those who did not reported a greater reduction as well as improvements in family functioning [25]. Also, the completion of exercise-related activities appeared to decrease drug use [55]. Another popular contingent activity that can be targeted is engagement in religion. For instance, individuals who became involved in religious activities (going to church or mosques or attending Bible studies), compared with those who did not, remained in treatment longer, had longer periods of drug abstinence, and submitted more drug-negative

Table 2 Sample activity contract

Specific activity	Goal area	Projected date/ time of completion	Things that could go wrong	Problem solve	Verification	Completed and verified?
1. Complete draft of resume	Employment	Wed pm	Don't feel like it, No blank paper in house	Do on Thurs if not Wed, Bring blank paper from clinic	Bring in draft	
2. Go to 3 AA meetings	Sobriety	Wed pm, Fri pm, and Sat afternoon	Don't feel like going, car won't start	Make plans will Sally to go together and for coffee after meeting, ask Sally to drive	Signed attendance slip and coffee receipts	
3. Go to church	Recreation/ spirituality	Sunday 10 A.M.	Oversleep, no transportation	Set alarm Sat night, make plans to go with John	Bring back dated bulletin	

Adapted from Petry et al. [43]

urine samples [38]. In sum, the reinforcement of salient non-drug-related activities through the use of tangible reinforcers has appeared to be an important method for decreasing drug use and should be more cost-effective than having therapists attend community events with their clients.

Issues Associated with Implementation of Contingency Management in Practice

While contingency management can be used to reinforce engagement in non-drug-related activities, it is most often applied to encourage abstinence from using substances. Irrespective of the target behavior reinforced, contingency management has been criticized for being costly to implement, especially the voucher-based version.

An important component of contingency management is that the value of vouchers earned increases with each consecutive instance of a desired behavior. Thus, the first negative specimen (or activity completed) may result in a $2.50 voucher, the second a $3.25 voucher, the third a $4 voucher, and so on [45, 46]. Thus, by the end of a 12-week treatment period, individuals may be earning in excess of $40 for each negative sample or activity completed, and most effective voucher-based contingency management programs arrange for about $1000 in vouchers over the course of a 12-week treatment period (see Table 3). Hence, the costs of voucher-based contingency management are prohibitive for most community-based settings.

Studies that have attempted to reduce the amounts of vouchers available show that the procedure is less effective in decreasing drug use. Stitzer and Bigelow [52, 53] found that nicotine abstinence increased as a function of the magnitude of the reinforcer, ranging from $0 to $12 per day. Dallery et al. [8] noted a direct relationship between voucher amounts and abstinence in another study of individuals receiving methadone maintenance treatment. These studies all suggest that the larger the magnitude of the reinforcer, the greater the improvement in treatment outcomes. Hence, reducing the value of the vouchers decreases their efficacy in promoting abstinence from substances.

Table 3 Sample voucher-based contingency management schedule

Week	Sample	Points	Dollars	Bonus	Cumulative earnings

Prize-Based Contingency Management

To address the issue of cost in contingency management interventions, Petry et al. [39]

developed a prize-based contingency management intervention that provided tangible reinforcement on a variable ratio schedule. Individuals who provided objective evidence of abstinence or other target behaviors earned the opportunity to draw slips of paper that could be redeemed as prizes. The number of draws earned, similar to the voucher-based approach, increased with each consecutive negative sample, such that the first negative sample or completed activity resulted in one draw, the second in two draws, and so forth. Typically, the drawing of prizes was capped (e.g., at a maximum of 8 draws per activity completed or negative sample submitted) after about 1 month of sustained behavioral change (see Table 4).

In most prize-based contingency management programs, clients draw from a bowl containing 500 slips of paper. Half the slips have encouraging messages but do not result in prizes, and half the slips result in a prize. There are typically three prize magnitudes, "small" (worth about $1), "large" (worth about $20), and "jumbo" (worth about $100). The majority of the slips (e.g., 209) are associated with small prizes, and when clients draw a small slip they select from items such as bus tokens, fast food gift certificates, food items, and toiletries. Fewer slips (e.g., 40) are exchangeable for large prizes such as portable CD players, telephones, telephone minutes, pot and pan sets, and $20 gift cards to stores and restaurants. One slip corresponds to a jumbo prize such a DVD player, stereo, or television. With this system, there is always an opportunity to earn something of high value, but overall earnings are expected to be relatively modest. On average, the maximal arranged reinforcement for a 12-week treatment period is about $250 to $400, and typically clients earn about half the programmed reinforcement.

Adapted from Petry et al. [35]

Prize-based contingency management was first evaluated in a sample of 42 alcohol-dependent men participating in a Veterans Affairs outpatient substance abuse treatment program [39]. Twenty-three participants were assigned to standard care, a 4-week intensive outpatient program that included 12-step meetings, relapse prevention, coping skills training, and AIDS education followed by 4 weeks of less intensive aftercare. Nineteen individuals received the same standard care plus contingency management for abstinence and for compliance with treatment goals (a modification of the community reinforcement approach). All participants submitted Breathalyzer samples at each daily visit to the treatment program, and those in the contingency management group who tested negative for alcohol earned the opportunity to draw for prizes. Contingency management participants also earned additional draws for completing activities related to their treatment goals, such as attending an Alcoholics Anonymous meeting, filling out a job application, or participating in planned recreational activities with non-drug-using family members. Individuals who received contingency management in addition to standard care were significantly more likely than those receiving standard

care alone to remain in treatment for the 8 weeks of the study (84% vs. 22%) and to remain abstinent from alcohol for the duration of the study (69% vs. 39%). Individuals who received contingency management compared with those who got standard care were less likely to relapse to heavy alcohol use by the end of the study (26% vs. 61%). The average value of prizes earned by each participant in the contingency management condition was $200.

A direct comparison of voucher- and prize-based contingency management interventions for cocaine-abusing individuals entering a community-based outpatient drug-free treatment program found both approaches to contingency management to be more effective than standard care alone [36]. Both contingency management interventions compared with standard care increased retention in treatment and the duration of continuous abstinence from drugs significantly. Individuals in standard care, voucher-based contingency management, and prize-based contingency management remained in the program for 5.5 (± 3.6) weeks, 8.2 (± 3.8) weeks, and 9.3 (± 3.7) weeks, respectively. While there was no statistically significant difference between the two contingency management groups, the trend toward longer retention in treatment in the prize-based contingency management group was notable. Individuals who received standard care achieved 4.6 (± 3.4) weeks of continuous abstinence compared with 7.0 (± 4.2) weeks in voucher-based contingency management and 7.8 (± 4.2) weeks in prize-based contingency management.

Petry and colleagues did a follow-up study to examine the relative efficacy of two contingency management approaches plus standard care vs. standard care alone among cocaine-dependent individuals who were receiving methadone [35]. Participants were assigned in a random fashion to standard care, standard care plus prize-based contingency management, or standard care plus voucher-based contingency management. The amount of arranged reinforcement was twice as high in the voucher-based vs. the prize-based contingency management condition. Both contingency management conditions increased the duration of abstinence and the proportion of cocaine-negative samples submitted; hence, even the prize-based contingency management approach of lower cost was efficacious.

Since the low-cost prize-based contingency management approach had similar therapeutic benefit to the voucher-based contingency management program, the extent to which prize values could be reduced and still reduce drug use was examined in another study of cocaine-abusing outpatients [42]. In that study, one group received standard care at community-based drug-free clinics, and two groups received prize-based contingency management plus standard care. One contingency management group offered the opportunity to earn up to an average of $240 in prizes, whereas the other offered the chance to earn up to an average of $80 in prizes. Both contingency management conditions offered a similar number of opportunities to draw for prizes; however, compared with the $240 group, the prizes available in the $80 group were less valuable. While contingency management with $240 available for prizes was significantly more efficacious than standard care, there was no difference between standard care and contingency management with $80 available for prizes. Therefore, although the prize-based version of contingency management does offer some cost advantage over its voucher-based counterpart, even within the prize-based version there appeared to be a lower bound or threshold in monetary value for it to be of greater therapeutic benefit than standard care.

Prize-based contingency management was selected by the National Institute on Drug Abuse Clinical Trials Network for more extensive evaluation in community treatment settings [41] based upon the encouraging results from controlled clinical studies. The goal of the Clinical Trials Network is to evaluate the effectiveness of treatments found to be efficacious in controlled studies done at specialized research centers in community-based clinical settings, where most individuals receive treatment for substance use disorders. In the largest studies of contingency management to date [32, 41], over 800 stimulant (cocaine, methamphetamine, or amphetamine)

abusers were recruited from community clinics throughout the United States. About half of the participants were recruited from psychosocial (drug-free) clinics ($N = 415$) [41] and half from methadone clinics ($N = 388$) [32]. The clinics were located primarily in urban settings, but suburban and rural settings were represented as well. The duration of the combined studies was 12 weeks. As in other contingency management studies, participants were assigned to one of two groups, standard care or standard care plus prize-based contingency management using a system of escalating draws for consecutive stimulant-free urine samples. The maximum number of draws available was 204, with average maximal expected earnings of about $400 in prizes. In the psychosocial programs [41], individuals who received contingency management plus standard care were significantly more likely than those receiving standard care alone to remain in treatment for the entire 12 weeks of the study (49% vs. 35%). Contingency management participants also attended more counseling sessions during the study period (19.2 ± 16.8) than did those receiving standard care (15.7 ± 14.4). The longest duration of continuous verified abstinence from stimulants was significantly greater in the contingency management group compared with the standard care group (8.6 ± 9.2 weeks vs. 5.2 ± 6.9 weeks), and contingency management participants were more likely than those receiving standard care to achieve 4 (40% vs. 21%), 8 (26% vs. 12%), or 12 (19% vs. 5%) weeks of continuous abstinence from stimulants. Similar results were noted for stimulant abusers maintained on methadone [32]. Individuals who were assigned in a random fashion to the contingency management condition were significantly more likely to achieve long durations of abstinence and to submit higher proportions of stimulant-negative urine samples. The average amount of reinforcement earned in the methadone programs was $120 per individual, and in the psychosocial programs it was $203 per individual. Thus, the costs of reinforcers in prize-based contingency management are relatively low, and the procedure is widely efficacious across settings and substance-abusing populations.

Cost-Effectiveness

Investigators have begun to examine the cost-effectiveness of contingency management. Using data from the Clinical Trials Network studies, Olmstead et al. [31] estimated resource utilization (treatment services including counseling sessions attended, urine and Breathalyzer tests, counselors' time associated with drawings, and value of prizes won) of individuals receiving standard care or standard care with contingency management at community-based outpatient psychosocial drug abuse treatment clinics. Unit costs of services were estimated via surveys administered at the 8 participating clinics. Participant outcomes (primarily duration of continuous abstinence) were also obtained from the trials. The incremental cost to lengthen abstinence by 1 week was $258 (95% confidence interval, $191–$401) in psychosocial clinics [31]. In a follow-up analysis of the same data, Olmstead et al. [30] sought to determine by how much the cost-effectiveness of contingency management varied across the 8 psychosocial clinics in the Clinical Trials Network trial. Incremental costs, incremental outcomes, and incremental cost-effectiveness ratios of contingency management versus standard care were calculated for each clinic. The incremental cost of contingency management ranged across the clinics from an additional $306 to an additional $582 per individual. The effect of contingency management on abstinence ranged from an additional 0.5 weeks to an additional 4 weeks across the clinics. Incremental cost-effectiveness ratios for abstinence ranged from $145 to $666 per individual across the clinics. Thus, the cost-effectiveness of contingency management did vary widely among clinics in the Clinical Trials Network trial, and future work is needed to focus on identifying sources of this variation, perhaps by identifying clinic-level best practices or identifying subgroups of individuals who respond the most cost-effectively, with the ultimate goal of improving the cost-effectiveness of contingency management overall.

Sindelar et al. [50] evaluated the incremental cost-effectiveness of contingency management in a study in which different magnitudes of the prize in the prize-based contingency management were compared. They found that the $240 prize-based contingency management condition produced outcomes at a lower per-unit cost than the $80 contingency management condition. This finding suggests that sometimes increasing up-front costs is more cost-effective overall. These results may be particularly relevant for substance-abusing populations who utilize high-cost resources such as inpatient medical and criminal justice services.

Challenges to Dissemination

While the efficacy of the community reinforcement approach and contingency management for the treatment of substance use disorders in controlled settings is established, the adoption of these procedures by treatment providers in clinical practice has been limited. As noted earlier, the costs of the reinforcers and of staff time for administration of the procedures are some obstacles to implementation.

The costs associated with contingency management can be decreased by providing contingency management in a group context. While typically implemented individually, prize-based contingency management can also be administered in a group format [1, 24, 40], perhaps facilitating its adoption, as group therapy predominates in practice. Witnessing others winning prizes appears to lead to a camaraderie among clients, and group- and prize-based contingency management has been implemented at a fairly low cost (e.g., $15–$20 per week in direct costs) [24].

Cost is not the only barrier to implementation of these evidence-based practices. Implementation also depends on familiarity with and proficiency in techniques and principles of behavior modification. These include behavioral therapy and behavioral contracting and—in the case of contingency management—consistently applying contingencies, frequently monitoring and reinforcing behaviors, integrating escalating or bonus reinforcers, and providing adequate reinforcement magnitude [33]. Developing comprehensive training procedures for the community reinforcement approach and contingency management for community-based treatment staff is a large undertaking, but efforts toward dissemination are under way. Budney and Higgins [5] provided a treatment manual for the combination of the community reinforcement approach and voucher-based contingency management, and a training manual and video are also available for prize-based contingency management at http://info.med.yale.edu/psych/research/psychotherapy/orderform.doc.

Other implementation concerns relate explicitly to prize-based contingency management. Because this procedure contains an element of chance, concerns have arisen that it might promote pathological gambling. However, gambling by definition involves risking something of value, which is not the case with contingency management. Examination of gambling behaviors among 803 individuals participating in the Clinical Trials Network prize-based contingency management studies found no evidence of increases in gambling behavior over time [37].

The ability of treatment systems that are under tight fiscal restraints and understaffed to absorb the additional costs of community reinforcement approach and contingency management is understandably met with skepticism. In the case of contingency management explicitly, reducing reinforcement magnitudes to under $240 for prize-based contingency management will compromise efficacy [42], but it may be possible to offset costs in part or in full via fundraising or other strategies including the use of clinic privileges for some prizes. Moreover, the immediate costs of contingency management and the community reinforcement approach may pale in comparison with the societal and individual costs of continued drug abuse. Comprehensive cost-effectiveness analyses are needed to evaluate more clearly contingency management and the community reinforcement approach, when delivered either alone or together, relative to other modalities for treating substance abuse.

Conclusion

The community reinforcement approach and contingency management are efficacious interventions for the treatment of substance use disorders. The community reinforcement approach addresses the multiple bio-psychosocial factors that contribute to substance abuse and provides intensive intervention to help individuals develop alternative forms of reinforcement to compete with substance use. Contingency management enhances the outcomes of the community reinforcement approach by providing tangible reinforcers for drug abstinence and other positive behaviors as clients learn self-reinforcement strategies, engage in new adaptive behaviors, and adopt a drug-free lifestyle. Numerous studies demonstrate the efficacy of these interventions as treatments for alcohol, cocaine, opiate, and marijuana use disorders.

Despite their efficacy, community reinforcement approach and contingency management have rarely been implemented in community settings. Many factors contribute to the implementation and sustainability of treatments, including the soundness of forged research-treatment partnerships, the readiness of communities to accept an innovation, and financial resources for training and implementation. Future adoption of these interventions for perhaps the most seriously impaired substance abusers may ultimately prove to be efficacious and cost-effective. Recent innovations such as using contingency management to reinforce community reinforcement approach activities (reducing the burden on counselors) and administering contingency management in group settings may facilitate wider adoption of these empirically validated treatments in practice.

Relapse Prevention and Recycling in Addiction

Carlo C. DiClemente, Meredith A. Holmgren, and Daniel Rounsaville

Contents

Introduction

In the struggle to be free from Addiction, repeated attempts are required for most individuals to stop the addictive behavior. Multiple attempts to change and multiple treatment events are the norm rather than the exception in recovery from addiction [28]. There seems to be a predictable cycle in the path to recovery. Once addicted individuals become convinced that they need to change problematic addictive behaviors (illegal or nonprescription drug use, excessive alcohol consumption, tobacco use, or gambling), they will attempt either to quit completely or to significantly modify these behaviors (e.g., cutting down or using methadone or buprenorphine instead of heroin). The majority of these individuals who make an attempt to change, however, are unsuccessful. In any cohort of individuals that enters treatment and makes a bona fide attempt to change, the majority, between 60 and 80%, return to the problematic behavior after some period of success [9, 28]. This event, though defined in various ways, has been labeled a "relapse".

Understanding the Concept of Relapse and Its Role in Recovery

The definition of what constitutes a relapse varies depending on the definition of success and failure in changing an addictive behavior. The most stringent definitions define

success as complete abstinence from the behavior and identify relapse as any engagement in the addictive behavior (any consumption of alcohol, use of cocaine, etc.) [58]. Other clinicians and researchers make a distinction between a slip or lapse and a full blown relapse [39]. Slips and lapses have been defined variably as a single use, a single period of use, minimal amounts of use, or use without any consequences. Relapse is then a more significant engagement in the behavior than a single event or a brief period of use. Lapses could extend into what has been defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision as "partial remission", indicating that there are some vestiges of the behavior present, but that there is an absence of the negative consequences and the physiological and psychological dependence that marked the problematic period of use [19].

Making a distinction between a lapse and a relapse can be clinically useful because the very strict definition of complete abstinence or failure can have unintended consequences, as will be described later. It is important first to note some common misconceptions about the phenomenon of relapse. Relapse is often viewed as a unique problem of substance abusers by practitioners and the public. However, relapse and lapsing back to unhealthy behaviors occurs in all types of health behavior change and is not limited to addictions. Many health behaviors, such as dietary change, diabetes management, regular physical activity, and medication adherence have a similar course with large numbers of individuals lapsing and relapsing [9, 42]. Relapse is not merely a function of physiological addiction; it is a function of the process of behavior change when individuals attempt to change difficult-to-modify patterns of behavior [20, 43].

Another misconception is that relapse is often viewed as failure since the desired behavior change is not sustained. However, although it does not represent complete success, relapse is an integral part of learning during the recovery process. Individuals do not become addicted, nor do they recover from an addiction, with a single learning event [20]. Within the stages of change model, relapse represents an event that not only involves a return to a problematic behavior but also signifies a return to an earlier stage of change for that behavior [11, 63]. After relapsing, individuals can return to any of the previous stages, Precontemplation (not considering change in the near term), Contemplation (considering and decision making), Preparation (building commitment and planning), or Action (initial change lasting for 3–6 months). Individuals returning to the Precontemplation stage after relapse likely believe they cannot change or are they are no longer interested in changing the addictive behavior. Relapsers who reconsider the pros and the cons of the addiction, try to resolve the associated ambivalence and make a new decision to quit have returned to the Contemplation stage. Those who determine what went wrong during the last quit attempt and are poised to make another attempt return to the Preparation stage. Relapsers who quickly make another attempt move back into the Action stage of change. The return to earlier stages of change after relapsing from the action or maintenance stage is called "recycling" back through the stages and often leads to another attempt that is successful [21, 54]. The cyclical movement though the stages of change represents the learning process of "successive approximations" whereby an individual learns gradually through trial and error how to avoid the problems from past attempts and to make a successful change in behavior.

Relapse, considered from this perspective, is not so much a failure as an opportunity to learn what went wrong and what was missing in the unsuccessful process of change. Most individuals who enter stable recovery do so only after multiple attempts to change. This pattern is true of individuals who have changed the addictive behavior without the aid of formal treatment as well as those who have been successful after a particular course of treatment [22, 45, 49]. In any case, understanding relapse and recycling is critical to understanding successful recovery. Helping individuals avoid relapse and/or to learn how to profit from the experience and become more successful is the goal of relapse

prevention and of successful recycling. This chapter will examine relapse prevention models, highlight critical components of relapse prevention, identify key clinical strategies that can be used in the service of preventing relapse, and discuss how to promote successful recycling for those who were unable to change their behavior at any one point in time.

Relapse Prevention

As the field of addiction moved from a moral explanation of addiction to a focus on habit and disease, the challenge of maintaining change and avoiding relapse became a focus of research and theory [9, 35, 39, 61]. Interest and research activity expanded to understand what precipitates relapse and the possible interventions that would reduce the relapse rate and increase the potential for recovery from a slip or a relapse. There were several dominant theories that were developed during the 20th century not all of which were compatible with one another.

Models for Relapse Prevention

The two partially compatible models for understanding relapse came from different explanatory frameworks. The Medical Model countered the prevailing perspective at the beginning of the twentieth century that alcoholism and other addictions were moral problems that could be overcome with willpower and by observing moral standards. The view of addiction as a disease was intended to change the conversation about addiction, remove some of the stigma, and make it a medical condition that was treatable. This model was not only adopted by the medical professionals but also by the influential founders of Alcoholics Anonymous and the 12-step model for recovery [58]. At the same time in the academic community, the social and behavioral learning perspectives described addictions as over-learned behaviors that were supported by contextual forces. Interestingly, both models arrived at some similar relapse prevention strategies.

Medical and Mutual Help Model

In the Medical Model addiction is viewed in terms of the changes that are made in the neurochemistry of the addicted individual, which causes physiological dependence. The perspective is that the addiction acts as a disease and changes biological processes which, in turn, pose significant barriers for change for the addicted individual. The physiological changes that result from prolonged substance abuse manifest themselves in craving, which continually pushes the addicted individual to return to the addictive behavior [52]. For the addicted individual their "normal" biological state inherently is resistant to behavior change [14, 33]. Medical Model oriented interventions to prevent relapse include periods of hospitalization that focus on breaking the physiological and psychological connections to addiction as well as using medications that decrease cravings.

In the Medical/Mutual Help or Twelve-Step Model, addiction is also described as an illness or disease that addicted individuals are powerless to control [53]. One analogy for the disease is an "allergy" such that the individual cannot have contact with the substance without a loss of control. This perspective supports the view of relapse as any contact with addictive substance or behavior. The addicted individual is seen as someone who has a defect such that willpower can not be the solution for recovery. Preventing relapse must include an admission of powerlessness and a reliance on a higher power, whether that is seen as a spiritual power or the power of the mutual help network that is created by associating with Alcoholics Anonymous and working the 12 steps of recovery. The program includes a number of strategies (e.g., approach recovery, one day at a time, you are always an alcoholic and must always be vigilant, meeting attendance) and support systems (e.g., sponsors, fellowship of Alcoholics Anonymous) for the prevention of relapse.

Social Learning Models

In 1980, G. Alan Marlatt and Judith Gordon developed the Relapse Prevention Model, an extensive, empirically focused conceptual model that we will use as the basis of our discussion of relapse in this chapter. Their cognitive-behavioral model of the relapse process [39] is based on social cognitive and learning models of behavior and posits that addiction stems from maladaptive habit patterns. Relapse is conceptualized as resulting from a series of predictable cognitive and behavioral events that lead to a return to substance use. This relapse prevention model hypothesizes that common cognitive, behavioral, and affective mechanisms underlie the process of relapse for a variety of problem behaviors. This view of recovery is based on learning theory and differs from the disease model in many ways, though does share some theoretical precipitants of relapse.

The model assumes that a complex array of determinants is involved in the development of an addiction and the ability to successfully change the addictive behaviors. Some influential factors include genetics, environmental/situational factors, family history of addiction, peer influence, early use of substances, and expectancies of the effects of the substance. During periods of abstinence, individuals move along a continuum of engagement in cognitive and behavioral activities that lead to successful behavior change. Along the way, they are likely to face situations that put them at risk for relapse. These high-risk situations are a core component of Marlatt and Gordon's Relapse Prevention Model. Eight categories of relapse determinants were formulated from detailed, retrospective interviews of substance abusers who had experienced a return to their substance use [40]. This was done to identity the experiences that immediately preceded relapse episodes. From this investigation, a taxonomy was developed which included interpersonal and intrapersonal factors. Cummings et al. [17] found that the most frequently reported precipitants of relapse included negative emotional state (35% of relapses), social pressure (20%), interpersonal conflict (16%), and urges and temptations (9%). Factor analysis on the Reason for Drinking Questionnaire [68] expanded beyond Marlatt's taxonomy of relapse precipitants to reveal three major factors that differentiated the types of relapses people experienced: (1) negative emotions, (2) social pressure and positive emotions with others, and (3) temptation and craving.

According to the cognitive-behavioral relapse model [39], individuals with effective coping responses and high self-efficacy are less likely to elicit the problem behavior. When an individual faces a high-risk situation and has access to the appropriate coping behavior, the successful use of this coping behavior increases self-efficacy [5, 6]. This accomplishment should reduce the probability of subsequent relapse in similar high-risk situations. If an individual does not use the appropriate coping behavior, the attractiveness of substances will increase while self-efficacy to abstain decreases, escalating the likelihood that the individual will use the substance in that particular situation. Guilt and low self-esteem can occur if the substance is used during this period of abstinence. These feelings can propel an individual from the initial use of alcohol, often termed a "lapse", into a full-blown relapse.

Marlatt and Gordon [39, 40] describe the onset of guilt and lowered self-efficacy as a possible effect of a lapse from an initial goal of abstinence. They label this reaction as the Abstinence Violation Effect. This reaction is related to the individual's causal attribution for the slip. For example, when drinkers attribute the lapse to their own personal failure they tend to experience guilt and negative emotions that can lead to increased drinking in an attempt to avoid or escape those feelings. When people attribute the lapse to stable, global factors that are beyond their control, they are more likely to avoid a full-blown relapse. A subsequent relapse is more likely for those who attribute the lapse to a personal inability to cope with high-risk situations [39]. It is the individuals who are able learn from the mistake and avoid future relapses that are better able to develop effective coping skills to deal with triggers [34].

Review of Relapse Prevention and Substance Abuse Studies

Since the advent of a focus on relapse and maintenance and, in particular, the response to the detailed, conceptual perspective of the Relapse Prevention Model, interventions designed to prevent relapse have been developed as a clinical application of Marlatt and Gordon's model [39]. The conceptual foundations of this model and a review of its applications have been recently updated by Marlatt and Donovan [38]. These interventions are designed to enhance the maintenance stage of intentional behavior change and emphasize self-management and coping skills in order to withstand the challenges presented by relapse precipitants [38]. The goals of relapse prevention are twofold: to prevent an initial lapse and to provide lapse management to prevent a complete relapse if a lapse does occur. Although treatment goals based on harm reduction and decreasing substance use have also been attempted, most controlled studies that administered relapse prevention treatment measured outcome success based on the goal of abstinence [12, 30].

The effectiveness of relapse prevention as an intervention has been reviewed for a variety of different substances, as well as compared with a variety of alternative interventions. Relapse prevention programs have been designed specifically for smoking, alcohol, marijuana, cocaine, and other drug use. Although early reviews concluded that there was little evidence for differential effectiveness of relapse prevention across classes of substance abuse [12], later reviews found some support for the greater effectiveness of relapse prevention when applied to alcohol or polydrug use disorders in combination with medication treatment [30].

In terms of comparative efficacy, relapse prevention has been found to be superior to no-treatment control groups , and equally effective as other treatments, such as supportive therapy, social support groups, and interpersonal psychotherapy [12]. Another review of relapse prevention [30] found that relapse prevention has a greater impact on improving psychosocial functioning than on reducing substance use. Relapse prevention also was more effective when combined with use of prescribed medication. Although results were based on a small number of studies and should be interpreted with caution, Irvin et al. [30] concluded that individual, group, and marital modalities were equally effective in preventing relapse in cohorts of substance abusers. What follows is a brief review of the literature on the efficacy and use of relapse prevention strategies with different types of addictive behaviors. A detailed presentation of the standard elements is included on the section entitled Strategies for Relapse Prevention.

Effectiveness Studies Across Addictive Behaviors

More research has been done on the effectiveness of relapse prevention for alcoholism and nicotine addiction than in any other area of addiction. The recent second edition of *Relapse Prevention* by Marlatt and Donovan [38] provides a detailed chapter on relapse prevention for each of the addictive behaviors. For most drugs of abuse, relapse prevention constructs and strategies have been applied in clinical settings. However, there is limited literature on specific relapse prevention treatments separate from more generic cognitive-behavioral approaches, and the research consists mainly of trials focusing on the Abstinence Violation Effect or other dimensions of the model. It is disappointing that there have not been more studies of the entire model and its efficacy specifically in preventing relapse across multiple behaviors. However, since cognitive behavior therapy approaches have incorporated many aspects of the relapse prevention strategies and evaluations of the cognitive behavioral approaches in addictions have been favorable in terms of effectiveness and efficacy in trials [12], there is some empirical support for many of the constructs and the strategies that are described later in this chapter.

Relapse Prevention has been found to be most effective in treating alcohol and poly-substance use compared with other substances alone (cocaine, marijuana, cigarettes, etc.) or abusive behaviors [30]. Reviews of alcohol and drug treatment studies generally report a broad, multidimensional range of outcomes that include reductions in use, increased time before relapse, and improvement in functioning [12].

A comprehensive review of relapse prevention interventions for smoking cessation conducted by the Cochrane Collaborative found insufficient evidence to support use of interventions designed specifically to prevent smoking relapse in those who already successfully quit [27]. Nevertheless, many relapse prevention strategies have been included in standard tobacco dependence treatment (knowing personal and environmental cues for smoking, delaying and urge management, relaxation, rewards, etc.) and are incorporated into self-help, and internet-assisted programs [59]. Thus, relapse prevention has become a core component of intervention for smoking cessation, rather than a separate and independent intervention specifically designed to prevent relapse. The advent of pharmacotherapies that can be used to promote smoking cessation and enhance long-term success (Chantix®, nicotine replacement products, Zyban®) have made them part of the standard empirically supported approaches to quitting and maintaining smoking cessation.

Critical Mechanisms for Relapse Prevention

An increasing number of studies indicate that the prevention of relapse or promotion of its inverse, successful maintenance of change, involves several overarching constructs. The key dimensions are motivation, coping, and self-efficacy. These three elements are critical to the long-term success of recovery and are important components to address in any program attempting to prolong abstinence and prevent relapse.

Motivation

Motivation plays an important role in relapse prevention. There is ample evidence that motivation for change as well as treatment outcome expectancy and client goals of abstinence are related to successful treatment outcomes [55, 56]. Motivation at the beginning of treatment and the attitudes and intentions that individuals bring into treatment are related to early cessation of drinking and drug use as well as long-term success [46]. Individuals who enter treatment after making a decision to change and taking steps toward change have a better prognosis compared with those who enter treatment not have yet made a decision or taken steps [31]. Those who appear more committed to change and demonstrate this in the treatment sessions by statements that indicate a determination to change (labeled "commitment language") also have better outcomes [1]. In addition, studies have found that relapse prevention is less effective for individuals who have low initial readiness [24].

How motivation and expectancies affect successful change and prevent relapse are not completely understood. Motivation is clearly multidimensional and involves different mechanisms of change [22]. If motivation is viewed as a series of tasks outlined by the stages of change, there are multiple elements that are necessary for the success of recovery and the prevention of relapse. For example, in order to avoid relapse, addicted individuals need to have some continuing, compelling reasons to abstain, a firm decision based on realistic expectations, commitment to follow through despite difficulties, an effective set of strategies and plans on how to manage triggers, and the ability to problem solve effectively when the plan is not working. These tasks outlined in the five stages of change have to be accomplished in a "good enough" manner to be able to sustain change and overcome the difficult challenges presented to anyone stopping or modifying an addictive behavior [20]. As individuals begin to have some success at changing the addictive behavior, their motivation to make an attempt to change has to shift to motivation to sustain the change over time in the face of the multiple personal and environmental barriers

that could undermine the decision, the commitment, the determination, and the plan. Triggers have to be met successfully and the centrifugal forces that bring one back to the addictive behavior, be they physiological, behavioral, or social/environmental, must be countered.

One way to understand the function of relapse in recovery is to see it as a sign that the motivational tasks involved in the stages have not been adequately addressed or successfully mastered. So relapse serves to indicate that the process of change has not been done well enough to support success. Recycling through the stages then serves to help the addicted individual "get it right" in terms of accomplishing these tasks to a degree that enables change to be maintained and relapse to be avoided. Much of the work of relapse prevention has focused on the cues and triggers that precipitate relapse. While those precipitants are important, they do not explain relapse [59]. Looking more broadly at the entire process of change and successful completion of multiple tasks of the stages can help clinicians explore a range of challenges and topics that span the entire motivational process instead of focusing only on the moment of the slip, lapse, or relapse.

Coping

Strong support has been found for a relationship between coping and relapse prevention [51]. Those who fail to use any coping response in a crisis have been found to be more likely to relapse [18]. There are two main theoretical aspects of coping responses: (1) the focus of coping and (2) the methods of coping [51]. In both of these areas there is an important distinction between active coping and avoidant coping. In terms of focus, active coping strategies are those which are oriented toward the problem, whereas avoidant coping strategies rely on avoidance of the problem. Active strategies are most appropriate when an individual has some control over the situation; whereas avoidant coping may be more useful when dealing with situations or events in which there is little or no control [48]. Methods of coping involve strategies and coping activities that involve both cognitive and behavioral strategies.

An individual's inability to utilize an effective coping behavior when he or she is experiencing a high-risk situation results in decreased self-efficacy and increased use of a substance as a coping mechanism [39]. However, differential effects have not been found for cognitive coping skills versus behavioral coping skills. Rather, actively engaging either type of coping skills seems to facilitate positive outcomes [9, 18]. In summary, it appears that in preventing relapse there is an important role for the addicted individual's response to any threats to abstinence or recovery. However, it is not only the actual effectiveness of the response but also the sense of confidence that the individuals have in their ability to perform the behaviors critical to recovery and to sustain change.

Self-Efficacy

Confidence in one's ability to perform behaviors seems a critical mechanism in intentional behavior change. Bandura [5] defined self-efficacy as the degree to which an individual feels confident and capable of performing a certain behavior in specific situations. The self-evaluation of one's confidence to remain abstinent has been associated with lower rates of relapse for both men and women, in inpatient and outpatient settings, and for both short-term and long-term follow-ups [10, 26, 55].

Deficits in abstinence self-efficacy have been found to be a significant predictor of relapse in a number of studies [29, 65]. Moreover, the longer an individual stays abstinent, the stronger their self-efficacy and sense of personal control becomes. Higher levels of self-efficacy have been found to be predictive of improved alcohol treatment outcomes in a variety of contexts [2, 55].

In a study that investigated abstinence self-efficacy of inpatient alcoholics in predicting their ability to remain abstinent after treatment, the level of abstinence self-efficacy measured at discharge from the residential center was the strongest predictor of abstinence at 1-year

follow-up [29]. Additional support has been found for the predictive power of abstinence self-efficacy using the Alcohol Confidence Questionnaire [65]. Higher levels of confidence to resist the urge to drink in high-risk situations were associated with greater likelihood to maintain abstinence 6 months after treatment. Also, lower levels of confidence in situations related to urges and testing control were found to predict relapse to heavy drinking during a 12-week treatment period [7]. Greenfield and colleagues [26] found that those who relapsed to alcohol the year after hospitalization had lower overall confidence scores than those who did not relapse. This later relapse onset for the group with higher self-efficacy indicates a relation between efficacy to abstain and duration of abstinent behavior following treatment.

A large clinical treatment trial for matching participants to optimal alcohol treatments based on a number of client characteristics, Project MATCH, considered abstinence self-efficacy to be an important variable for determining appropriate treatment. Levels of abstinence self-efficacy were measured at the start of the study (baseline) and at the end of treatment (post-treatment). For the outpatient arm of the study, baseline abstinence self-efficacy was predictive of drinking outcomes during treatment, throughout the 1-year follow-up, and at a 3-year follow-up [23, 56]. However, for aftercare clients, baseline self-assessment of abstinence self-efficacy did not predict post-treatment drinking, suggesting that efficacy was a more powerful predictor for those individuals who were just beginning therapy, compared with those who were continuing treatment and may have already experienced changes to their levels of abstinence self-efficacy or who evaluated their self-efficacy in a residential setting.

Strategies for Relapse Prevention

The challenge of preventing relapse is one of trying to find strategies that can support and increase motivation, can teach or implement appropriate coping activities when internal or external cues trigger a desire or temptation to drink or use drugs, and can encourage and strengthen the self-efficacy of the addicted individual. Proper motivation, coping and efficacy would then support recovery and prevent relapse. Most programs and models of treatment and mutual help provide activities and support that target these variables. Alcoholics Anonymous, for example, encourages continued self-reevaluation (e.g., moral inventories, reading supportive literature), active coping both in avoiding high-risk situations, and turning to meetings and a sponsor to support sobriety, and supports efficacy with a focus on one day at a time and messages of empowerment based on support from a higher power. However, the most extensive discussion of relapse prevention strategies comes from the social learning and relapse prevention models.

Relapse prevention is best used with clients who have finished an initial detoxification round of treatment and/or may be coming to the end of initial phases of treatment since they are the ones who have been able to achieve some measure of abstinence or change. In addition, rates of relapse are highest in the initial phases of the action stage and once initial treatment has been completed. Relapse prevention would also be appropriate for individuals who have experienced a slip after a period of sustained abstinence, and as a follow-up treatment for individuals in the maintenance stage of change [42].

Relapse prevention treatment strategies have been divided into five specific categories of activities: (1) assessment, (2) increasing insight/awareness, (3) skills trainings, (4) cognitive strategies, and (5) lifestyle interventions. Each of these activities will be described in detail below. The activities are interconnected and there is a logical flow beginning with the initial strategy of behavioral assessment, which often starts with self-monitoring by the client. The goal of this behavioral assessment is to get a clear and complete picture of the circumstances surrounding potential substance use, and the client's reactions to each of those situations or cues. If the client is still actively

using substances, it is critical to obtain accurate information about the amount, environment surrounding the use, and the events that preceded and followed the use. The next step is to identify high-risk situations, coping skills, and the effectiveness of both cognitive and behavioral coping strategies being used to address the cues [32].

Once key skill deficits are identified, coping skills training can be conducted using either group or individual sessions. An advantage of the group format is that peers are natural partners for role plays, and can provide examples of coping or scenarios for group brainstorming. Including significant others in sessions can also potentially assist in cue reduction and coping training and have a comprehensive impact on a client's recovery [32]. Finally, the focus turns to the lifestyle of the individual to see how overall patterns of life activities can help of hinder continued recovery and the maintenance of change. We will review each of these components in greater detail and then discuss two newer strategies that have been added to the relapse prevention tool box: mindfulness strategies and medications.

Assessment

Behavioral assessments can be conducted using direct observation by a therapist (when cues are available or presented), role plays, interviews with family members or peers, self-report questionnaires (Alcohol or Drug Abstinence Self-Efficacy; Alcohol Confidence Questionnaire, Situational Confidence Questionnaire), and self-monitoring [34, 64, 66]. In fact, self-monitoring serves not only as a means of gathering information, but also as an intervention. While clients may initially be resistant to self-monitoring as a homework assignment, frequently after completing it, they report it is a positive experience. In addition to the insight gained though the self-assessment, monitoring often acts as a catalyst for behavior change and leads to a reduction of the monitored behavior [35]. Self-monitoring can also be an effective tool to combat denial, challenge cognitive distortions, and identify substance-related automatic processes and negative thoughts, by which a client is on "autopilot" during a sequence of behaviors that lead to using [66].

If the individual is still engaging in the addictive behavior then using self-monitoring to assess the factors surrounding use is important. If the client has been able to achieve abstinence, a self-assessment of cravings is appropriate to identify their personal high-risk situations. A frequently used type of self-assessment is assigning a drinking diary or craving diary to identify habit patterns, potential triggers, high-risk situations, consequences of use to themselves as well as others, and the physical, emotional, and financial costs of using. It is important for the individual to understand the social, situational, emotional, cognitive, and physiological precipitants of relapse that make up a high-risk situation [66].

High-risk situations are any situation that threatens an individual's abstinence self-efficacy and poses a strong potential for relapse back to the addictive behavior. High-risk situations include both intra-personal determinants as well as inter-personal determinants. The intra-personal determinants include both positive and negative emotional states as potential risk factors. Negative emotional states such as anger, depression, anxiety, boredom, and frustration can be triggering particularly if substances were used as a way of dealing with the emotional states. Clients may need additional treatment such as anger management or therapy for depression in addition to drug counseling to give them the coping skills to deal with such negative emotions [32]. Positive emotional states such as feeling good, confident, or celebrating can bolster overconfidence in being able to handle "just one" use of the substance [34]. Interpersonal determinants include conflicts with friends, spouses, family members, and co-workers. Another interpersonal determinant is social pressure that can either be overt encouragement to use, or covert pressure to conform in a situation where everyone else may be smoking, drinking, or drugging [66].

Once the self-assessment has been completed, this information can be used to create a decisional balance sheet that helps to concretely lay out the pros and cons of using in particular situations. Such a worksheet can clarify the specific reasons for maintaining abstinence and increase motivation particularly for individuals who are not fully committed to treatment or recovery. Assessments can not only identify high-risk situations but also examine the commitment, self-efficacy, and coping skills that the individual may use to address challenging situations.

Insight and Awareness

Increasing insight and awareness assists clients in understanding the processes that trigger a relapse including social pressure, physiological mechanisms, or emotion management. Understanding these mechanisms is an important part of preparing for high-risk situations and unexpected triggers and urges. This can be made more concrete by creating an ongoing road map to relapse by which clients identify upcoming high-risk situations, as well as potential unexpected risks and emergency situations. They can also identify early warning signs that predict a high-risk situation [25]. The road map can also identify ways they can refrain from using with an effective coping strategy for a particular situation [34]. The next challenge is to make sure that they have access to the types of skills and self-management strategies that would be needed to effectively address their risk situations that could provoke a return to the substance use or addictive behavior.

Behavioral Coping Skills

The behavioral skills training component involves training in a number of skills and strategies in different life domains to assist clients in resisting relapse. Skills training is designed to develop specific skills needed to cope with situations and to increase the client's sense of self-efficacy to sustain recovery and overcome risks for relapse. For example, relaxation training can be particularly helpful with clients who used substances to alleviate anxiety or to cope with stressful situations. Progressive relaxation training or mindfulness meditation can assist in decreasing anxiety in a high-risk situation enough that an alternative coping strategy can then be employed [67]. Assertiveness training can assist clients with poor social skills in navigating interpersonal pressures to use, as well as encouraging use of social support for continued abstinence. Practicing ways to refuse substances, deal with criticism, and appropriately express feelings of frustration, anger or anxiety can assist clients in building their repertoire of coping skills [66].

Cue exposure is another cognitive behavioral technique that is used to build up client's abstinence self-efficacy through gradually exposing them to substance-related cues. It is a counter conditioning procedure in which clients are progressively desensitized to the stimuli associated with the addictive behavior in controlled conditions. Clients practice using coping skills as they are gradually exposed to different high-risk situations. In order to avoid iatrogenic effects from putting clients in potentially very unsettling conditions, exposure should always end with adequate processing of the experience and debriefing such as a relaxation exercise or meditation [3, 67].

There are numerous skills that can be developed and there are manuals for various types of addictive behaviors that contain modules for specific skills training in effective communication, anger management, coping with negative emotions, depression, assertiveness, handling rejection, meditation, and managing family members who use substances. These modules can be used depending on the types of situations that are identified by the addicted individual so that the relapse prevention strategies can be personalized to the types of situations and cues that are most salient for that individual [47].

Cognitive Strategies

In addition to behavioral skills, there are also a number of cognitive strategies that can be taught and used to combat relapse. Often relapse is precipitated not just by the external cues but by the interpretations and self-statements from within the individual when confronted with a high-risk situation. Cognitive strategies are designed to challenge and change ways that individuals process information and problematic self-statements that undermine coping and efficacy. These cognitive strategies include cognitive restructuring, relapse rehearsal, labeling and detachment, and coping imagery. Cognitive restructuring is the process of correcting addiction-related cognitive distortions and frequent patterns of thinking such as seemingly irrelevant decisions and the abstinence violation effect. Seemingly irrelevant decisions are decisions which are not inherently related to the actual substance use, but can put the client in a high-risk situation. An example would be a client getting his car fixed at a mechanic one block from his favorite bar (alcohol-associated cues). Doing so could prompt him to go in to see if any friends (interpersonal pressure) were around as a way to alleviate the boredom (negative emotion) of waiting for his car to be fixed [34]. The goal of cognitive interventions is to help individuals examine and prevent such seemingly irrelevant decisions that put individuals in harm's way and can lead to relapse.

As was previously noted, the abstinence violation effect is a potential reaction to initial use or reengagement in the addictive behavior. If after a lapse clients feel they failed and experience a significant decrease in abstinence self-efficacy, they are more likely to go back to using as much as they used to rather than attempt to regain abstinence. It is important to put a lapse into proper perspective so that clients can return to the recovery process rather than returning to their prior habits. Recovery from a slip seems to require an interpretation and attribution of the lapse as caused by external or environmental factors, a continuing commitment to the change goal, a confidence in the ability to recover from a lapse, and a reactivation of active coping to avoid or manage the triggering situations or cues [34].

Relapse rehearsal and relapse fantasies are a means of associating the coping skills learned in treatment with a crisis situation. By imagining a high-risk situation and using an effective coping skill to avoid substance use, the client is able to prepare for a variety of high-risk situations and evaluate the expected effectiveness of different coping strategies. Labeling and detachment are coping strategies aimed at helping clients experience urges and cravings without succumbing to them. This strategy reframes cravings as temporary sensations of desire as opposed to unending compulsions that dictate a client's behavior. Helping clients view cravings as coming from environmental cues, and not coming from within themselves, can assist in decreasing the subjective strength of the cravings [66].

Other coping strategies to deal with urges include challenging the urges, recalling negative consequences of using, thinking of the benefits of not using, thought stopping, distraction, delaying a decision of whether to use or not, leaving the situation, and getting support from others [32]. Coping imagery is another cognitive technique that can assist with combating high-risk situations. Making use of guided fantasy, the therapist and client can make use of personally relevant imagery that can bolster the individual's self-efficacy to avoid relapse [66].

Seeking support for abstinence and recovery from a slip involves both cognitive and behavioral strategies. Individuals that have social networks filled with drinking or drug use that they cannot leave are more prone to relapse and need to recognize the need to change the composition of the network and build another one that is supportive of recovery [37]. Mutual help groups like Alcoholics Anonymous and Smart Recovery offer opportunities to listen and understand the perspectives and experiences of others and offer both cognitive and behavioral coping activities for the addicted individual [53].

Lifestyle Interventions

The final stage of the process of change is to integrate the new behavior into the lifestyle of the individual [20]. Replacing dependence with abstinence or excess with moderation generally involves a change not only in one behavior but in the addict's overall way of life. Lifestyle interventions for relapse prevention include lifestyle balance, substitute indulgences, positive addictions, and stimulus control techniques. Lifestyle balance is a global strategy to ameliorate stressful situations, promote appropriate coping, improve problem solving, and increase pleasurable activities such as hobbies or spending time with friends and family that were replaced by substance use. It is also important for clients to understand that their desires not to be depressed or to be social, which can lead to high-risk situations, are reasonable desires. However, they need to find alternative ways of fulfilling these needs without using substances or turning to other problematic, addictive behaviors [34]. Mutual help groups and activities can play an important role in offering a venue and a series of activities that can support the lifestyle changes.

Substitute indulgences are activities that are immediately gratifying and can serve as a substitute for the addictive behavior when a client experiences an urge or craving. One example is to take a hot shower or bubble bath instead of going to a bar to relax after a difficult day at work. It is important however, that the pleasurable activities are not harmful in the long term. Positive addictions have a similar function in that they replace the activity of substance use, but have more long-term rewards and value, rather than immediate gratification. Examples of positive addiction include taking up a sport, regular exercise, or a new hobby. It is important that positive addictions be practical and something that the client is able to perform and sustain on their own [34].

Stimulus control techniques attempt to address the physical cues for relapse. A frequent example is the strong association of drinking and smoking, either of which could serve as a cue for the other. While experiencing some cues is inevitable, it is an important step for a client to eliminate the cues under their control by changing their routine as much as possible. An example for a client who is quitting smoking would be to throw out all cigarettes, ashtrays, and lighters, rearrange the furniture so that a favorite smoking area is not present, and change the morning routine so that it does not revolve around the first cigarette of the day [34].

Mindfulness-Based Strategies for Relapse Prevention

Recently another set of strategies has been added to relapse prevention treatment called mindfulness based relapse prevention. The basic structure and goals of relapse prevention remain the same but there is an emphasis on the use of mindfulness techniques throughout the intervention process. Mindfulness meditation is a metacognitive skill learned through practice of meditation that allows the individual to achieve perspective, patience, and inner peacefulness that can reduce relapse cues and create lifestyle changes to promote recovery [8].

Mindfulness is a state of detached awareness of emotions, cognitions, and physical sensations. It is a state of attentional focus which can be used to change client's attitudes towards their thoughts, feelings, and sensations. Mindfulness based relapse prevention uses development of the mindfulness state to disrupt maladaptive cognitions by heightening awareness of cravings without identifying with, judging, or reacting to them. The mindfulness state interrupts the chain of cognitions and emotions that follow an urge or craving thus decreasing the likelihood of an action based on them [67]. Mindfulness appears to work differently than thought suppression, which prior studies have found to be an ineffective coping technique [8]. There have been promising initial findings regarding the usefulness of mindfulness in relapse prevention with incarcerated substance abusers, though more thorough investigation is necessary [8].

Medications for Relapse Prevention

Medications have also been found to be useful adjunct to promote change and prevent relapse in treatments for nicotine, alcohol, and opiate addiction. Since the 1990s both Naltrexone and Acamprosate (Campral®), have been added to disulfiram (Antabuse®) as approved medications in the United States to be prescribed for alcoholism treatment [36]. Use of disulfiram causes a flushing or sick reaction when alcohol is ingested, which results in extremely low compliance, and as a result has not been found to be superior to placebo. Meta-analyses have shown that both acamprosate and naltrexone can help reduce cravings and increase days abstinent [42]. Acamprosate may be more effective in promoting complete abstinence, while naltrexone may be more effective when the treatment goal is reduced drinking, though there have been mixed clinical outcomes [57].

Methadone, buprenorphine, levo-alpha-acetylmethadol, and naltrexone have been used to treat heroin addiction. Opiate maintenance using methadone, buprenorphine, or levo-alpha-acetylmethadol assist in decreasing the extremely high rates of relapse in treatment for opiate addiction, although the medications themselves can be addictive at high doses as well as have negative side effects [62].

Medications for nicotine cessation include a variety of nicotine replacement products, varenicline tartrate (Chantix®), and the antidepressant bupropion (Zyban®). In an analysis of over 6,000 articles, researchers found that use of medications for nicotine replacement therapy including gums, inhalers, patches, and nasal sprays, as well as the antidepressant bupropion at least doubles the likelihood of quitting compared with placebo. In addition, the effects of medications are substantially increased when added to behavioral interventions [16].

Although there have been studies of medications to treat cocaine addiction, they have not resulted in improved treatment outcomes with any consistency [42]. It is generally recommended that medications be administered in addition to a psychosocial intervention such as relapse prevention for opiate and nicotine treatment [15, 16, 62], though investigations of combined therapy and medication have showed mixed results compared with either alone for treating alcoholism [4, 57].

When Relapse Prevention Fails

All of the above strategies are designed to help the addicted individual achieve and maintain change once initiated. However, as many of the studies demonstrated, these strategies are helpful to some but not others [9, 28]. Even individuals who have been taught coping strategies and acknowledge the critical cues or triggers that make them vulnerable to relapse have not been successful in preventing relapse. This is when successful recycling promotion has to be substituted for relapse prevention. Clinicians and researchers working in addictions have to take a life course perspective, abandon the single attempt, linear model of success, and see the process of successful change as better represented by a cyclical process that in the long run yields success change [54]. We will discuss the life course perspective and the cyclical model below.

A Life Course Perspective on Recovery

Alcoholism and drug addictions are chronic conditions that can span decades and numerous periods of treatment, remission from drinking or drug use, relapse to uncontrolled drinking, and treatment re-entry. Treatment providers have a comparatively small amount of contact with clients in their overall treatment and recovery careers. It is important to understand the factors and context outside of treatment that are related to clients' entry into treatment and that precipitate relapse episodes. Taking the life course perspective of recovery is an important step for researchers in order to truly appreciate the full context in which a particular treatment episode "succeeds" or "fails" [21].

Some individuals with less severe dependence are able to avoid the cycle of relapse and maintain either continued abstinence or a lower level of non-harmful substance use [41]. However, the recovery process of many addicted individuals is marked by multiple transitions in their treatment career. In long-term follow-up studies spanning up to 16 years, researchers have consistently found that individuals who received treatment sooner and spent more time in treatment had longer periods of remission from alcohol dependence. Greater use of alcohol was predicted by less self-efficacy, greater use of avoidance coping, and less of a perception that drinking was a significant problem [49, 50].

Successive Approximations, Recycling, and Learning from the Past

As described earlier, learning how to overcome an addiction and to avoid relapse is essentially a process of successive approximations whereby addicted individuals try to modify the addictive behavior, fail to complete the change, then try again until they are successful or until death, disability, or prison intervenes. There is no guarantee of success even after multiple attempts since the learning may not be complete or the physiological or environmental barriers are too great for this individual to overcome. However, large numbers of individuals who have been classified as dependent on a substance have been successful in significantly changing addictive behaviors after multiple attempts. Half of the "ever smokers" in the U.S. have quit smoking successfully and we have over 40 million of these success stories [13]. A recent epidemiological study by Dawson and colleagues [19] examined over 4,000 individuals who had had a lifetime diagnosis of alcohol dependence. Based on past year drinking, they estimated that approximately 47% could be considered in full remission and were classified as either abstinent (18.2%), low-risk drinker (17.7%) or asymptomatic risk drinker (11.8%) with only 25% meeting the criteria for being dependent during the past year. This study highlights once again that the definition of relapse determines whether you consider someone in recovery or relapsed. Nevertheless, recovery does happen for many addicted individuals, demonstrating that over time there is significant change and successful self-management of addictive behaviors.

Relapse represents a problem in the preparation, planning, or implementation of the action plan. As such, it highlights some deficit or barrier that needs remediation or a different solution. Relapse then, should be viewed from a pragmatic and learning perspective. Trial and error are an integral part of psychological principles and medical practice. If one strategy or medication does not seem to help the individual completely manage the problem or begins to cause more problems than it solves (e.g., side effects), practitioners would quickly try another strategy or medication. However, often with addictions the inability to succeed has been viewed as a deficit of motivation, will, or character. A learning perspective that views the relapse as an opportunity to learn from the past and do something differently accurately reflects longitudinal research and would be critical to creating effective relapse prevention activities that reflect the reality of recycling.

Promoting recycling represents a valid relapse prevention strategy that accepts the occurrence of relapse. Recycling engages individuals who have relapsed in a review of past success and failure with a view of finding what went right or wrong and when or where it occurred so that the deficits in motivation, coping, or self-efficacy can be remediated and the types of barriers that led to the relapse surmounted. In longitudinal studies, many individuals get stuck in the process of change and remain in precontemplation or contemplation for months or years [11, 63]. The goal of recycling is to help individuals make another more successful attempt to change the addictive behavior more quickly and effectively. Policies and practices that limit access to services after a relapse or interpret relapse as a failure of the treatment undermine the recycling process.

Treatment Recommendations

There are several important considerations that summarize this review of relapse prevention and recycling in the addictions. Each of these considerations has important implications for treatment and research. We will highlight below the key considerations and implications.

1. Relapse is part of the process of successful behavior change. Partial success and outright failure offer opportunities for learning that are critical for long-term successful recovery. As in other areas of life, the important reality is not that you have fallen down, but that you get back up and try again, hopefully having learned important lessons about how to achieve the goal without falling down again. Relapse prevention begins at the start of the change process and should be an integral part of all treatment programs. However, addicted individuals may not be able to avoid and practitioners may not be able to prevent all relapse. In their efforts to promote maintenance and prevent relapse, treatments and treatment providers should concentrate on helping individuals manage motivation, engage in critical coping activities and support and increase their self-efficacy to perform the behaviors needed to achieve abstinence and recovery. In addition, special attempts should be made to engage or reengage individuals who relapse in a conversation and collaboration to promote recycling to remedy the problems in the process of change that contributed to the relapse.
2. Maintaining change is the goal of relapse prevention. A number of elements have been identified as important maintenance enhancers that also act to prevent relapse. Commitment fueled by solid decision-making leading to adequate planning, skills acquisition and implementation, and a long-term goal and perspective seem to be critical to sustaining significant modification of addictive behaviors. A comprehensive perspective on the process of change and a life course perspective appear to be essential when addressing and comprehending relapse.
3. Support sustains success. Support from family, friends and peers seems to play an important role in prevention relapse. Individuals who seek support and engage in mutual help groups have better outcomes [60]. Creating or supporting existing support groups and helping individuals access and utilize the support can assist in relapse prevention. Integrating the relapse prevention model perspective with the mutual help perspective offers social interactions and support that can enhance personal coping, motivation, and self-efficacy.
4. Multiple problems complicate maintenance of change. Pay attention to complicating life problems be they financial, family, social, medical, legal, and psychiatric in origin that can have an impact on successful recovery from addictions [44]. Psychiatric illness and emotional distress are risk factors for becoming addicted and act as barriers to beginning and remaining in recovery. Integration of treatment efforts across multiple problems seems to offer the best potential for successful change of the addiction as well as the other problems.
5. Stigma stifles success. Viewing relapse as a failure and relapsers as "defective people" who cannot change promotes the stigmatization of addictions in general, and relapsers in particular. Relapse is a problem of behavior change and not a unique problem of addictions. Addressing and managing relapse is part and parcel of all efforts to change established patterns of behavior and to manage chronic illnesses.

Contents

Drug Use and Problems

A broad range of treatment approaches are available and necessary for the management of persons with problem drug use. Individuals with problem drug use can present anywhere along a continuum from early-stage problems associated with acute, "recreational", or binge use to severe drug dependence with major physical and psychosocial problems. This latter group commonly has multiple health problems with poor or negligible non-drug-using social support and requires intensive intervention, often with the objective of achieving abstinence. Traditionally, most therapeutic resources were directed at the management of this group. These interventions have generally been intensive in nature and costly to deliver, and have failed to reach the majority of those using these substances [64].

While the impact of drug dependence on health and society is widely recognized, the effects of non-dependent excessive drug use are often underestimated by the community and the health-care system. For example, the number of non-dependent heavy drinkers far outweighs the number of dependent people [63], with most alcohol-related problems resulting from people drinking below levels that cause major physical dependence, so this group has a greater influence on the community's burden of alcohol problems: the so-called prevention paradox [42].

In 1990, a report by the Institute of Medicine recommended that given the number of people with mild or moderate alcohol problems, a range of therapeutic approaches needed to be developed to cover the full gamut of alcohol use problems [35]. Similar conclusions could be drawn concerning clinical and subclinical use of other types of substances. Table 1 summarizes

Table 1 Categories of substance use disorders and problems

Category	Description
Dependence – DSM-IV [3]	A period of maladaptive substance use and the presence of three or more criteria relating to tolerance, withdrawal, and impaired control of consumption levels occurring anytime over a 12-month period. In addition, social, occupational, or recreational activities are largely abandoned and replaced by substance-related behaviors (obtaining, using, and recovering from substance use)
Abuse – DSM-IV [3]	A maladaptive pattern of usage that causes significant clinical distress or impairment over a 12-month period and impacts on social and functional capabilities
Dependence – ICD-10 [85]	A syndrome of psychological and biological symptoms that have occurred for at least a month or repeatedly over 12 months. The criteria cover impaired control, withdrawal, tolerance, and preoccupation with use of the substance and persistent use despite evidence of the harmful consequences
Harmful – ICD-10 [85]	Clear evidence of physical or psychological harm, including impaired judgment or dysfunctional behavior
Hazardous – WHO [22]	Use of a drug that will probably lead to harmful consequences for the user if it continues at the same level
Risky [33]	Those who drink/use other substances in a way that creates a risk of harm to themselves or others

Current United States alcohol guidelines recommend no more than two drinks (12 fluid ounces of regular beer, 5 fluid ounces of wine, or 1.5 fluid ounces of 80-proof distilled spirits) per day for men and one for women, with zero drinks being the only safe option in some cases (e.g., pregnancy, whilst operating machinery, or with some medications) [77]
DSM-IV = *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition; ICD-10 = International Statistical Classification of Diseases and Related Health Problems, 10th Revision; WHO = World Health Organization

key definitions for problematic use of alcohol or other substances.

Drug Treatment in Primary Care and Non-Specialist Settings

People who consume hazardous levels of alcohol (use that will probably lead to harmful consequences for the user if it continues) rarely seek treatment [63]. Indeed, less than 30% of individuals with alcohol use disorders are likely to have sought professional care in the previous year [75], and only 14% of those with other substance use disorders seek professional help [4]. People with early-stage problem drug use commonly present to general practitioners or community health services for reasons that are not drug-related, whilst in hospital emergency departments, health workers typically encounter a greater proportion of cases, such as acute trauma presentations, accident, injury, and overdose, that are common consequences of drug use [16].

The non-dependent population, unlike their dependent counterparts, typically have an intact psychosocial fabric and, therefore, do not require the intensive interventions directed at dependent individuals [55]. The identification and effective management of these individuals before the development of more significant drug use, dependence, and associated major physical and/or psychosocial problems are clearly desirable. Those who have early problem drug use but who are not dependent are a major target group for early identification, with the most widely accepted method of achieving changes in drug use by this group being via use of brief interventions.

Screening of clients that is directed at the early identification of "at-risk" drug users and the use of brief interventions provide an efficient way of reaching a larger portion of those with alcohol or other drug problems than do traditional intensive interventions, and may be especially suited to those with less severe diagnoses [53]. By using opportunistic interventions, brief interventions may be able to reach a proportion of those who may never present at

specialist treatment facilities [12, 80]. Moreover, screening in primary care for subclinical alcohol consumption or other drug use to identify "at-risk" individuals allows preventive measures or treatment to be initiated before clinical-level disorders and the associated health and social problems develop.

A large number of short screening tests are available to aid in the systematic identification of alcohol or other drug use problems in primary care [10]. Two of the most commonly used tests are the Drug Abuse Screening Test [68] and the 10-item Alcohol Use Disorders Identification Test. The latter was developed by the World Health Organization and validated in numerous countries and populations [64, 65]. It is also available in three shortened versions and has been used widely [58]. The Drug Abuse Screening Test is available as a 28-item form [68] or a 10-item short form [29] and screens for general drug abuse rather than a specific class of drug. The brevity of these instruments and their ease of use make them suitable for a range of general medical settings. Biological screening tests (e.g., breath, hair, urine, saliva, laboratory markers) would appear to offer a more robust assessment, but to date these are of limited use in primary care, where results are needed quickly, must be inexpensive, and must show more than just recent use [1, 10, 36]. Therefore, biological assays may be more appropriate in specialist settings or where they are required to comply with judicial requirements.

What are Screening and Brief Intervention?

Screening and brief intervention are generally used as part of a consultation in a primary care setting—for instance, general practice or a community health service. However, as is explored in more detail below, some brief interventions may be initiated at a "teachable moment" such as in general hospital emergency, medical, or surgical departments, when individuals may be highly motivated to change their behavior.

Brief interventions are sometimes described as "minimal" interventions due to the less intensive nature of the intervention required to effect changes toward more positive drug use patterns in these non-dependent individuals, or as "early" interventions because they are directed at individuals who have not progressed to more serious drug use patterns. However, even at the extreme end of the spectrum, screening and brief intervention have a role in identifying people with dependence and enhancing referral for treatment.

There is no universally accepted definition of what constitutes a "brief" intervention. Babor provided a convenient heuristic where a single client contact with a professional constitutes a "minimal" intervention, 1–3 sessions constitute a "brief" intervention, 5–7 sessions a "moderate" intervention, and 8 or more an "intensive" intervention [7]. Miller and Wilbourne suggested that 1 or 2 sessions of treatment constitute a brief intervention [51], whilst Moyer and colleagues used a threshold of 4 sessions to define brief interventions [53]. In the first section of this chapter, the focus will be on interventions that can be delivered in 4 or fewer sessions. In the second section, the focus will be on brief interventions to increase compliance with pharmacotherapies used in the treatment of problem alcohol or other drug use, which often extend over 12 or more sessions.

Notably, none of these definitions delineate the length or content of the intervention. Interventions are typically of 30–45 min duration; however, within a community/primary care setting, interventions can be incorporated within a 5- to 10-min physician consultation [25]. Five key elements have been identified for inclusion in an intervention. First, the clinician assesses the quantity and frequency of alcohol or other drug usage and provides direct feedback to the client on information regarding health or psychosocial morbidity relevant to his or her level of use. Second, goals for alcohol or other drug use are established that are acceptable to both provider and client. These goals may be a reduction in consumption, such as using alcohol at a "safe" level, or complete cessation,

as is commonly employed with tobacco use. Third, the provider uses behavioral modification techniques—for example, to help the client identify high-risk situations and develop strategies to deal with these. Fourth, the clinician should supply support material on problems associated with substance use plus self-help techniques. Fifth, the provider should offer ongoing support [25]. Others have summarized the content under the acronym "FRAMES" [12]—that is, *F*eedback on personal risk, personal *R*esponsibility for the problem, *A*dvice that is clear and explicit, a *M*enu of options on how to change, an *E*mpathic style of counseling to avoid coercion or authoritarianism, and enhancement of the client's *S*elf-efficacy [12].

Babor and colleagues provided a thorough discussion of the psychological principles and behavioral change strategies thought to underlie early or brief intervention programs; these incorporate principles from social, cognitive, and behavioral psychology to increase motivation and commitment to change [9]. For example, a health professional can be seen as having social power, and, as a credible source of relevant health information, the provision of normative information allows social comparison and support networks to use social influence to modify behavior [9].

A concept that often arises in the screening and brief intervention literature is that of the "teachable moment" when a person is particularly likely to be open to changing his or her behavior—for example, when a major health event or hospitalization related to substance use occurs [30]. McBride and colleagues suggested a model to help determine whether a given event, such as hospitalization for a substance-related morbidity, will cue the client to reduce his or her substance use [50]. First, does the event (e.g., hospitalization or ill health) serve to increase perceived risk from the client's use of the drug and the potential for positive outcomes to occur if the use is reduced or ceased? Second, does the event provoke a strong emotional response? Third, does it lead to redefining the person's self-concept? For instance, a child being diagnosed with asthma may be associated with smoking by a parent, leading to the parent re-evaluating his or her role as a protective caregiver. Even in the presence of all these factors, pre-existing individual factors may override the impact of the event. Nevertheless, delivering interventions at a teachable moment is likely to amplify greatly the impact of the intervention—for example, increasing cessation of smoking by up to 70% compared with a background quit rate of about 5% [50].

Nevertheless, some have contended that the stress associated with a hospital presentation and the often chaotic environment in hospital emergency departments may mean that this is not a conducive setting in which to deliver an intervention. However, it may still be appropriate to use the opportunity to arrange a follow-up intervention [47], and there is the possibility of using motivational techniques to encourage people to attend treatment rather than attempting to deliver "treatment" under these difficult conditions. Indeed, one of the earliest brief interventions based in emergency departments was an attempt to facilitate referrals for treatment for those individuals with alcohol-related problems [15].

Screening and Brief Intervention—Effectiveness and Delivery

Alcohol

Of all the strategies and pharmacotherapies for treating alcohol use problems, there is more evidence, particularly from studies of high methodological quality, to support the use of screening and brief intervention than any other type of intervention. This is still true even when motivational interviewing is categorized separately from other forms of screening and brief intervention [51]. Brief interventions are also the highest ranked intervention in clinical populations, although this form of intervention is most effective when those with more severe disorders

are excluded [53]. The focus on clients with less severe alcohol use problems means that "safe" use of alcohol can be the goal of the intervention rather than complete abstinence, which has been the traditional goal of more intensive interventions.

Although there is robust and extensive literature on the use of screening and brief intervention for alcohol use problems [12, 53, 82], a criticism has been raised that these conclusions were based on select populations and from tightly controlled clinical trials [39]. From a health care perspective, a critical concern is whether or not this type of intervention can be translated into the clinical setting of primary care. A meta-analysis of trials conducted in primary care using interventions that would be suitable for inclusion in clinical practice (i.e., physician interventions of 5–15 min or nurse interventions of 20–30 min) identified 28 trials, including 5 that used the motivational interviewing approaches [39]. Overall, brief interventions reduced alcohol consumption by 41 g/week at 1 year. Brief interventions also seem to be effective at reducing binge drinking and heavy drinking, albeit that these conclusions are based on a limited number of studies and that the studies used different definitions to categorize heavy use of alcohol (criteria ranged from 20 to 35 drinks/week for men and 13–35 for women) [39]. The main caveat identified by the research was the lack of a significant reduction in alcohol use by women, but this may be related to lack of statistical power, with only 499 female participants out of the 7,286 included in the review [39]. This is a potentially important limitation as women are more likely than men to seek help from primary care providers [75]. On the other hand, a recent meta-analysis did not find gender differences in the effectiveness of screening and brief intervention [53], suggesting that lack of statistical power may indeed be the explanation.

Brief interventions also have a sound health economics rationale with a positive cost-benefit ratio, with significant savings through reduced health costs as well as reduced costs to society—for instance, in reducing vehicle accidents [27]. The magnitude of this effect has been estimated at 5.6:1 at 12 months and 4.3:1 at 48 months when considering just reduced health system costs [26, 27]. Thus, an intervention that costs $205 per individual to deliver resulted in an average benefit of $1151 [26]. Including savings to the wider community, the total benefit was $7985 per intervention [27].

Tobacco

All forms of intervention to encourage the cessation of tobacco use are cost-effective in terms of cost per life-year saved [79] and with the cost of these interventions comparing favorably with virtually any other health care program [76, 79]. Whilst improved rates of cessation accrue from more intensive interventions, these improvements do not keep pace with increased costs. However, this should not be used as a reason for not delivering more intensive interventions, which may be particularly efficacious in those with more severe problems, for whom brief interventions are typically less effective [79].

Guidelines are available for primary care practitioners, such as physicians, nurses, and dentists, to aid in the development of screening procedures and the delivery of appropriate interventions for users of tobacco [24, 81]. The United States guidelines evaluate a range of different psychosocial and pharmacological interventions as well as the management strategies for identifying and treating smokers in different primary care settings. The guidelines emphasize the importance of screening all patients for tobacco use and recommend strategies for approaching those willing to quit, those unwilling to quit, and those who have recently quit [24]. However, it also has been suggested that repeated advice to asymptomatic smokers may be counterproductive [67], contrary to the guideline recommendation that smokers should be asked about their use of tobacco on every visit. Potentially, the importance of this guideline may be derived from the development of systems that help to ensure that cessation of tobacco use is

thoroughly integrated into clinical practice rather than through increased benefits to an individual.

The initial approach recommended is a brief intervention that can be delivered in approximately 3 min, summarized under the mnemonic the "5 A's" (Ask, Advise, Assess, Assist, and Arrange). These guide the practitioner to ask every client about tobacco use at each visit, to advise them clearly and in a personalized manner to quit tobacco use, to assess their current willingness to quit, to assist them in forming a cessation plan, to provide them with access to counseling and appropriate pharmacotherapies, and, finally, to arrange a follow-up appointment, if possible within a week of the agreed-upon quit date [24].

If the client is not willing to quit, a further brief intervention can be delivered that focuses on increasing the motivation to quit (see Chapter "Motivational Interviewing" for detailed information on motivational interviewing). This brief intervention is formulated under the mnemonic the "5 R's" (Relevance, Risks, Rewards, Roadblocks, and Repetition). Thus, the intervention should focus on aspects that are personally relevant, such as current health problems, and should encourage the smoker to identify the risks of tobacco use and the rewards that will accrue with cessation. Any potential roadblocks to cessation should be addressed and solutions generated. Finally, the intervention should be repeated on each occasion that the client is seen.

Given the chronic relapsing nature of nicotine dependence and other addictive disorders, it is important also to plan and deliver relapse prevention interventions, especially in the first 3 months after a person has quit smoking. This typically involves the use of open-ended questions to encourage discussion of benefits, successes, and problems encountered as well as providing encouragement and help with significant problems, such as depression or withdrawal symptoms.

A recent meta-analysis of randomized trials with at least 6 months follow-up of brief interventions by physicians found that a single session lasting up to 20 min, plus up to one follow-up session, increased the rate of cessation by 1–3% over the background rate of cessation (2–3%) [69]. However, the effectiveness of this approach is derived from screening all participants and intervening with those who are smokers. The main drawback identified was the difficulty of persuading physicians to incorporate it into regular practice.

Brief interventions by nursing staff are also effective at producing small but significant increases in successful quitting. However, the authors of the analysis stress that statistical heterogeneity indicates that this finding may not generalize to all patient groups or clinical settings equally [59]. Nevertheless, the United States guidelines recommend that interventions by all non-physician clinicians (i.e., nurses, psychologists, and dentists) can be justified empirically compared with no treatment or self-help [24].

Smoking cessation interventions delivered in a hospital would appear to be an ideal opportunity, particularly with the expansion of "smoke-free" hospital policies in many developed countries. However, a recent meta-analysis concluded that high-intensity behavioral interventions initiated in a hospital that included at least 1 month of post-discharge support were effective, but that lower-intensity and shorter-duration interventions were not found to be effective [60].

Illicit Drugs

The weight of evidence supporting the utility of brief interventions in treating alcohol use or cigarette smoking is in striking contrast with the dearth of studies on the use of these techniques for illicit substance use problems. Two Cochrane reviews of psychosocial treatments for opiate use and of psychosocial and pharmacological treatment for opioid detoxification did not identify any studies that used brief interventions for the psychosocial component [2, 49]. Similarly, a Cochrane review of psychosocial interventions to treat cocaine and other psychostimulant disorders failed to identify any brief

interventions that matched the inclusion criteria [41]. A third Cochrane review of interventions to reduce drug use by young people conducted outside the school setting [28] and an earlier review of interventions for adolescent alcohol, tobacco, and other drug use [72] identified one brief intervention with adolescent substance users [54].

Oliansky and co-workers delivered different interventions at each of three sites that served different substance-using clients. An adolescent clinic and female-only clinic received a primarily information-based intervention on the adverse effects of substance use. The third clinic, which served general adult clients, delivered a 10-min intervention to empower clients to take responsibility for their drug use. Compared with usual care, the adolescents and the general adult group reported reduced drug use at 3 months [54]. A more recent brief intervention used the screening and referral approach where adolescents who presented to emergency departments with alcohol or other drug problems were encouraged to attend external agencies for treatment. The authors reported that this type of intervention could be successfully delivered in emergency departments but noted that the yield (proportion of adolescents attending treatment), although significant compared with usual care, was low [73, 74].

A number of programs have used brief interventions in individuals with cannabis use problems, but the dominant paradigm has been the motivational interviewing approach [8, 19, 48, 70]. Lang and colleagues conducted a pilot study using brief but intensive psychotherapy, which had promising outcomes in reducing the quantity and frequency of cannabis use [43]; however, the assessment and intervention took 2.5 h and the theoretical framework falls outside the basic information approach of brief interventions. In addition, the study did not contain an effective control group, so the improvements cannot be attributed reliably to the treatment. As with the interventions for cannabis use, motivational interviewing techniques also have been used in other illicit drug treatment projects [6, 13]. With respect to volatile substances, little research has been conducted on treatments specifically for inhalant users, so clinicians have adopted methods from interventions for other addictive disorders, including cognitive behavioral therapy and motivational interventions [83]. Similarly, there have been few studies of brief interventions to reduce the misuse of licit drugs [11, 20].

Conclusions—Screening and Brief Interventions

Brief interventions are a well-recognized and empirically validated approach to the treatment of addictive disorders, particularly in the primary care setting. However, the key aspect is initiating procedures so that all clients are regularly asked about their alcohol or tobacco use and appropriate actions are taken. Nevertheless, some key shortcomings have been identified. First, there are sparse data on the use of screening and brief intervention with illicit substances or the misuse of licit substances. Second, the effectiveness of screening and brief interventions with women, at least for alcohol use problems, has yet to be established definitively. Given the greater use of primary care by women, this potential deficit is of concern. Third, the effectiveness of non-clinician screening and brief intervention programs for tobacco use needs further clarification [24].

Future Research

In 2007, Wilson Compton of the National Institute on Drug Abuse concluded that there were currently few data to support the use of screening, brief intervention, referral, and treatment for illicit drug use and no research to support this with respect to prescription drug use [18]. However, this is likely to change in the near future, with the National Institute on Drug Abuse and the Substance Abuse and Mental Health Services Administration calling for research project submissions in this area. In addition, the Substance Abuse and Mental Health Services Administration-funded programs have already

screened over 500,000 people, with preliminary data indicating benefits in reducing alcohol and illicit drug consumption [66]. The increasing misuse of prescription and over-the-counter medications, with emergency department visits up 21% between 2004 and 2005 [71], is a cause of concern that has resulted in calls for research funds to be directed to this area, including the evaluation of screening, brief intervention, referral, and treatment programs to identify and intervene with the users of these licit substances [17]. Furthermore, whilst there is extensive evidence for the effectiveness of screening and brief interventions, further work is required to determine the best referral processes for specialist treatment for those who do not respond to brief interventions [10].

Improving Compliance/Adherence to Pharmacotherapies

The first section of this chapter assessed brief interventions that aimed directly to address problem use of alcohol or other drugs. One limitation was that these interventions were most effective with individuals who had less severe disorders. However, brief interventions also can be used to increase compliance with pharmacotherapies. Used in this manner, they can have a role outside the specialist addiction treatment setting in addressing alcohol or other drug dependence. The second section reviews two models that have been used under this rubric.

Brief Behavioral Compliance Enhancement Treatment

Brief behavioral compliance enhancement treatment provides a standardized manual [37] that aims to improve the outcomes associated with pharmacotherapy, rather than constituting an independent intervention. It does this by enhancing behavioral compliance with a pharmacotherapy, in particular by increasing expectations of the effectiveness of that therapy. Brief behavioral compliance enhancement treatment was developed from the clinical management used in the National Institute of Mental Health collaborative trial on depression [23]. The original trial included clinical management that aimed to maximize the effectiveness of the pharmacotherapy through improved compliance and, simultaneously, to minimize loss to follow-up to maintain the validity of the trial. It should, however, be emphasized that the clinical management used in the National Institute of Mental Health collaborative study did not include any elements that can be considered psychotherapy and that its content was not based on any validated data but on clinical experience [23].

A manual-driven and standardized version of brief behavioral compliance enhancement treatment has been developed for clinical trials in the addictions, especially in the alcoholism field, and has now been used in several multi-site studies. The brief behavioral compliance enhancement treatment program is spread over 13 10- to 20-min sessions and is usually provided as weekly sessions [37]. An advantage of the brief behavioral compliance enhancement treatment program over other brief interventions is that it is customized to suit the development of different types of medication. As part of this customization, brief behavioral compliance enhancement treatment can be adapted to treatment protocols that target either abstinence or a reduction in hazardous drinking as the clinical endpoint. Brief behavioral compliance enhancement treatment encourages compliance not only with pharmacotherapy but also with general treatment adherence. Indeed, providing encouragement to the patient, even for small treatment gains, is an important aspect of brief behavioral compliance enhancement treatment. Generally, the brief behavioral compliance enhancement treatment program consists of three phases covering initiation, maintenance, and termination of treatment. The initiation phase is critically important and seeks to engage the client in a positive and trusting relationship that fosters adherence with the treatment regimen and educates the patient with regard to the harmful effects of alcohol

and the potential side effects of the medication. The clinician performing brief behavioral compliance enhancement treatment emphasizes the importance of medication use, develops simple behavioral repertoires to enhance medication compliance, and builds a realistic expectation of success but also discusses how potential side effects can be managed. Indeed, a flexible and naturalistic clinical feature of brief behavioral compliance enhancement treatment is that it can be administered by a trained provider within the scheduled format for the collection and discussion of side effects. Also, from the first session, the clinician providing brief behavioral compliance enhancement treatment establishes a platform for ascertaining progress with drinking changes. Notably, a unique aspect of brief behavioral compliance enhancement treatment over other brief interventions is that the patient sets a weekly target drinking goal. The second phase aims to maintain compliance and particularly to avoid early termination of pharmacotherapy. The clinician explores the gains made by the client and addresses any medication side effects that have appeared. The final phase examines how medication use can be terminated while still maintaining improvement in drinking outcomes and how these gains can be maintained without assistance [37]. The moderate amount of time required to implement brief behavioral compliance enhancement treatment means that it can be incorporated easily within research programs [38] and has the potential to translate into primary care. The potential for brief behavioral compliance enhancement treatment to translate into primary care is important because it increases access to care for alcohol-dependent individuals. Studies are needed to determine the utility of brief or compliance-based treatments in severely disadvantaged groups [62] or among those who presently receive complex treatment regimens [32].

Medical Management

Medical management is another intervention that has been developed to enhance compliance in pharmacotherapy trials for alcohol dependence. Medical management was derived originally from brief interventions. It is designed to be delivered in a medical setting and provides a cohesive program of brief intervention, pharmacotherapy support, and information [57], with the aim of achieving abstinence [45]. However, in considering the content and delivery of medical management, it should be remembered that it was developed as part of a research intervention and, as such, was also constrained so as not to overlap with the alternative behavioral intervention delivered in that program (combined behavioral intervention) [46]. Given that limitation, medical management may not contain the optimum elements for an intervention. For example, medical management specifically excluded elements that require specialist training or that were deemed too intensive and would impede the contrast with combined behavioral intervention [45, 57].

Medical management focuses on three areas: education, adherence to medication, and support to aid recovery. The key element in the education program is an individualized report by the clinician to the client on his or her health status and the role of alcohol in the development of health problems. Although derived from brief interventions, medical management can be quite lengthy in its administration. For instance, the initial session typically takes 40–60 min. Additionally, information is provided on the medication that the client will receive (i.e., naltrexone or acamprosate). Like brief behavioral compliance enhancement treatment, medical management also emphasizes the importance of adherence to the medication regimen. This includes discussion of side effects, likely time scale for treatment, and, importantly, why the medication is likely to be effective. The final element of medical management is support and optimism about successful treatment. A detailed manual [56], including information sheets for the practitioner and client, is available from the Web site listed in the Resources section below.

Medical management was designed to be delivered over 4 months with nine sessions [45, 57]; thus, it falls outside the typical criteria for a brief intervention, and the extent to which it will be adopted in the primary care setting has yet

to be established. Indeed, medical management might not translate readily into primary care because the training of providers can be an intensive process. Nevertheless, within the research paradigm of the COMBINE study, medical management had the lower intensity of the two behavioral interventions (i.e., medical management and cognitive behavioral intervention) that were evaluated along with two pharmacotherapies [5]. In that study, naltrexone in combination with medical management, but not cognitive behavioral intervention, was effective at reducing heavy drinking [5]. A different approach to the delivery of medical management, termed BRENDA [78], was used in the evaluation of targeted nalmefene, a mu opioid antagonist, as a treatment for alcohol dependence. Study results suggested that targeted nalmefene might have utility as a treatment for alcohol dependence [40].

Conclusions—Compliance Enhancement

Brief interventions provide primary care health workers with a framework to deliver interventions to any client presenting with substance use disorders. Brief behavioral compliance enhancement treatment and medical management provide an extension to brief interventions if clients are interested in receiving pharmacotherapies to aid in cessation. Some elements of these pharmacotherapy compliance approaches appear simply to be "good clinical practice", such as advising clients on how medications should be taken and warning of potential side effects. However, by providing these treatments as a structured manual-driven framework, they enable the clinician to approach with confidence a group of clients who are often regarded as difficult to treat in a variety of settings.

Future Research

There is a growing literature on methods of improving adherence (now generally used instead of "compliance" due to its less pejorative connotations) to psychotropic medications, especially among individuals with severe mental illness, such as those with schizophrenia [14]. It is estimated that about 76% of individuals with physical health problems are compliant with medications, compared with 65% of those prescribed antidepressants and 58% of those prescribed antipsychotic medications [21]. However, the high prevalence of comorbid alcohol or other drug problems and other mental health disorders, with an elevated level of associated mortality and morbidity [44, 84] combined with the low rates of successful cessation in this population [31, 61], illustrates the urgent need for the development of cessation programs for this group. The existing literature on adherence to psychotropic medication and the compliance enhancement programs for pharmacotherapies in treating alcohol or other drug problems suggests that it should be possible to design effective programs for this highly disadvantaged group.

Compliance enhancement interventions may also prove beneficial in supporting the use of pharmacotherapies with other addictive disorders. For instance, oral naltrexone has been approved for the management of heroin dependence, but poor compliance means that it is not generally regarded as an effective treatment [52]. However, in highly motivated individuals or with daily supervision, the effectiveness is increased [34]. Therefore, a trial using brief behavioral compliance enhancement treatment with oral naltrexone in a general heroin-using population appears to be warranted.

Defining Self-Help

Help from without is often enfeebling in its effects, but help from within invariably invigorates. [111]

Self-help behavioral treatments encompass those strategies designed to moderate or extinguish substance use or associated negative consequences. Inherent within the definition are two fundamental and essential properties of self-help: (1) the strategies are self-initiated and self-maintained, and (2) the strategies do not involve enduring relationships with professional care providers, professional supervision or authority, or illicitly obtained prescription drugs. Under this umbrella fall techniques such as non-prescription substance substitution or replacement, bibliotherapy, helplines, spirituality and mindfulness, and Internet resources, as well as a variety of self-help groups. Each technique ranges in cost, intensity, availability, and effectiveness depending on the type and severity of the addiction. This chapter begins with a brief review of relevant literature related to self-help in addiction including reviews of natural recovery [113] and processes of change described

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_40,

in the Transtheoretical Model of Change [99]. Following description of this literature, with the exception of self-help groups (discussed in detail in Chapter "Substance Use-Focused Self-Help Groups: Processes and Outcomes"), this chapter reviews several specific self-help approaches and their applicability to various substance addictions as well as their availability to self-administrators.

Why Use Self-Help?

There are several reasons why an individual may opt for self-help methods as an alternative to professional care to manage substance use. One reason may be barriers of access to treatment. In a national telephone survey of 14,985 residents from 60 randomly selected U.S. communities, of those who reported that they needed help for substance abuse, well over one-third received no professional treatment, less treatment than they needed, or delays in treatment [119]. A common barrier to formal services for drug addiction concerns the cost of treatment, which can lead some individuals who want help, but don't believe they can afford it, to manage their own care. Stigma and the associated negative attitudes that practitioners, medical staff, and other health professional may convey toward the addicted, as well as the person's own feelings of shame or embarrassment, can also deter someone from seeking professional rehabilitation services [86]. In these instances, certain self-help methods can allow for anonymity and affordability in the recovery process.

Is Self-Help Good for Everyone?

Addictive behaviors can be modified or even terminated through self-initiated processes [99]. As described later in this chapter, individuals who were once dependent on various addictive substances have managed, through means of self-help alone, to change their behavior. Notwithstanding this, there are certain substance addictions from which it is virtually impossible or impractical to attempt to recover solely through the means of self-help. In fact, many self-help materials are not available for certain substance addictions (e.g., heroin or cocaine) without adjunct supervision from a caregiver or institution. With the exception of natural recovery (see below), heavy drug users are unlikely to recover by relying exclusively on their own resources. Therefore, most of the sections in this chapter will cover self-help methods that are available and potentially effective for substance addictions.

Self-Help as Empowering

Lacking professional guidance, self-helpers run the risk of potentially acquiring inadequate or ineffective information. However, self-help has the advantage of enabling individuals to achieve the internal resources necessary to feel a greater sense of control over their behavior and their environment. This cultivated sense of power can have positive effects on self-esteem, self-efficacy, and personal responsibility [68]. These personal tools can breed the confidence and stimulation necessary to prevent relapse or sustain the recovery process [99]. It may also motivate individuals who need extra assistance to seek professional help for their addictions [56].

Can Individuals Help Themselves?

At least two somewhat overlapping and extensive bodies of research literature have directly addressed the extent to which people can and do transition from problematic substance use, abuse, or dependence to less problematic use, moderate use, or abstinence without treatment or attendance in "self-help" groups such as 12-step affiliated programs. These bodies of literature roughly correspond to the topics of

natural recovery and the *Transtheoretical Model of Change.*

Natural Recovery

Natural recovery refers to the process by which many individuals who experience considerable difficulties related to substance use change without any formal assistance. Some individuals appear to simply "mature out", whereas others change in response to a specific event or set of circumstances. The most comprehensive review to date of natural recovery from problematic alcohol and/or drug use (excluding tobacco) considered 40 samples of participants in 38 studies published between 1960 and 1997 [113]. The majority of studies of natural recovery have focused on alcohol, with heroin being a distant second. Studies of natural recovery have largely relied on retrospective reports of participants' reasons for changing. These narrative accounts raise questions regarding potential memory distortions, self-serving biases, and/or inaccurate attributions of the effectiveness of specific factors leading to change. Nevertheless, they provide potentially important insights into successful self-help strategies. In the Sobell et al. [113] review, health concerns were the most frequently reported reason for reducing or eliminating substance use by successful self-changers, followed by financial reasons and negative personal reasons (e.g., shame and guilt). More importantly, the factor most strongly associated with successful maintenance of change was *social support*. Other factors for which successful maintenance was attributed included: *development of or return to involvement in activities not related to substance use; work-related changes; general lifestyle changes; religion; willpower*, and *changes in residential situation*. Another factor that has been consistently associated with natural recovery is *cognitive evaluation*, where individuals begin to consider that the costs of their substance use come to outweigh the benefits. In many cases, this process may correspond to maturation and may occur in different stages of the life cycle.

Maturation Effects

Related to the idea of natural recovery is the process of "maturing out". Epidemiological literature and studies of "natural history" indicate that the highest rates of alcohol and other substance use occur during late adolescence and early adulthood [107]. Increasingly referred to as "emerging adulthood", the period of time corresponding from about high school graduation through the early 20s is associated with increased risk behaviors and experimentation. A majority of young adults who use substances as part of this period, even at problematic levels, reduce or eliminate use as they assume career and family responsibilities [107]. Individuals who experience substance use later in life and who reduce use without formal help tend to be in their mid 40s and report their heaviest use to be in their mid-to-late 20s [105], further suggesting that, for many, natural recovery may be a maturational process.

With respect to research related to natural recovery, the majority of the literature has focused on alcohol. Other specific substances have also been examined in the context of natural recovery, including nicotine, marijuana, cocaine, and heroin, with relatively similar findings across substances. Natural recovery from nicotine, alcohol, and marijuana is reviewed below.

Nicotine

The vast majority (>80%) of individuals who quit smoking do so without treatment [73, 113]. Narrative accounts of successful quitters versus temporary quitters or non-quitters suggest that successful quitters report more severe consequences, more focused reasons, and more negative affect in describing reasons for quitting [46, 49]. Successful quitters also are more likely to have and/or take advantage of good social support for quitting, to change their environment, and to feel less ambivalent about changing.

Alcohol

By far the majority of the literature on natural recovery from addictions has focused on alcohol. Consistent evidence now suggests that a large proportion of individuals who experience problems with drinking are able to transition to moderate use or abstinence without formal help [105, 112]. Nevertheless, public perceptions have remained more consistent with an incurable and progressive disease model of alcoholism. These sentiments are likely reinforced by 12-step programs, which begin with the assumption that individuals are powerless over alcohol use and that it is not possible ever to recover fully but only to keep the disease at bay by remaining abstinent [20, 21].

Individuals who successfully maintain natural recovery from problematic drinking often report initial motivation related to fear or anticipation of unacceptable life changes resulting from drinking, concern for the influence of one's drinking on his or her children, and religious inspiration [13]. Successful self-changers are more likely to have positive social support networks, be married, have higher self-esteem, and report less drug use and lower frequencies of intoxication [105].

Marijuana

Relatively little research has examined natural recovery from problematic cannabis use [113]. One 25-year follow-up of Vietnam veterans found that 82.5% of cannabis quit attempts were without treatment and that 88.3% were successful [98]. Consistent with findings from the alcohol literature, a recent study examining natural recovery from cannabis use [31] found that self-change was most often initiated in response to changing views of personal use (cognitive evaluation) as well as negative effects of use. Strategies associated with successful change included changes in lifestyle and the development of interests unrelated to cannabis use.

Processes of Change

Directly related to natural recovery, "processes of change" have been described as part of the Transtheoretical Model of Change (or Stages of Change Model) [28, 99]. The Transtheoretical Model of Change, which has been extensively applied to the field of addictions and beyond, began with interviews of former smokers regarding their experiences with change. The model describes a sequence of stages in which individuals who are not initially aware of a need to change, and are not in any way considering change (pre-contemplation), over time begin to consider the possibility of change (contemplation) and subsequently prepare for (preparation) and implement change (action). In the absence of relapse or regression to previous stages, individuals are ideally able to maintain change successfully (maintenance) over time. In the context of developing their model, Prochaska and DiClemente defined a number of processes that individuals identified as being important in their efforts to change. The processes of change include substitution, seeking information, cognitive evaluation, seeking support from others, self-rewards for change, affirmation of commitment, and restructuring one's environment.

Self-Help Drug Replacement

Substance substitution represents a potentially valuable self-help strategy for drug addictions. Drug substitution focuses on replacing harmful and addictive drugs with a less harmful substance and/or often a safer route of administration. The ultimate goal is to moderate, reduce, or extinguish substance use and the various adverse consequences associated with use. Although physiological dependence particular to each substance is discussed below, it is important to note that addictions to substances common in our culture, such as nicotine, caffeine, and alcohol, often involve a psychological component that may be difficult to overcome, particularly when the substance serves a social

role in one's life. These events may act as potential environmental triggers to relapse, and actively avoiding these social situations, whether they are interactions during a cigarette or coffee break or an evening out with friends at a bar, adds to the difficulty of quitting. Drug substitutions may serve as a beneficial self-help strategy by acting to replace the function of the addictive substance and/or alleviate the symptoms of drug withdrawal. Replacement in this manner may involve significantly lower doses or a safer route of administration of the same substance of use. Although there are a number of prescription pharmacotherapies that are administered under medical supervision, this section will focus on self-help drug replacements that are available over-the-counter, and will address drug substitution and replacement therapy for three commonly used legal substances with significant addictive potential: caffeine, nicotine, and alcohol.

Replacement and Caffeine

Caffeine is a plant alkaloid found in numerous species, which acts as a central nervous system and metabolic stimulant. It is believed to be one of the most widely used psychoactive substances in the world [34]. Caffeine is typically consumed to overcome lethargy, to promote vigilance and alertness, and to elevate mood. The major source of caffeine is coffee beans, but it is also commonly found in chocolate, tea, and soft drinks, as well as in energy drinks and over-the-counter medications for headaches, pain relief, and appetite control. Although unscheduled and recognized by the Food and Drug Administration [122] as a "safe food substance", caffeine is an addictive substance that can potentially lead to withdrawal symptoms after cessation of consistent use. Caffeine may be commonly overlooked as a drug of abuse, in part due to its nearly universal legal status and prevalence as a normative food staple. Furthermore, there is a great potential that people may be unaware of, or may underestimate, their daily caffeine consumption, as the drug is mainly associated in connection with coffee. These factors together may contribute to the development of caffeine dependence.

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition–Text Revision recognizes four caffeine-related disorders: caffeine intoxication, caffeine-induced anxiety disorder, caffeine-induced sleep disorder, and caffeine-related disorder not otherwise specified. The symptoms of acute caffeine intoxication may include restlessness, nervousness, hyperexcitability, insomnia, gastrointestinal disturbance, muscle twitching, rambling, tachycardia, and agitation. Very rarely, high doses of caffeine (>10 g) may produce respiratory failure or seizures. Regular users commonly develop tolerance to caffeine and may experience intense cravings after discontinuation. Withdrawal symptoms include headaches, flu-like symptoms, feelings of lethargy and reduced motivation, and depressive or irritable mood.

Individuals seeking to abstain from caffeine may find that the cravings can be managed by substance replacement. Because caffeine is less addictive than are other socially acceptable substances (e.g., alcohol or nicotine), replacement in social settings may be more easily achieved, providing a particularly effective way to reduce caffeine use and mitigate adverse health consequences. The most popular replacement for caffeine is decaffeinated coffee, which contains roughly 3 mg of caffeine per cup compared with an average of 85 mg per cup of regular drip coffee. International standards require that decaffeinated coffee beans are 97% free of caffeine, while the European Union standard requires beans that are 99% caffeine free by mass. This small amount of the active substance may help attenuate withdrawal symptoms including headaches, nausea, vomiting, muscle pain, and stiffness. Decaffeinated and herbal teas offer another option for caffeine replacement. Those individuals who are interested in reducing caffeine intake from soft drinks have a variety of brand options offering caffeine-free drinks. Although there is scant literature concerning the effectiveness of decaffeinated substitution for

caffeine use, replacement in this manner can be a helpful harm reduction approach to reduce significantly one's intake of the drug (in the case of decaffeinated coffee) or to eliminate intake altogether.

Replacement and Nicotine

Nicotine, another central nervous system stimulant, is a plant alkaloid found most abundantly in tobacco leaves and is thought to be the main factor responsible for the dependence-forming properties of tobacco smoke. Although inhalation of tobacco smoke is the most common route of nicotine administration, tobacco also may be insufflated or chewed. Tobacco smoke contains carbon monoxide, as well as a mixture of particulate substances generated by the combustion process that make up tobacco tar [34]. Inhalation of carbon monoxide and tar is primarily responsible for the various diseases resulting from long-term use. Researchers regard nicotine as one of the most addictive recreational substances in use [50, 51]. Similarly, the American Heart Association considers nicotine to be one of the hardest addictions to break.

According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition–Text Revision, the criteria for nicotine use disorder include any three of the following within a 1-year time span: tolerance to nicotine with decreased effect and increasing dose to obtain the same effect, withdrawal symptoms after cessation, smoking more than usual, persistent desire to smoke despite efforts to decrease intake, extensive time spent smoking or purchasing tobacco, postponing work, social, or recreational events in order to smoke, and continuing to smoke despite health hazards. Additionally, nicotine withdrawal is classified as a nicotine-induced disorder that includes symptoms such as difficulty concentrating, nervousness, headaches, weight gain, decreased heart rate, insomnia, irritability, and depression.

Because a majority of serious health hazards related to nicotine use result from smoking tobacco, nicotine replacement through other modes of administration may provide a successful harm reduction substitute. Such approaches are based on the concept that the administration of a maintenance level in a non-toxic format will alleviate the withdrawal symptoms associated with smoking cessation and reduce the risk commonly associated with the inhalation format. Indeed, nicotine replacement therapy may aid in abstinence from tobacco smoking by reducing general withdrawal symptoms, resulting in some psychological effects on craving, mood, and attention states [87, 115]. There are a number of nicotine replacement options available over-the-counter for individuals who are interested in smoking cessation. Unlike inhalation of tobacco, nicotine replacements lead to slower onset and more stable plasma nicotine concentrations [52]. Thus, the use of nicotine replacement therapy allows for the accurate titration of nicotine dose and enables a reduction of daily nicotine administration over time. A recent comprehensive review of nicotine replacement concluded that each commercially available form of nicotine replacement therapy increased significantly the rate of cessation over the placebo or no-nicotine-replacement-therapy groups and that these rates of quitting smoking increased by 50–70% [115]. Preliminary data from this review suggest that individuals who begin nicotine replacement therapy soon before their quit date may increase their success [115]. Additionally, the authors mention that there is evidence of a benefit from combining the nicotine patch with an acute dosing type (for acute cravings). Finally, they conclude that to date, there does not appear to be an overall difference in the effectiveness of any form of nicotine replacement therapy over another and, thus, the choice of which form to use should reflect an individual's specific needs and tolerability [115].

Nicotine Replacement Options

Nicotine-containing chewing gum was approved by the FDA as a pharmacotherapeutic prescription medication for use in the treatment of cigarette dependence in 1984. Now available over-the-counter in both 2-mg and 4-mg doses,

the gum leads to nicotine absorption (~50%) in the mouth through the buccal mucosa. Nicotine gum also contains 30 mg of sodium carbonate and sodium bicarbonate to enhance absorption of nicotine [50]. Individuals are instructed to chew the gum until it is soft and a peppery taste is felt, after which it is pressed between the cheek and teeth until the taste fades. Then the process is repeated. This procedure, known as "chew and park", seeks to maximize absorption of nicotine. Although individuals are instructed to chew the gum as needed, they are typically encouraged to chew at least 10 pieces/day (at a rate of 1 piece every 1–2 h) but are advised not to exceed 20 pieces of 4-mg gum or 30 pieces of 2-mg gum per day. A schedule of 10 pieces of 2-mg gum yields approximately 10 mg of nicotine, while the same number of 4-mg pieces yields approximately 20 mg/day. As the average nicotine intake per cigarette smoked is roughly 1 mg, chewing 10 pieces achieves about one-third to one-half the daily nicotine intake of a user who smokes 30 cigarettes/day [8]. A number of studies have demonstrated that the use of nicotine chewing gum when quitting smoking approximately doubles the rate of abstinence compared with placebo [54, 57, 106]. A recent comprehensive review of 53 trials assessing nicotine gum versus placebo concluded that the use of nicotine replacement gum alone significantly increased rates of abstinence [115]. Furthermore, heavy smokers have been shown to achieve greater benefit from the 4-mg gum [87, 115]. Potential side effects of chewing nicotine gum may include hiccups, nausea, indigestion, mouth sores, jaw muscle aches, headaches, dizziness, and insomnia.

The nicotine lozenge was first introduced in 2002 as another over-the-counter alternative for nicotine replacement therapy. The lozenge is a hard candy that releases nicotine slowly as it dissolves in the mouth and is available in the same 2 and 4-mg concentrations as the nicotine chewing gum. Individuals are instructed to use one lozenge at a time and to abstain from food or drink in the 15 min prior to and during use. Only one lozenge should be used at a time because using too many lozenges in a short time may increase the incidence of side effects such as heartburn and nausea. One should allow the lozenge to dissolve slowly (for up to 30 min) in the mouth, being careful not to chew or swallow the lozenge. During the first 6 weeks of nicotine lozenge treatment, individuals are advised to use one lozenge every 1–2 h. After this time, consumption is encouraged to be systematically restricted to one lozenge every 2–8 h. Heavy smokers and/or smokers who have their first cigarette within 30 min of awakening are encouraged to use the 4-mg lozenge. Consumption should not exceed 5 lozenges in any 6-h period. Similar to the nicotine gum, there is a recommended limit of 20 lozenges/day, and use is advised for up to 12 weeks. The most common potential side effects resulting from the use of the nicotine lozenge are soreness of the teeth and gums and throat irritation.

Transdermal nicotine patches, although first introduced in 1991, were marketed as an over-the-counter aid for smoking cessation starting in 1996. They consist of multilayered adhesive patches saturated with a lipid-soluble nicotine solution, leading to relatively stable transdermal delivery of nicotine throughout the day. Nicotine patches are currently available in doses ranging from 5 to 20 mg for duration of wear from 16 to 24 h. Patches come in several steps, enabling users to gradually phase out their use. This replacement method provides a continuous-release, long-acting mode of nicotine administration, resulting in relatively constant plasma levels of nicotine that are slightly lower than the concentrations produced by nicotine chewing gum. While wearing a nicotine patch, individuals are warned of the importance of abstaining from smoking as this may lead to nicotine overdose, potentially resulting in adverse cardiovascular events [34]. A number of reviews have documented that nicotine patches are a highly effective form of replacement resulting in a greater number of abstainers than placebo treatment [38, 39, 115]. A comprehensive meta-analysis found borderline evidence of a benefit of using the higher dose compared with the lower dose patch and further suggested that although the transdermal nicotine patch is generally easier to use than

other forms of nicotine replacement therapy, the patches are not effective for relief of acute cravings [115]. Potential side effects resulting from use of the nicotine patch may include skin irritation, dizziness, elevated heart rate, sleep disturbances, headache, nausea, vomiting, muscle aches, and stiffness.

Replacement and Alcohol

Alcohol is a psychoactive drug that acts as a central nervous system depressant and is a product of the metabolism of carbohydrates converted through the process of fermentation. Moderate consumption of alcohol decreases pain and anxiety, produces relaxation, elevates mood, and stimulates appetite. In higher doses, alcohol promotes drowsiness, reduces motor coordination and self-control, may lead to emotional volatility, memory impairments, and confusion, and can be fatal at extreme doses. Roughly three in four Americans are occasional drinkers, individuals who consume one or two drinks to "unwind" after a long day or participate in moderate alcohol consumption at social gatherings such as dinners and celebrations. This pattern of drinking is practiced by a majority of alcohol users without serious harmful consequences or development of dependence [34]. Conversely, the National Institute on Alcohol Abuse and Alcoholism states that roughly 1 of every 12 adults in America abuses alcohol or is alcohol dependent.

Alcoholism is defined by *The Journal of the American Medical Association* characterized by impaired control over drinking, preoccupation with alcohol, use of alcohol despite adverse consequences, and distortions in thinking [83]. Alcohol dependence includes the four symptoms of craving, loss of control over use, physical dependence, and tolerance as outlined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition–Text Revision. Mild-to-moderate symptoms of alcohol withdrawal are numerous and include nervousness, anxiety, irritability, depression, fatigue, headache, nausea and vomiting, and insomnia. Severe symptoms can be extremely dangerous and include delirium tremens (state of confusion often accompanied by hallucinations), fever, and convulsions.

Alcohol abuse can be extremely difficult to overcome, possibly requiring intensive medical treatment. There are currently three oral medications approved to treat alcohol dependence that are available by prescription under medical supervision. While it is highly recommended that an individual seek medical help for alcohol addiction, there are harm reduction measures that one may take for alcohol self-help. When dealing with alcohol abstinence, non-alcoholic beverages such as near beer and alcohol-free wine may serve as an effective replacement. These substitutes typically contain one-half of one percent or less of ethanol by volume—i.e., the maximum content that a beverage may contain to be legally called non-alcoholic in the United States. In addition to the strong pharmacological dependence, overcoming alcohol addiction can be difficult to overcome psychologically, in part because the environment associated with the substance may serve an important social role in one's life. The use of non-alcoholic replacement may help in the maintenance of abstinence by allowing an individual to continue to engage in social situations.

Drug substitution for alcohol may also be achieved with the use of herbal substances. As another legal central nervous system depressant and mild intoxicant that shares similar properties with alcohol, kava (piper methysticum) root is consumed in Pacific culture to alleviate stress and combat insomnia and has been demonstrated to be effective in reducing anxiety [95, 123]. Although there are no data concerning the effectiveness of kava use as an aid to quitting alcohol, the anti-anxiety and mildly intoxicating effects of kava may prove useful by replacing the role of alcohol in one's life and potentially mitigating some of the less severe symptoms of alcohol cessation. There is a clear lack of controlled studies concerning the effectiveness of drug substitution for substances other than nicotine and a need for direct investigation of this potentially useful strategy.

Bibliotherapy

Perspectives in Bibliotherapy

Bibliotherapy, the concept that positive change can be affected through an individual's relationship with the content of books or other written words, has been a recognized method of self-help throughout history [103]. In historic and contemporary cultures, religious materials such as the Bible serve as enduring and prominent examples of self-prescribed tools for growth and change. The concept of bibliotherapy has changed over time such that modern references may describe a spectrum of behaviors, from an individual reading a self-help manual to a professional care provider prescribing a relevant book chapter. The terminology has similarly evolved, revealing an array of alternative terms including but not limited to: biblio-counseling, bibliopsychology, biblioguidance, bookmatching, information prescription, library therapeutics, and literatherapy. At its most basic, the practice of bibliotherapy consists of a self-prescribed selection of reading materials that have relevance to an individual's life and situation. It also refers to the guided use of literature toward a desired therapeutic outcome, usually as a complement to traditional psychotherapeutic approaches [58].

Evaluating the efficacy of bibliotherapy proves more challenging than reporting on its varied uses. For the purposes of this chapter, and consistent with a number of published studies [5, 70], the term bibliotherapy will refer to the first situation, or any therapeutic intervention presented in a written format, which is designed to be read and implemented by an individual largely in the absence of professional guidance. Those empirical investigations employing congruent definitions of bibliotherapy related to substance abuse were restricted primarily to the reduction of nicotine, alcohol, and marijuana.

Bibliotherapy for Nicotine

A vast array of self-help materials designed to promote smoking cessation exist [43], from brief motivational pamphlets (e.g., American Cancer Society [2]) to comprehensive manuals addressing initial cessation through relapse prevention (e.g., American Lung Association [3]). These manuals are often based on cognitive behavioral models (e.g., social learning, transtheoretical model, and relapse prevention) and designed as translations of therapist-administered multicomponent cessation programs. Despite the assortment of literature available, the evidence for the efficacy of these resources is mixed (cf. [26]).

Although individuals who are interested in smoking cessation appear to prefer self-administered treatments such as bibliotherapy [37], research has not consistently demonstrated the ability of such materials to increase cessation rates above that of population quit rates [36], telephone counseling [25, 90], or nicotine replacement therapy [61]. This failure may be due at least in part to the populations used to evaluate self-help techniques, the majority of which have involved volunteer smokers who tend to be older, more addicted, and less confident and to have less social support than the general population of smokers [125]. Thus, the full potential of self-help interventions may not be reflected in this population, who would likely benefit from more intensive interventions [23].

With certain caveats, research has supported the efficacy of self-help interventions involving bibliotherapy for smoking cessation. Curry [23] notes that self-help materials are as effective as intensive group programs when individuals participate in the prescribed activities associated with the reading. With this qualification, the use of self-help materials is associated consistently with higher abstinence rates at initial and long-term follow-ups (cf. [23]). Some research suggests that this may be due to compliance with the program, inasmuch as individuals who are able to use self-help programs successfully are better able to adapt programmatic change into long-term lifestyle changes [24].

Bibliotherapeutic efficacy appears to be increased in some cases by tailoring the cessation materials to individual characteristics (e.g., stages of readiness to quit) relative to more general cessation materials [100]. Thus, a number of recent studies have investigated the influence of

tailored bibliotherapeutic resources, with varying degrees of success. For example, although attempts to tailor written material to firefighters by employing language common to the fire service did not produce benefits beyond the American Lung Association's guide [3] designed for the general public [89], the combination of tailored smoking outcome and self-efficacy-enhancing information produced a significant effect on smoking abstinence [29]. The most promising effects for bibliotherapeutic interventions appear to be found in combinations of personalized adjuncts, such as written feedback in conjunction with outreach telephone counseling [25, 90]. Thus, bibliotherapeutic interventions' greatest efficacy may be as an important component of a more comprehensive minimal-intervention smoking cessation strategy.

Bibliotherapy for Alcohol

Bibliotherapy materials designed to reduce at-risk and maladaptive alcohol use are conceptually similar to smoking cessation publications in that they are also often based on cognitive behavioral models, which are intended as translations of multicomponent, therapist-administered programs. Consistent with the smoking cessation literature, the evidence regarding these resources is mixed but appears promising, particularly when construed as the initial intervention in a stepped-care approach to alcohol treatment [70, 114].

Meta-analytic reviews of self-help programs designed to address maladaptive alcohol use have revealed differentially effective rates, largely dependent on the nature and severity of the treatment target. Some research suggests that maladaptive alcohol use may not be as amenable to bibliotherapeutic interventions relative to other problematic behaviors. A number of meta-analytic reviews found smaller effect sizes for bibliotherapeutic interventions addressing disruptions of "habit control" (i.e., alcohol consumption, smoking, nail biting, and overeating) relative to other treatment issues, such as mood disorders [45, 108]. In addition, a study conducted by the World Health Organization [129] found that among heavy drinkers, bibliotherapy alone was not as effective as bibliotherapy in conjunction with brief advice or counseling. Thus, some research suggests that bibliotherapeutic interventions may be more amenable to other clinical considerations, and, particularly among heavy drinkers, a more intense treatment approach may be required.

Despite these considerations, a number of studies support bibliotherapeutic interventions, particularly for mild alcohol abuse. In their 2003 review, Mains and Scogin [70] note that bibliotherapeutic interventions are better suited to address cases of mild alcohol abuse, with less proven efficacy for moderate-to-severe alcohol abuse. Moderate support was revealed for bibliotherapy in a recent meta-analysis of 22 studies evaluating self-help programs [5]. Overall, self-help treatments were found to result in decreased rates of at-risk and harmful drinking, and a small-to-medium-size effect for bibliotherapy relative to no-treatment controls was found. In a series of studies involving only limited professional contact (i.e., brief telephone contact and one 1-h session), Miller and colleagues found reductions in alcohol consumption associated with a self-help manual that matched reductions associated with more involved treatment options [78–80], which were found to be enduring at 2 [77] and 8 years [81].

In sum, although the research regarding bibliotherapeutic interventions for maladaptive alcohol use appears promising, several caveats exist. Bibliotherapeutic interventions have the benefit of being non-intrusive and inexpensive and, based on existing research, are perhaps best framed as an initial intervention in a stepped-care approach to mild or moderate alcohol abuse [70]. Consistent with the stepped-care approach, initial treatment failures or presentations involving more severe alcohol abuse may be best addressed with more intense and sophisticated interventions [109, 114].

Bibliotherapy for Marijuana

Based on a review of the literature to date, it is difficult to come to any sound conclusions

regarding the utility of bibliotherapy as an intervention for marijuana, particularly as a standalone intervention. Cunningham [18] reported that a mental health survey conducted in Canada revealed that individuals acknowledging weekly cannabis use were more interested in receiving an evaluative self-help book or a computerized normative use summary than telephone counseling or individual psychotherapy. This finding appears to suggest that similar to that for alcohol users, bibliotherapy may be a viable initial outreach intervention in a stepped-care approach among cannabis users. Cannabis users may be well suited to such minimally intrusive interventions since the majority, including those who meet the criteria for dependence, will never seek treatment [17]. However, further research is required to elucidate better the appropriateness and enduring benefits of bibliotherapy within this population.

Helplines

A helpline is a telephone-based service that provides help, information, support, and advice to callers with a wide range of problems or concerns. Common areas of service include financial advising, mental health, relational issues, technological support, and the focus of this chapter, substance addictions [40].

Helplines offer a variety of distinct advantages unique to other forms of self-help, which may make them more accessible or appealing than seeking face-to-face counseling or professional treatment. Helplines provide an efficient means for delivering treatment to populations across wide geographic areas by eliminating barriers of access (e.g., transportation, child care, or scheduling conflicts). Many helplines are government funded and free of charge to callers, which enables them to reach more underserved populations (e.g., uninsured or low socioeconomic status) [4, 9, 91]. Finally, helplines provide immediate treatment and support while preserving the caller's anonymity, a feature that may attract drug users who are already battling with the stigma associated with their drug use [55].

Helplines for Different Types of Addiction

Helplines for Nicotine

The majority of published research on substance-abuse helplines has focused primarily on nicotine dependence, often referred to as "quitlines". Therefore, the bulk of this section will be devoted to the evidence-based literature regarding quitlines. Quitlines took off in the early 1980s and have since spread throughout North America, Europe, parts of South America, Asia, Australia, and South Africa [4].

Nicotine Helpline Services

At a minimum, the majority of quitlines offer self-help resources and other mailed information to callers. This is the most ubiquitous and standard service provided by quitlines. Another common feature includes reactive smoking cessation counseling—reactive in the sense that the call is initiated by the smoker, who is able to speak with a counselor. Other services may include proactive counseling (counselor calls the client), replacement or cessation medication, chat rooms, and recorded messages [9, 59, 91].

Characteristics of Nicotine Helpline Callers and Specific Protocols

In general, smokers are four times more likely to use quitlines than face-to-face clinics [59, 130]. A recent study [91] examining the characteristics of callers to a national reactive telephone quitline found an overrepresentation of disadvantaged (i.e., African-American, women, poorer, urban, less educated, older) and heavier smokers compared with the general population. Due to the wide range of consumers, many quitlines have adopted specialized protocols to address the unique concerns of specific populations. Common specialized protocols exist for pregnant women, older adults, adolescents,

ethnic minorities, smokeless tobacco users, and callers with multiple addictions [16, 121].

Nicotine Helplines and the Transtheoretical Model of Change

Although individuals committed to smoking cessation appear to benefit most from quitline support, research suggests that quitlines may be efficacious for individuals in a wide range of readiness to change. Previous research suggests that many first-time callers to smoking quitlines have already made plans to quit, and that these individuals tend to benefit most from the quitline intervention [48]. Helgason and colleagues found that 22% of first-time callers were in the action stage (had quit for 6 months or less), 76% were in the preparation (planning to quit within the next 4 weeks) or the contemplation (interested in trying to quit within the next 6 months) stage, while only 2% were in the pre-contemplation stage (not interested in trying to quit within the next 6 months). Although those who were smoke free (action/maintenance) at the start of the intervention had the highest likelihood of being abstinent at the end of the study, there were also positive outcomes for callers in the other three stages. Half of the first-time callers in the pre-contemplation stage advanced to either the contemplation or the action/ maintenance stage by the end of the quitline intervention. Similarly, for those in the contemplation stage at baseline, half progressed to either the preparation stage or the action/maintenance stage, while only 10% (i.e., 1 of 10) regressed to an earlier stage [48]. Interestingly, although this research suggests that quitlines can help move callers from one stage of change to the next (e.g., from contemplation to action) [48, 92], many quitlines in the United States restrict services to callers who are planning to quit [16].

Helplines for Alcohol

Despite the abundance of alcohol helplines, there is a surprising dearth of research on their protocol, services, or effectiveness. In a controlled experiment based in Wisconsin [12], researchers recruited nearly 900 patients from clinic waiting rooms who were not necessarily seeking help for their drinking problems. Half of the participants received pamphlets about healthy living, while the remaining participants received telephone counseling in which counselors assisted in setting drinking goals and overcoming barriers to behavioral change. Telephone counseling reduced alcohol consumption by 17.3% for men and 13.9% for women, compared with 12.9 and 11%, respectively, for pamphlet-only conditions [12].

The most promising research on alcohol helplines has been conducted on the UK telephone-based service known as "Drinkline". Established in 1993, Drinkline receives about 6,000 calls a month, the majority of which are problem drinkers seeking help for themselves. Callers are given information about safe drinking levels, advice about how to control drinking or avoid alcohol, and suggestions for how to overcome any related problems. A survey of callers showed that 81% received the information that they needed and 91% intended to carry out a plan of action after calling Drinkline [127]. An extensive search failed to identify any comparable literature for alcohol helplines in the United States.

Helplines for Anabolic-Androgenic Steroids

One of the most advanced, established, and researched helplines that specializes in steroid use is the Anti-Doping Hot-Line founded by Swedish health authorities with the support of the Swedish National Institute of Health [30]. This helpline provides information about side effects and risks associated with anabolic-androgenic steroids, as well as facilitating contact between users and health care agents. The telephone service not only reaches out to anabolic-androgenic steroid users and concerned family and friends but also informs health professionals and organizations (e.g., public schools) about doping issues. In fact, the

majority of callers to the Anti-Doping Hot-Line are non-abusers [30]. Since the implementation and subsequent success of this Sweden-based helpline in 1993, Japan and other nations with high rates of anabolic-androgenic steroid abuse have followed suit with their own steroid helplines (primarily targeting athletes and adolescents) [121].

Helplines for Cocaine, Methamphetamines, and Opiates

Due to the highly addictive and harmful nature of drugs like cocaine, methamphetamines, and opiates, strictly outpatient and self-help methods of recovery, such as helplines, are less common. Tellingly, there is nominal research on the topic. However, 24-h, 7-days-a-week phone services do exist (e.g., National Meth Helpline, Cocaine Addiction Helpline, and Heroin Addiction Helpline) that offer no-cost assessments and dispense advice on how to stop, how to help a loved one quit, interventions, information, and various signs to look for in a potential addict. Upon calling these helplines, however, the most likely intervention is a referral to an inpatient treatment and drug rehabilitation facility.

Helplines as Self-Help

Helplines ride a fine line between self-help and assisted interventions. On the one hand, many first-time callers to drug abuse helplines have taken proactive and self-initiated measures to make the call. From there, it is often up to the caller to decide the extent or breadth of services that he/she desires. Staying within the definition of self-help, callers can have a few questions answered or request that some information be sent to their homes. Helplines start to cross over into the zone of assisted, professional help when multiple counseling sessions are involved, the individual is referred to the helpline by a hospital or medical professional, or the caller enters proactive counseling with multiple phone sessions initiated by the counselor.

Religion, Spirituality, and Meditation

The last decade has been witness to significant increases in research investigating the influence of religion and spirituality on physical and mental health, including addiction. Religion and spirituality are innately internal endeavors, albeit ones that often include corresponding external activities and, to varying extents, enduring relationships with professional providers and larger communities. A review of the literature did not produce research evaluating the role of religion or spirituality in recovery from dependence or addiction in a traditional, empirical fashion. The absence of such literature makes intuitive sense as it would be challenging to assign a random sample to a religion or spirituality condition or the absence thereof. However, given the emergence of significant research regarding these constructs in addiction, it is important to include a discussion of relevant findings. Thus, this section will include a brief review of contemporary literature on religion and spirituality in the sense that these constructs are self-initiated and self-maintained and are not externally imposed by scientists, physicians, or secular care providers. Additionally, this section will address empirical research involving meditation, which has received more recent attention as an intervention tool for addictions [10, 128].

Religion and spirituality are conceptually distinct constructs although they share some common features. For the purposes of this chapter, definitions of religion and spirituality will be based on those in the *Handbook of Religion and Health* [65] and consistent with existing literature [42]. Religion is defined as an organized system of beliefs, practices, rituals, and symbols designed to facilitate a relationship with the transcendent or sacred as well as with the greater community. Spirituality is defined as a less formal and more personal quest for

meaning, designed to address questions about life and one's relationship with the transcendent or sacred.

Religion, Spirituality, and Nicotine

Although previous research has found that both religion and spirituality act as protective factors against smoking onset [41, 44, 74], their utility as self-administered, independent interventions is less clear. Koenig and colleagues [64] found that among the elderly, individuals with a strong religious commitment were less likely to have ever smoked and, among those who did smoke, were likely to consume fewer cigarettes. With regard to smoking cessation, a review of the literature revealed one study examining religion as an intervention strategy. An intensive, culturally and religiously specific smoking cessation intervention designed to be conveyed through local churches for rural African Americans was more likely to promote positive movement in readiness to change than was a tailored, minimal self-help intervention [124]. The rituals and community associated with religion appear to have been instrumental agents for change in this population. However, these findings may better support the role of the church as a dissemination point for proactive health interventions rather than the efficacy of religion as a self-administered intervention. Further research is required to better identify the role of religion and spirituality as an independent, self-administered intervention for smoking cessation.

Religion, Spirituality, and Alcohol

Religion and spirituality appear to be influential in resiliency against maladaptive patterns of alcohol use as well as smoking. A substantial body of research delineates the protective role that religion [60, 62] and spirituality (cf. [76]) play in resiliency against alcohol use disorders. Lower rates of alcohol use disorders have been associated with private practices of prayer and scripture reading [63]. Consistently, research has demonstrated that alcohol-related negative consequences and alcohol use disorders among the highest-risk religious group, drinking members of conservative Protestant denominations [63, 71], are still only 40% of those for drinkers without religious affiliation [53].

In addition, the absence of religion or spirituality may be a risk factor for developing abusive and addictive patterns of alcohol use. Individuals with alcohol and drug problems generally report lower religious commitment and involvement relative to the general population [67, 126]. Consistent with these findings, descriptive studies suggest that individuals with alcohol and drug problems believe that receiving spiritually focused treatment would be helpful to their recovery [6, 27].

A number of sources suggest that religious or spiritual growth is an influential element in lasting recovery and a healthy life. Alcoholics Anonymous [1] frames addiction as a physical, mental, and spiritual disease requiring treatment in all three domains, the latter of which is an identified treatment stage (i.e., spiritual affiliation and growth) in their model of healthy and stable sobriety. Previous research has found that Alcoholics Anonymous members' spirituality is positively associated with life satisfaction [15], purpose in life, and duration of sobriety [14, 96]. Similarly, a study of individuals in recovery found that higher levels of religious faith and spirituality were associated with a more optimistic life orientation, greater perceived social support, higher resiliency to stress, and lower levels of anxiety [93]. Some speculate that inasmuch as religion and spirituality are protective against addiction, adoption of religious or spiritual variables may facilitate the process of recovery [84].

Religion, Spirituality, and Other Substances

Consistent with the alcohol literature, religion and spirituality appear to have protective influences against the onset of illicit drug use among

adolescents [75] and adults [41, 44, 74]. Also analogous to the alcohol literature, a lack of religious commitment may be a risk factor for illicit drug use [62]. Finally, the current literature regarding religion and spirituality and recovery from illicit drug abuse and addiction appears to be at a similar stage of development, where positive indications have been found to be associated but not yet fully elucidated.

Previous research suggests that religious and spiritual involvement exerts a positive influence in drug treatment. A recent study examining spiritual activities among heroin- and cocaine-dependent individuals revealed a weak but positive ($r = 0.16$, $p < 0.04$) association between spirituality and treatment outcome [47]. Individuals in this study who reported that they frequently spent time on religious or spiritual activities demonstrated significantly better outcomes in terms of subsequent drug use and treatment retention. Spirituality also has been associated with reduced severity of post-treatment relapses [82] and counselor-assessed treatment responsiveness [94]. In a study examining the effectiveness of coping techniques to reduce cocaine use after treatment, spirituality was one of a number of techniques associated with less cocaine use and abstinence at a 6-month follow-up [102]. While these studies are promising, they do not address the role of religion and spirituality independent of formal treatment. As such, questions remain about the utility of religion and spirituality as an independent, self-administered mechanism of change for addictive disorders.

Meditation and Mindfulness-Based Approaches

Meditation has been a spiritual and healing practice in some parts of the world for more than 5,000 years. It also has become an increasingly common practice in Western cultures within the last 40 years. In the recent past, meditation and mindfulness-based approaches to substance use disorders have received a resurgence of attention in the empirical literature and popular press. Consistent with the National Center for Complementary and Alternative Medicine, a division of the National Institutes of Health, meditation will be referred to as those techniques or practices intended to focus or control attention [85]. Similar to religion and spirituality, meditation has been characterized and defined a number of ways in the literature, often confusing the empirical picture. Also analogous to the findings on religion and spirituality, research has revealed some initial support for this technique in substance use disorders [11, 72] although a number of important questions remain.

Previous research suggests that meditation and mindfulness-based approaches to substance use disorders hold promise as a protective mechanism, intervention technique, and self-help approach. Research has demonstrated the protective influence of transcendental meditation against alcohol use disorders [7, 110]. Furthermore, some research suggests that transcendental meditation may be an effective coping technique for those at risk for developing alcohol use disorders. In a study evaluating various forms of relaxation techniques (transcendental-esque meditation, deep muscle relaxation, or quiet recreation) on patterns of heavy alcohol use among college students, Marlatt and colleagues [72] found that each technique produced reductions but that meditation demonstrated the most consistent and reliable reductions over a 6-week intervention period, an approximate 50% reduction in daily consumption. Similarly, among an incarcerated population, Bowen and colleagues [10] found significant reductions in alcohol, marijuana, and crack cocaine use post-incarceration among individuals who had participated in a Vipassana meditation course in conjunction with standard alcohol and drug classes. Those who completed the Vipassana meditation course also demonstrated decreases in self-reported psychiatric symptoms and increases in positive psychosocial outcomes. Successful addiction recovery is often related to an individual's ability to develop and employ a repertoire of coping behaviors. This research suggests that meditation may be an effective coping tool and thus may extend the duration of treatment effects by providing the skills to

prevent relapse [10, 11, 128]. However, questions remain about the mechanisms promoting change associated with meditation (cf. [128]).

In sum, existing research appears to support the positive influence of religion, spirituality, and meditation in a multidimensional approach to recovery from substance use disorders. In general, religion, spirituality, and meditation appear to increase resiliency against abuse and addiction. More specifically, religion and spirituality are associated with increased personal satisfaction and resiliency in recovery from alcohol use disorders, and all three are associated with decreased use following treatment among other substance use disorders. Thus, it seems practical to consider the positive impact of religion, spirituality, and meditation in self-initiated endeavors to address substance use disorders. However, further research is required to elucidate the influence of these constructs distinct from formal treatment and treatment groups, and to evaluate their efficacy as stand-alone interventions. Thus, although they may play a positive and potentially significant role in recovery, it is not yet understood how and in what ways religion and spirituality [76, 93] or meditation act to promote positive change (cf. [128]) and whether those effects will extend to self-initiated and self-maintained treatment.

Internet Resources

Recent years have witnessed a logarithmic expansion of reliance on the Internet for all types of health-related information. In 2004, an estimated 15% of all Internet users accessed health information related to problems with drugs, alcohol, or help in quitting smoking, corresponding to over 15 million individuals [116]. Research evaluating Internet self-help Web sites and brief interventions has expanded similarly in recent years. The bulk of the research in this area has demonstrated that the Internet is a feasible and potentially efficacious source for self-help. Relatedly, a recent meta-analysis evaluating 75 randomized controlled trials of computer-based interventions revealed that Internet interventions were associated with increased knowledge and changed attitudes across a wide variety of behaviors [97]. More specifically, the review found Internet-based interventions, in comparison with other methods of delivery, to be effective in changing tobacco use but less successful in changing the use of other substances.

A number of advantages of Web-based self-help resources have been identified, including, most notably, convenience, low/no cost, availability, and anonymity. The number of Web sites relevant to self-help for addictions is overwhelming in comparison with the relatively small burgeoning literature on Internet self-help. A quick Google search (May 21, 2008) on the phrase "quitting smoking" revealed over 2 million hits, with similar searches for alcohol (42,500) and marijuana (15,500) revealing smaller but still impressive numbers. Not surprisingly, a major challenge in using the Internet as a self-help tool is sorting wheat from chaff in identifying accurate and helpful information [117, 131]. "Webliographies", such as the one printed in *Substance Use & Misuse* in 2002 [88], can help in this process and typically include descriptions of content and purpose of a relatively small number of Web sites that are directly relevant and informative. However, the rate at which Web sites address change gives any static catalog of links a limited life span [131].

Internet Resources for Nicotine

Currently there are hundreds of commercial and free smoking cessation Web sites available, many of which have similar content, functions, and suggestions [33]. Typical content and functions focus on: setting a quit date; finding alternative activities; recruiting social support; choosing a medication; information regarding risks and benefits; chat applications, and automated e-mails. While limited research has evaluated these kinds of self-help resources, recent randomized clinical trials have shown significant but small effects on short-term abstinence,

with quit rates ranging from 3 to 18% for up to 3 months [32, 33, 69, 118, 120].

Internet Resources for Alcohol

In comparison with self-help Web sites for smoking, fewer options are available for self-help for drinking. Nevertheless, a large number of Web sites are available that offer suggestions and tools for reducing or eliminating alcohol use. Self-help Web sites related to drinking often include: a short questionnaire followed by feedback regarding responses, including how the respondent's drinking compares with population norms for same-age, same-sex individuals; assessment of risk based on a screening measure; information about alcohol's effects on the body; tools for calculating blood alcohol content; and contact information for professional help or self-help groups [19, 35]. Controlled trials of Internet-based self-help programs have generally demonstrated efficacy, with effect sizes in the small-to-medium range (e.g., [22, 66, 101]).

Internet Resources for Other Substances

Self-help options for substances other than nicotine and alcohol over the Internet are relatively sparse. While there are undoubtedly numerous Web sites that are relevant to self-help for substances other than nicotine and alcohol, the related research literature is virtually void, with the exception of a few feasibility studies (e.g., [104]).

Conclusions

Many individuals utilize self-help strategies in their efforts to overcome substance dependence and addiction. Existing research literature suggests that self-change (i.e., natural recovery) is in fact the most common route through which substance use changes occur. Self-help strategies seem to be less effective for individuals with more severe dependence. From a public health perspective, self-help strategies represent ideal mechanisms for reducing substance use-related problems because they are almost invariably low cost relative to formal treatment, and because they can be disseminated widely (e.g., bibliotherapy, helplines, and Internet). Moreover, the existing literature on self-help strategies is relatively promising, suggesting that in addition to being lower cost and widely available, self-help is also relatively effective.

The quantity and quality of the literature provide an important caveat for the rosy prospectus on self-help approaches. In comparison with the treatment literature, the literature on specific self-help strategies is considerably smaller and with fewer controlled studies. To some extent, this may be due to the inherent nature of self-help, the typical focus of health professionals on more formal treatment approaches, and perspectives on addiction that are incompatible with self-help as a viable option. By their nature, self-help strategies are less likely to draw attention from health care professionals or researchers in addiction. Thus, the prevalence of self-help strategies has remained under the radar until recently. While there is reasonably strong literature related to certain self-help approaches for some behaviors (e.g., replacement, bibliotherapy, and helplines) and substances (tobacco and alcohol), the literature related to other strategies (e.g., Internet resources and meditation) and other substances (e.g., steroids, cocaine, and heroin) is sparse. In some cases, this presents a quality control issue given the wide availability of Internet sites or self-help books with limited or no evidence that the specific suggestions proposed will be of benefit to the individual seeking change.

A number of deeper and broader issues underlie the consideration of self-help for addictions. To the extent that addiction is defined by one's inability to control use, self-help is somewhat of an oxymoron (i.e., if a person can stop, were they really addicted?). On the other hand, even formal treatment approaches require that

individuals help themselves—whether practicing thought exercises or driving themselves to an appointment with a therapist. Regardless of how either self-help or addiction is defined, it seems clear that a desire to change is fundamental in determining the success of change efforts. For many, experiencing negative consequences related to substance use is enough to initiate a self-correction process, although the form of that process may vary by individual and by substance. This chapter represents an attempt to provide a broad overview of self-help approaches for addiction, with specific examples for specific substances. Based on the available evidence, self-help strategies appear to work well for many, especially those on the less severe end of the continuum, but more nuanced questions, such as which ones work for whom under what conditions and for what substances, are in need of critical and systematic investigation.

Introduction

The first section of this chapter traces the history of community clinic treatment for substance use disorders. Then the chapter reviews various venues for community treatment and the effectiveness of approaches used where this is known. We take our definition of substance use disorders from the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision [2]. There, "substance use disorders" is defined and diagnostic criteria provided for: substance dependence, with or without physiological dependence and course specifiers; substance abuse; substance intoxication; and substance withdrawal. The disorders discussed in this chapter refer to these disorders as described in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision. Where reviewed publications do not use these definitions, other terms used by the primary source are reported.

Although alcohol and nicotine abuse and dependence are listed in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision, we limit our coverage

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_41,

of community treatment to exclude community interventions for these disorders. We define community clinic as an intervention that occurs in non-hospital settings and affiliated with individual health practitioners, or community organizations.

Literature Review Methods

In conducting this review we have used several forms of literature search software. Our primary sources have been PubMed and PsycINFO, but we have used Google Scholar as a backup supplement. Key words used were: community clinic treatment for drug dependence (abuse, addiction, substance use disorder); community treatment for drug dependence (abuse, addiction, etc.); history of community clinic treatment for drug dependence (abuse, addiction, etc.); history of community treatment for drug dependence (abuse, addiction, etc.); substance-related disorders, psychotherapy, group, community health services, and adult. In addition, where particular authors or groups of authors have published widely, we have searched sources by author names. Thus, by definition we have excluded other forms of addictive phenomena such as alcohol dependence, gambling, compulsive eating, sexual behavior, and other behaviors sharing similarities with *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision—defined substance use disorders.

History of Community Substance Abuse Treatment

We could find no historical marker for when group treatment or community clinic treatment for substance use disorders began. It is likely the first community treatment for substance use disorders in America originated in pharmacies when opium and laudanum were sold over the counter in community pharmacies. These drugs were widely available in the 1800s and much earlier before that in China, Great Britain, and other countries involved in trade with Asian sources of opium [49]. Historical sources document extensive morphine dependence as both a result of the U.S. Civil War treatment of wounded soldiers and sales of over-the-counter potions and tonics laced with opium and cocaine. The residual addiction among Civil War veterans was called “army disease”, and was extensively treated by physicians and community pharmacists with morphine or laudanum maintenance (our term), before the scientific discovery of the cause of addiction [52]. Likewise dependence upon cocaine laced tonics and potions was treated by community pharmacists in the same way by making maintenance or restorative doses of “Mrs. Winslow’s Soothing Syrup”, “Godfrey’s Cordial”, and other available over-the-counter tonics for those having the, as yet to be identified, withdrawal syndrome, and the modest fees to purchase them. Godfrey’s Cordial was a mixture of opium sweetened by molasses and flavored with sassafras [6]. It appears these early community treatments were individual ones rather than group interventions.

When the Harrison Act was passed in 1914, it required registration with the Internal Revenue Service by those involved in any phase of the opium or coca industry, and careful record keeping. The United States government made an effort to establish some 40 community clinics to treat those who were addicted to morphine, and other opioids, and for whom the new law restricted and cut off their supply [52]. However, these clinics became the source of much controversy and were soon abandoned when the Department of Internal Revenue declared them illegal and forced their closing. Those still addicted faced obtaining illegal supplies and risked arrest and incarceration for their opioid addiction. Some physicians continued to treat opioid addiction with prescription opioids, including morphine, even after the Harrison Act. However, in 1919 the Supreme Court ruled physicians could no longer prescribe narcotics for the purpose of treating addiction [39]. By making this community-based treatment illegal, the ruling curtailed this humane medical

practice, driving addicted individuals to sources of illegal drugs, to immediate withdrawal, or attempts at detoxification.

The period between the Harrison Act in 1914 and 1935 marked a period where there were strong cultural beliefs and community emphasis on legal and moral sanctions against all narcotic addiction. This social context, including court rulings and Internal Revenue Service actions, proscribed a more humanitarian approach to addiction. Thus, during this period there appears to be little, if any, available community clinic or group intervention for substance abuse disorders. However, 1935 marked a "sea change" in the United States government's approach to addictive disorders.

A New Era Begins

In 1935 the U.S. Public Health Service opened large institutions to treat narcotic addiction, first in Lexington, Kentucky, and three years later in Forth Worth, Texas. These programs were large federal facilities drawing clients from across the United States, mostly incarcerated addicts convicted of crimes. Though not community clinics, they marked a new and growing attitude toward addictive disorders. These facilities set a precedent for subsequent development of local community clinics, group treatment, and other resources to "treat" addicted persons. Opening of these two federal treatment facilities that used a civil commitment approach to treat addiction was the beginning of a new era. Addiction became increasingly accepted by society as a disorder in need of special intervention, including medical intervention by community physicians and non-medical individual and group intervention in various community agencies and programs. These were added to, but did not replace, the predominant community model and legal-based sanctions. Thus, more humane intervention for addictive disorders slowly developed and was accepted, if not widely supported, in subsequent years. Noteworthy is that research conducted at Lexington and Fort Worth greatly established a scientific understanding of the pharmacology and psychopharmacology of addiction, and many scientific behavioral principles which support and maintain addictive behavior, such as the function of drugs as behavioral reinforcers. These facilities also provided a platform for psychosocial assessment, individual and group treatment intervention and follow-up, and epidemiological methods that gradually spread to American urban areas where addictive disorders were prevalent.

The Impact of the Community Mental Health Movement

In response to federal court rulings, the community mental health movement spread across the country during the 1960s providing outpatient treatment for mental disorders. Many clinics developed group interventions for substance abuse and dependence. Most of these embedded substance use disorder clinics focused upon alcohol dependence, which was the most prevalent disorder. However, forms of drug dependence were treated in community clinics, most using the Alcoholics Anonymous model prevalent at the time. Also, during this period religiously affiliated clinics developed to provide spiritually guided individual and group intervention for substance use disorders. Several of these are described in Milby [52], but rarely, if ever, did reports of their work or evaluations of their effectiveness reach the professional health and addiction literature.

The Alcoholics Anonymous model can be conceptualized as a spiritually guided intervention that uses a manual. The manual, called the "Big Book," describes 12 steps guiding recovery from "alcoholism". The recovery process is guided for each individual by a recovering sober sponsor. A key component of this intervention was the use of ubiquitous Alcoholics Anonymous community groups. As the Alcoholics Anonymous movement grew, the model provided widespread community intervention for alcoholism and gradually came

to accept persons with other substance use disorders into their network of community Alcoholics Anonymous groups. Increased acceptance of individuals with substance use disorders was aided by the fact that most substance abusers also abused or were dependent upon alcohol. The expansion of Alcoholics Anonymous peer-led community group meetings to Narcotic Anonymous helped gather and focus those with substance use disorders to participate in aftercare and continued rehabilitation and recovery efforts. Many persons entered these community-based groups after formal medical or psychosocial-based community treatment. However, in spite of the fact that Alcoholics Anonymous was one of the most widely utilized community interventions to treat substance use disorders, it was rarely scientifically evaluated. Only over the last 20 years have the Alcoholics Anonymous interventions been scrutinized with rigorous scientific methodology to study its efficacy and effectiveness [65]. A problem for individuals with co-occurring mental disorders and alcohol/drug dependence who utilized Alcoholics Anonymous-model treatment, especially peer-run aftercare groups, was the cultural bias against using a medication to treat a co-occurring disorder. Individuals with dual diagnoses sometimes found a lack of peer support for their medication treatment.

As community group interventions expanded, two predominant models emerged across American communities. One was the Alcoholics Anonymous movement, which initially focused on alcohol treatment and was especially influential as an aftercare intervention for the other, a medical model intervention. The medical model conceptualized addiction as a drug-induced disorder or disease maintained by an artificially induced biological drive from chronic addictive drug use [21, 35]. Intervention required inpatient hospitalization for detoxification and restoration of abstinence and normalizing of natural biological drives devoid of addiction side effects and biological disruptions. To this medical approach was usually added various psychosocial models, especially group rehabilitation and recovery procedures to support a drug-free lifestyle. As medical detoxification was studied, outcomes defined as return to abstinence after medical detoxification were considered successful, especially for inpatient detoxification. But outcomes defined as sustained abstinence at follow-ups were recognized as a dismal failure [13, 30, 32, 38, 43, 44, 52, 53, 75, 85]. Such accumulating evidence provided the impetus for greater emphasis on developing psychosocial intervention to support behavioral life style change both during medical treatment but especially following hospitalization and in outpatient clinic group intervention and aftercare.

Community mental health interventions for substance abuse disorders and co-occurring mental and substance use disorders predominantly used a rehabilitation model for intervention, as distinguished from pharmacological and other somatic interventions [24]. Initial efforts to treat co-occurring disorders involved separate clinicians working for separate treatment agencies. These initial efforts met with failure, mainly due to problems in coordinating care and accessing needed services [69].

The development of second-generation neuroleptic medication for serious mental illness was concurrent with refinement of psychosocial treatments, including group interventions, which, within community mental health clinics, served as a floor intervention. These emphasized development of a trusting relationship to help clients cope with a chronic mental illness. Within this relationship, clinician and client establish goals to maximize self-control over symptoms and minimize interference from the illness. This intervention is collaborative, utilizing psychosocial education, especially about the illness, and cognitive behavioral therapy. The intervention often involves peer groups to supplement individual counseling, psychotherapy, and medication monitoring. The recent decade has seen increasing emphases on involving families and use of evidence-based family interventions, and psychoeducation [24]. Drake and colleagues have contended that since the 1990s psychiatric rehabilitation became the dominant method employed in most community mental health clinics.

In the 1990s specific approaches for treating co-occurring mental and substance use disorders began to be developed and tested [7, 62, 87]. However, as Drake et al. noted [25], though controlled research has provided support for effectiveness of these integrated approaches, they are yet to be widely adopted in community clinics.

Effectiveness of Community Clinic Approaches 1935–1980

Community methadone maintenance treatment was initiated in New York City by Vincent Dole in 1965 [20]. Based on a disease model of addiction, methadone, as a long-acting synthetic opiate, is given orally to opioid-addicted individuals as a treatment medication. It both alleviates withdrawal symptoms and blocks effects of illicit opioid use. It is a federally regulated, commercially pure medication, devoid of often dangerous adulterants (drug cutting/mixing agents), and administered in once daily doses in a medically supervised clinic. After initial assessment many clients are administered take home doses which require less than daily attendance. As originally developed, psychosocial counseling and access to other community rehabilitation services provided additional therapeutic leverage for a changed lifestyle and sustained abstinence. Dole and colleagues' outcome studies showed excellent treatment success as measured by ability of addicts to reduce criminal activity, obtain or return to jobs or training programs, and otherwise make lifestyle changes to support abstinence [20, 22, 23]. The success of this early work soon led to a proliferation of methadone maintenance treatment across the nation and was supported by government grants to establish and maintain them with community matching funds. Though not as successful as original efforts by Dole and Nyswander, subsequent research from other communities generally found successful outcomes defined as treatment retention, reduced illicit drug use, criminal activity, and increased employment and other measured lifestyle changes [4, 52, 55]. However, when outcomes were considered as successful detoxification from methadone and sustained abstinence at follow-ups, results were much less impressive [43, 53]. Detoxification success was complicated by the discovery of a detoxification phobia, which hampered about 20–30% of addicts in methadone maintenance from even attempting detoxification despite their goal to eventually do so [33, 54, 55]. Though it seems likely that some group psychosocial intervention was utilized in community methadone maintenance during this era, its use was not described in the studies cited here.

Much of predominantly opioid dependence treatment and most other polydrug abuse and dependence disorders were not treated in methadone maintenance programs. Rather they were treated by other interventions. Many of these are reviewed later. Hospital-based inpatient treatment usually utilized medical procedures for detoxification, but these were embedded within a floor psychosocial recovery and rehabilitation intervention. When first evolved, hospital stays of 1–2 months were common. However, these long stays succumbed to economic pressures from health insurance companies and gradually evolved to 28 day interventions.

Therapeutic community intervention usually involved the longest stays in a controlled access institutional environment of up to 6 months or more, and many utilized psychosocial intervention conceptualized as community, as the treatment intervention [18]. The community as intervention utilized peer group review and confrontation for antisocial and other non-adaptive behaviors which the community evaluated as non-adaptive for a drug-free lifestyle. These were usually staffed by few professional health personnel and relied heavily on recovering persons as peer mentors and group leaders. Lastly, by far the widest used community intervention was drug-free clinics where a variety of psychosocial and religious-spiritual intervention models were employed. Up until 1981 there was little scientifically sound clinical research on the effectiveness of any of these approaches. See Milby ([52], Chapters 9 and 10) for a review of these. Where outcome data were published,

because of flawed research methods, occasional reported successful outcomes were interpreted with much skepticism.

Community Responses to the 1980s Cocaine Epidemic

During the 1980s, cocaine abuse and dependence increased dramatically in the United States with the availability of less expensive free base "crack" cocaine crystals which could be smoked instead of snorted or injected. This caused a great influx of clients to existing substance abuse community treatment programs at a time where there was no scientifically based effective treatment (medication or psychosocial intervention) available. University and community clinics treated this influx of new clients with their usual care medical or Alcoholics Anonymous models. However, the few studies which assessed clinical outcomes showed very disappointing results of high treatment dropouts and high relapse rates after treatment established abstinence [28, 29, 40, 82, 83].

In response to this frustrating failure to provide a scientifically supported effective treatment for cocaine dependence, several empirically supported innovative interventions emerged in the 1990s. Two effective outpatient interventions emerged from university clinics and utilized either a group treatment model or a more individualized contingency management behavior therapy program [12, 34]. Soon after that, Milby and colleagues [57] described a sufficient effective community-based intervention for cocaine-dependent homeless persons that utilized contingency-managed access to abstinence-contingent housing and paid work/training along with a group-based behavioral day treatment. This effective community intervention has been improved and systemically replicated in three subsequent randomized trials [56, 58, 60] and found to be cost-effective [73]. However, to date there have been few efforts to transfer and systematically replicate this evidence-based intervention in other communities. Also, during this period other researchers developed community-based empirically supported effective group psychosocial interventions for cocaine dependence [16, 48, 57, 67, 76] .

Since initial studies by Higgins et al. [34] and Carroll et al. [12], there has been steady development of effective psychotherapeutic interventions for cocaine dependence from randomized controlled trials employing both different study populations and interventions [10, 16, 27, 48, 56, 63, 68]. All of these, except perhaps Higgins et al. (who utilized an individual focused intervention), utilized group interventions, which included psychoeducational group psychotherapeutic approaches, sometimes including couple or family interventions [27, 68]. Importantly, some of these recent studies have shown sustained abstinence at follow-up after initial treatment. This increased availability of research-based efficacious psychosocial interventions for cocaine dependence has led Carroll [9] to persuasively argue that manual-guided psychosocial treatment should be used as a therapeutic platform to evaluate the efficacy of new pharmacotherapies.

Categories of Community Clinics

Rodgers and Barnett [70] examined types of community treatment programs and defined two main types: public and privately funded programs. These were further divided into four main types: public non-federal programs (i.e., state-run or local programs), public federal programs, private non-profit programs, and private for-profit programs. Data were derived from the 1991 National Drug and Alcoholism Treatment Unit Survey, and included a final total of 8,865 programs. Some of these programs were inpatient hospital facilities, which are outside of the scope of this chapter, but this study provides an introduction to different categories of substance abuse programs, as well as providing information about differences among them. Overall, the largest number of programs were

private non-profit, followed by private for-profit, public non-federal, and public federal programs. Thus, the majority of programs were private programs composing approximately 82.7% of the sample.

A key issue examined in comparisons among categories was staffing. Rodgers and Barnett [70] found that public non-federal programs had the highest number of staff, followed by private non-profit and private for-profit programs. Although public federal programs had the fewest number of staff, they were the most likely to employ doctoral level staff, followed closely by private for-profit programs. When examining the size of residential programs, federal programs were the largest, and private for-profit programs were the smallest. Public drug-free outpatient programs were also larger than the private drug-free outpatient programs. For-profit programs were the smallest. For methadone maintenance programs, private for-profit programs were the largest, with the rest of the categories lagging far behind.

Rodgers and Barnett's study [70] also provided information on specific services offered by the different categories of substance abuse programs. Both public federal programs and private for-profit programs were most likely to offer aftercare and follow-up. Public federal programs were the most likely to offer medical care. All programs were equally likely to offer individual therapy; private non-profit programs were slightly more likely to offer group therapy than for-profit programs, and private programs were more likely to offer family therapy. Their survey of services for special populations (discussed in more detail later), showed public non-federal programs were more likely to offer special services for pregnant individuals and youth. Private for-profit programs were more likely to offer services specialized for cocaine users.

There were also differences in funding sources for the categories of substance abuse treatment. Both private non-profit and public non-federal programs were more likely to receive Medicaid funding, although private for-profit programs that did receive Medicaid funding received more money than did public non-federal programs. Also, private for-profit programs were more likely to receive funding from both private insurance and client fees, and they also received the most from these funding sources, followed by nonprofit programs. Public federal programs received the least funding from these sources.

Overall, Rodgers and Barnett [70] found that private for-profit programs were smaller (with the exception of methadone maintenance programs), more specialized, and had less staff, but had staff with a higher level of training. These programs were also more likely to receive funding from private insurance and client fees, as opposed to Medicaid.

Types of Community Clinics

Therapeutic Communities

Therapeutic communities are one of the more common treatment methods present in community programs, and have been included in large-scale studies such as the Drug Abuse Reporting Program [78]. The therapeutic communities are long-term, residential programs that utilize a social treatment approach. Therapeutic communities view drug abuse as a disorder of the person, and the recovery process as development and integration of both psychological and social goals [80]. The community as a group aspect of treatment is seen as the major impetus towards growth and change. The community is made up of the social environment, the peers, and the staff, many of whom are successfully recovered addicts themselves [18].

Both behavioral and social learning principles are utilized in therapeutic communities, and some techniques include efficacy training, social role training, and vicarious learning [80]. Physical addiction is seen as a symptom, and is secondary in importance to the behavioral and psychological aspects of the individual's drug abuse. Maintaining a drug-free lifestyle is the main goal of therapeutic communities, which also utilize a present-oriented approach that emphasizes personal responsibility as well as the

development of positive values such as honesty, good work ethic, and community involvement [80]. While each individual is responsible for their own recovery process, the role each individual plays in the recovery of others is also emphasized. Some of the daily activities of therapeutic communities include work, group sessions, and recreation. Individuals in the group serve as mediators and role models. They also confront misbehavior, rule violations, and share with one another during group sessions. Attitude and behavior change in relationships developed in the therapeutic communities serve an important function by helping maintain recovery after the individual leaves treatment [80].

Condelli and Hubbard [15] provide a comprehensive chapter that discusses client outcomes for therapeutic communities from admission to post-treatment. These outcomes were not derived from scientifically controlled studies using rigorous randomized control methods. However, they do reflect what happens to clients admitted to therapeutic communities in community settings. This chapter examines outcomes from a large-scale series of studies derived from the Drug Abuse Reporting Program. Clients in these studies showed a decline in drug use, including opioid use as well as non-opioid use; and also showed a decrease in arrest rates and incarceration rates. One of the most important and consistent predictors of the success of individuals was the amount of time they spent in therapeutic communities, although the length of time necessary to see positive outcomes varied from study to study. In a Drug Abuse Reporting Program follow-up study, therapeutic communities showed more favorable outcomes than outpatient detoxification and intake-only, they did not differ significantly from methadone maintenance or outpatient drug-free counseling [78].

In addition to the various categories of community clinics, there are also a variety of treatment approaches utilized. While the list of various specific approaches is very long, there are a handful of approaches that were most commonly seen. What follows is a list of some of the most commonly used approaches, along with a description of some of the techniques and results of research studies, when available. Approaches discussed are: contingency management, where group methods are employed, cognitive behavioral treatment (including relapse prevention), integrated group therapy for co-occurring bipolar and substance use disorders, 12-step facilitation, pharmacotherapeutic approaches (including methadone maintenance, buprenorphine, etc.), where group psychosocial or educational methods are used, and faith-based approaches.

Prize-Based Contingency Management

Prize-based contingency management is a viable option for community clinics and utilizes "an intermittent reinforcement contingency management approach" usually in the context of behavioral group therapy [64]. This differs from a voucher program in that prizes are not continuous, thus decreasing program costs. Many programs that utilize this approach offer draws from a container of chips that have different reward values marked on them, ranging from "Good Job" (no value) to Jumbo (gets to pick from prizes worth about $80–$100) [1, 46, 64]. These draws can be made contingent on negative urine samples, participation in planned activities, or any other behaviors that the clinicians wish to reinforce. Another option is to set the program up with prize drawings every week. In this approach, clients are allowed to place their names into a bowl for each session that they attend, and then names are drawn each day to receive prizes [1]. These techniques can be utilized independent from each other, or combined.

Petry et al. [64] utilized several programs from the Clinical Trials Network to look at the efficacy of prize-based contingency management in stimulant abusers. These programs all utilized the approach where clients earned draws from the container for chips with various reward values. The prize-based contingency management programs were compared with usual care, which was mostly group counseling. Participants in

the prize-based contingency management programs showed more negative urine samples, as well as longer periods of abstinence. Other studies, which looked at both cocaine- and opioid-dependent individuals, showed similar results, each showing that participants in the prize-based contingency management program demonstrated longer periods of abstinence compared with those receiving standard treatment [46], although the Alessi et al. [1] study failed to show an impact of contingency management prizes on attendance when prizes were awarded during group.

Day Treatment with Abstinence Contingencies and Vouchers

Day treatment with abstinence contingencies and vouchers [56, 58, 59, 74] is an intensive program that focuses on substance abuse rehabilitation of homeless crack-cocaine abusers. Clients participate in 5.5 h each day in the program for the first two months during which time they are provided with lunch and transportation to and from the treatment center. Treatment services include: individual assessment and goal setting, individual and group counseling, and multiple psychoeducational groups. During weekly goal review groups, clients review contract goals and provide support and encouragement to each other and receive vouchers for goal attainment that may be applied towards renting low-cost, drug-free housing. Participants may also earn vouchers by engaging in pro-abstinence social and recreational activities. After two months, participants enter a four-month vocational phase that includes both paid work and program provided housing which are abstinence contingent.

This day treatment approach has been shown to be effective compared with a treatment-as-usual individual and group counseling based on an Alcoholics Anonymous model, where clients were referred to community resources for housing and work. Subsequent studies have utilized a dismantling design strategy where investigators systematically replicated the original behavioral day treatment [57], while examining the contribution of key components [56, 58, 74].

Results from Milby et al.'s most recent study [58] are shown in Fig. 1. In this study, designated H4, abstinence outcomes were compared between the two treatment groups to which participants were randomly assigned. The "CM" group received contingency-managed abstinence-contingent housing, work training, and paid work. The "CM+" group received the same contingency-managed components as the CM group, but in addition received a manualized effective cognitive behavioral day treatment used in previous studies. As Fig. 1 shows, abstinence levels for both groups during active treatment (weeks 1–24) are moderately high ranging from 59 to 79%, with no differences between groups. However, at post-treatment follow-ups, at 12 and 18 months, the CM+ group receiving additional cognitive behavioral intervention showed a delayed treatment effect of superior sustained long-term abstinence, which was rigorously measured using urine toxicologies. In a meta-analysis of treatment components, Schumacher et al. [74] found contingency-managed components to be those associated with greatest abstinence. All of these studies have shown modest improvements in both reduced homelessness and increased employment for all treatment groups from admission to long-term follow-up.

Cognitive Behavioral Treatment

According to McCarty et al. [50], about one-third of treatment programs in the Clinical Trials Network utilized National Institute on Alcohol Abuse and Alcoholism treatment manuals, and 28% of those utilized cognitive behavioral treatment. In addition, approximately 26% of programs that utilized National Institute on Drug Abuse treatment manuals used *A Cognitive Behavioral Approach: Treating Cocaine Addiction*. The National Institute on Drug Abuse [63] provided a general description of cognitive behavioral therapy for substance use disorders as well as some information regarding its efficacy. Cognitive

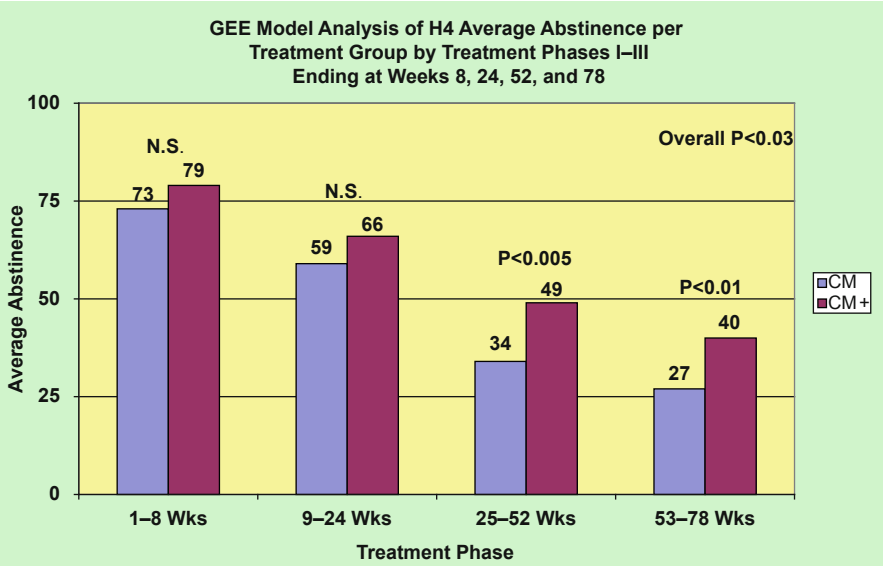

Fig. 1 H4 abstinence per group across phases: average abstinence per group across four phases of treatment as measured by observed urine collection and testing multiple times per week up to 24 weeks, and randomly thereafter through week 78 (18 months follow-up). H4 = the study by Milby et al. [58]; GEE = generalized estimating equations; N.S. = not significant; CM = contingency management. Reprinted from Milby et al. [58], with permission from Elsevier

behavioral treatment is based on social learning theory and can be applied in a group or individual setting. Some of the foci are on increasing self-efficacy and reducing positive expectations about substance use, as well as teaching coping skills, especially in relapse situations. He reports that there are several studies that provide evidence for the efficacy of cognitive behavioral therapy in treating substance use disorders. In addition, a study by Maude-Griffin et al. [48] of crack-cocaine abusers showed that clients in cognitive behavioral treatment were more likely than clients in a 12-step facilitation program to achieve consecutive abstinence for one month. Clients in cognitive behavioral treatment also showed significantly better abstinence results at each of the follow-ups (weeks 4, 8, 12, and 26).

Rawson et al. [68] completed a study comparing cognitive behavioral treatment, contingency management, contingency management + cognitive behavioral therapy, and standard methadone treatment in a community clinic affiliated with the University of California in Los Angeles. All of these treatments utilized group methods. During treatment and at the week 17 follow-up, clients in the cognitive behavioral therapy did not show significantly more positive abstinence results than the standard methadone treatment, while both of the other two treatment conditions did. However, at the week 26 and week 52 follow-ups, the clients in the cognitive behavioral therapy showed the most positive abstinence results of all the treatment groups.

Relapse Prevention

Relapse prevention is a cognitive behavioral approach that strives for eventual abstinence by emphasizing reducing the risk of relapse. It is based on the theory that substance use disorders involve learned maladaptive behavior, and clients have the potential to re-establish previously adaptive non-drug use behaviors and develop new behaviors.

Clients are taught to identify problem behavior and replace unhealthy behaviors with healthier substitutes. The cognitive behavioral treatment techniques are employed to identify risks and coping strategies to deal with those risks. Specific techniques utilized include (1) identifying disadvantages of continuing drug abuse; (2) self-monitoring drug use behavior to help identify situations that trigger maladaptive behaviors; and (3) developing effective coping strategies to curb craving and reduce stress. Though relapse prevention methods can be utilized in individual or group therapy, most community programs utilize groups.

Studies indicate that relapse prevention helps recovering drug addicts maintain abstinence longer by reducing the risk of relapse [8, 47]. This method has also been found to reduce the impact of relapse if it should occur by preparing clients ahead of time with knowledge and tools to cope during distressing situations. The interested reader will find an excellent review by Carroll and Onken [11] of behavioral and cognitive behavioral therapies, some of which were conducted in group format or combined individual and group behavioral interventions. The review included studies with families and couples.

Integrated Group Therapy

Integrated group therapy is a manualized 20-session, 1-h weekly group intervention that addresses substance use disorder simultaneously with co-occurring bipolar disorder. It emphasizes interaction between the disorders by examining similarities in cognitive and behavioral patterns involved in recovery from both [84]. Adverse effects of each disorder on the other are emphasized. For example, one session is "Dealing with Depression without Using Alcohol or Drugs". Sessions involve a "check-in" where clients report on substance use, moods, medication adherence, and risky and stressful situations confronted. The "check-in" is followed by a planned psychoeducational topic and discussion. Their randomized controlled trial compared 20 weekly sessions of integrated group therapy with group drug counseling focused on the substance use disorder. Group drug counseling was an adaptation of the treatment delivered in the National Institute on Drug Abuse's Drug Abuse Collaborative Cocaine Treatment Study [16], designed to approximate treatment in community substance use disorder programs. Group drug counseling also involved 20 weekly group sessions, each focused on a specific topic. Sixty-two participants with bipolar disorder and current substance dependence were treated with mood stabilizing medications for two weeks or more and randomized to $N = 31$ in each group. Main outcomes were number of days substance use and number of weeks ill with a mood disorder.

Results showed fewer days of substance use for integrated group therapy. Groups were similar for number of weeks ill with bipolar disorder during both treatment and follow-up; however, integrated group therapy had more depressive and manic symptoms. This study is notable for two reasons. First, the intervention was designed to be comparable to what many community clinics already do. That the integrated group therapy group showed better substance abuse outcomes, but not superior reductions in number of weeks ill with mood disorder, was a surprising finding. Integrated group therapy needs replication with larger N values and replication attempts in community clinic settings. If integrated group therapy is shown effective in community clinics, its manualized format and straightforward procedures could yield significant impact on the treatment of co-occurring mental and substance use disorders in community substance abuse treatment programs which rely heavily on group interventions. Integrated group therapy's potential impact on weekly mood disorder symptoms is troubling and could be a function of its weekly review of mood and medication compliance which could increase participant's sensitivity to their bipolar symptoms. This impact is another reason for further study and replication before extensive community adoption is encouraged.

12-Step Facilitation

According to McCarty et al. [50], of programs in the Clinical Trials Network that utilized National Institute on Alcohol Abuse and Alcoholism treatment manuals, 20% of those utilized 12-step facilitation. While literature searches did not identify many studies on the efficacy of this approach specifically in community clinics, except as a comparison or control group, we have included some more general information about it.

Moos [61] provides a general description of 12-step facilitation for substance use disorders as well as some information on its efficacy. Twelve-step facilitation is based on the ideology of Alcoholics Anonymous and the disease model of addiction. Some of the main foci of this approach are on getting clients to admit that they have a problem, and that they are an alcoholic or addict. The emphasis is on abstinence, without accepting controlled drinking as an option. Clients are directed to develop and maintain strong relationships with positive individuals who support their sobriety, such as their family and other sober networks. They are also encouraged to turn themselves over to a Higher Power. Coping skills are taught, and self-efficacy is enhanced. Twelve-step facilitation is an all-encompassing approach, in that clients are asked to attend 12-step meetings, get a sponsor, read the literature, and regularly attend 12-step groups. Moos reports there are several studies that provide evidence that 12-step facilitation is effective for several different types of substance use disorders.

Faith-Based and Religiously Affiliated Programs

The faith-based and religious approach to substance use disorders is fairly common in community clinics [52, 77]. However, there is little to no research on the efficacy of these approaches. Also, there is little to no information regarding standard practice or techniques of these programs, other than that which is available on individual program websites. Twelve-step facilitation is spiritual in its approach, although it is not affiliated with a specific religious organization.

An article by Cnaan and Boddie [14] discusses a section of the Personal Responsibility and Work Opportunity Reconciliation Act of 1996 called “Charitable Choice”. This section encourages the participation of faith-based organizations in federally funded welfare services, including health services such and drug and alcohol treatment. Also, since 1996, there have been other acts passed to further encourage the involvement of faith-based and religious organizations in social services. There is also more protection for religious-based programs to maintain their themes and religious methods by being able to keep all religious symbols, literature, etc., as well as protecting their ability to only hire employees who share or practice their religious beliefs and to fire those who do not.

Cnaan and Boddie [14] also discuss those studies that are focused on the effects of Charitable Choice. However, these studies only look at the awareness of Charitable Choice and an “assessment of the scope and nature of contracting relationships between faith-based organizations and the public sector”. They also state that there are no studies on the effectiveness of the services provided by faith-based organizations.

Interventions for Specific Populations

The Substance Abuse and Mental Health Services Administration at the National Institutes of Health conducted the 2006 National Survey of Substance Abuse Treatment Services [19]. Data were collected on treatment facilities in the 50 states, the District Columbia, and U.S. territories. The survey included information about programs tailored to treat specific populations. Specialized treatments include

the treatment of adolescents, older adults, individuals with co-occurring mental/substance abuse disorders, gays/lesbians, driving under the influence/driving while intoxicated offenders, other substance-related criminal offenders, adult men, adult women, pregnant/postpartum women, and individuals with HIV.

It seems likely that clinics servicing large numbers of individuals are more likely to have sufficient clients in more of these subgroups to enable the provision of specialized services. Thirty-two percent of facilities offer programs specifically for adult women and 25% for adult men. Services directed at treating pregnant or postpartum women are offered by 14% of facilities. Thirty-two percent of institutions also offer services designed for adolescents and 7% for older adults. Adolescent and senior services are offered most frequently by facilities operated by tribal governments (52 and 12%, respectively).

Women are often a minority in substance abuse treatment programs. Women have unique needs and problems associated with their gender, like child care and custody, and abuse by their partner, which may not be revealed or get much attention in male-dominated, mixed-gender group sessions. Thus, many clinics have developed women's recovery groups. An example of such a specialty program for women is that of Greenfield and colleagues [31] in Boston. They have developed and completed an initial study of a manualized 12-session Women's Recovery Group. Women were randomized to either Women's Recovery Group or mixed-gender Group Drug Counseling. No differences in substance use were found during the 12-week treatment. However, at 6 months follow-up, Women's Recovery Group, but not Group Drug Counseling women, showed continued reductions in substance use. Also, Women's Recovery Group women with alcohol dependence showed greater reductions in drinking. Importantly, these results were associated with greater satisfaction among women treated in the Women's Recovery Group. Though this specialty group is early in its development and needs replication, both by the authors and those in another setting, it does suggest such specialty groups can be supportive of longer-term clinical outcomes for women with substance use disorders.

Thirty-one percent of facilities offered special programs to driving under the influence/driving while intoxicated offenders. The majority of facilities offering offender services are private for-profit facilities (46%). Tribal government facilities offered 38% of substance abuse treatment specifically for persons with driving under the influence/driving while intoxicated charges. For other types of substance-related criminal offender populations, 28% of facilities offered tailored treatment. It is important to note that most, if not all, state and federal correctional facilities offer group interventions for inmates with substance use disorders, and some include within the correctional facility a residential therapeutic community where inmates are usually separated from the regular prison population.

Fewer facilities report offering services specifically designed for specialty populations such as individuals with HIV/AIDS, older adults, and gays/lesbians. Only 10% of facilities report offering services for people with HIV/AIDS. Only 10% of federal government-operated facilities report offering services for older adults; however, this was greater than most other facilities. For the gay/lesbian client population, only 6% of facilities report offering specifically designed services. The percentage increases slightly (8%) for private, for-profit institutions who offer targeted treatment interventions for homosexuals. The literature we reviewed did not mention whether these varieties of services are group services. However, we assume that many of these categories are conducted in group intervention formats especially therapy or psychoeducational groups.

Use of Evidence-Based Services in Community Clinic Substance Abuse Treatment

Treatment services operate with limited money and resources. Community substance abuse

treatment services strive to be cost neutral for their planned budget expenditures. For-profit/private clinics aim to make a profit so the program can sustain, if not expand, its services. Thus, a cost-effective program may come at the expense of maximizing treatment gains. Clinics using interventions that lack empirical evidence or have been deemed less beneficial than alternative methods, may prove in the long run to cost more to operate because of the need for longer treatment or increased risk of relapse. Thus, it appears to be in the best long-term interest of facilities to find the most effective treatment that also results in long-term abstinence or maintenance of risk reduction, relapse prevention, shorter treatment time, and less manpower required for implementation. Overall, a treatment program that is both effective and efficient may be most beneficial for most treatment centers and clientele. Realistically, however, few community clinics have the resources to collect valid treatment outcome data to inform administrative decisions about what interventions are most effective or most cost-effective.

Community clinics that specialize in treatment of substance abuse or co-morbid substance abuse and mental health disorders face an even greater need to maximize treatment gains in treating substance abuse because funding is often contingent upon these services. The 2005 American Psychological Association Statement defines effectiveness as treatment methods that are "... the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" [3].

Treatment quality and effectiveness can be graded according to specific criteria. The Agency for Healthcare Research and Quality, U.S. Department of Health and Human Services reported 40 systems of "grading the strength of a body of evidence." The National Guideline Clearinghouse, for example, requires developers to submit treatment guidelines based on quality of evidence criteria.

Standardization is important in promoting effectiveness of treatment by: (1) comparing outcomes of one treatment to another, and thereby holding facilities accountable to reach expected outcomes, and (2) training employees to administer treatment to clients while maintaining consistency of practice. Use of treatment guides and manuals can help employees check their actual treatment methods and behavior compared with what is specified and described in manuals or guidelines for high quality and/or effective treatment. In this way treatment delivery fidelity may be more likely to result in positive outcomes obtained in clinical research using these same treatment manuals and methods. Standardization also helps identify client variables that may contribute to good or poor treatment response by controlling for treatment methods. This form of standardization may facilitate practitioners to meet more needs of the clients.

Treatment guidelines are also published by agencies such as the National Institute of Drug Abuse [63]. Effective manualized interventions selected by or developed for the National Institute on Drug Abuse's National Drug Abuse Treatment Clinical Trials Network are available in the published clinical literature and posted on their website for use by community clinics outside of the network where original effectiveness research has been completed.

The Substance Abuse and Mental Health Services Administration has published and continues to provide an expanding library of treatment improvement manuals that are evidence-based and written for community substance abuse treatment program adoption. In our opinion there appears to be a slowly growing trend among the more stably supported community substance abuse treatment programs, most of which utilize group interventions extensively, to adopt evidence-based interventions. However, it also seems that the diffusion of these evidence-based interventions is slow, and that the majority of community clinics have not yet fully embraced evidence-based services for their clients with substance use disorders.

The National Institute on Drug Abuse has produced a comprehensive handbook of evidence-based substance abuse treatments entitled *Principles of Drug Addiction Treatment: A Research-Based Guide* [63]. The guide

outlines principles of effective treatment available in the United States and scientifically based approaches to drug addiction treatment as well as a list of resources and answers to some frequently asked questions for individuals and families seeking treatment. The document briefly describes studies supported by the National Institute on Drug Abuse that investigated interventions for substance use disorders, which were found to be efficacious and/or effective. Group treatment programs include long-term residential treatment, short-term residential programs, and outpatient drug-free treatment utilizing group intervention formats. The National Institute on Drug Abuse guide also describes agonist maintenance treatment (e.g., methadone treatment programs), narcotic antagonist treatment using naltrexone, and medical detoxification.

The National Institute on Drug Abuse's National Drug Abuse Treatment Clinical Trials Network

The mission of the Clinical Trials Network is to improve interventions available to persons with substance use disorders by studying the effectiveness of evidence-based treatment services in collaboration with community treatment agencies. Effectiveness research is conducted at collaborating community programs. The Clinical Trials Network aspires to replicate efficacious and effective treatment in clinical trials of substance abuse research by publishing findings from multiple community clinics and by allowing studies funded by other agencies to utilize Clinical Trials Network protocols. Also, the Clinical Trials Network provides capabilities for access to Clinical Trials Network Node facilities (community clinics), new investigations, and Clinical Trials Network Nodes to serve as National Institutes of Health Training Centers.

The Clinical Trials Network consists of: (1) 17 Nodes (Regional Research and Training Centers, all associated with 5 or more Community-Based Treatment Programs), (2) a Clinical Coordinating Center, and (3) a Data and Statistical Center. The network of multi-sites allows researchers to test the effectiveness of treatment on a large array of populations across the United States. The Clinical Trials Network also allows for new evidence-based practices to be diffused to and implemented by community clinics.

Virginia, Maryland, and Washington, D.C, for example, are regions overseen by the Mid-Atlantic Node. This Clinical Trials Network Node is operated out of Johns Hopkins University (a Regional Research and Training Center) and is linked to 7 Community-Based Treatment Programs such as the Chesterfield (Virginia) CSB Substance Abuse Service and the REACH Mobile Health Services in Catonsville, Maryland. The Mid-Atlantic Node, alone, has been involved in the implementation of 9 substance abuse treatment protocols throughout this Node's affiliated community clinics.

Analogous to the network of National Institutes of Health-supported national cancer centers, but on a smaller scale, it is possible the Clinical Trials Network could have a similar impact on community intervention for substance use disorders. Before national cancer centers were developed, effective treatments for cancers developed in academic medical centers were not transferred to local communities. Thus, best practices remained relatively non-implemented by local physicians. Treatment for substance use disorders is in a similar situation. Though there is an array of effective substance use disorder treatments, most studies at academic treatment centers have not yet been diffused to community clinics and programs. It is hoped that the Clinical Trials Network will increase the slow rate of diffusion of effective treatment and also accelerate discovery of the most effective of the efficacious interventions it studies.

Drug Abuse Reporting Program Studies

The Drug Abuse Reporting Program yielded a series of major large-scale studies that examined

community-based drug abuse treatment agencies and their short- and long-term outcomes. The Drug Abuse Reporting Program was initiated in 1969 by the Institute of Behavioral Research at Texas Christian University. An article by Simpson and Sells [78] describes both the studies and the outcome measures. The Drug Abuse Reporting Program originally started with six treatment agencies, and expanded to include 52 in the United States and Puerto Rico, totaling 43,943 clients. It utilized client intake records, bi-monthly treatment status records, and follow-up samples. Follow-up research began in 1974, after client intake records stopped being collected. Surveys lasted, on average, 5–7 years after admission, and 4 years after the end of treatment. The emphasis in the Drug Abuse Reporting Program was on community services and outcomes, not experimental interventions. Clinics included in the Drug Abuse Reporting Program continued with their normal procedures to collect data on client outcomes.

Follow-up outcome data were collected through a sample of reimbursed, face-to-face interviews. Interviews used retrospective self-reports on employment, drug and alcohol use, and return to treatment. The follow-up sample included 4,627 clients from 34 Drug Abuse Reporting Programs. Five different types of community intervention in the follow-up sample included: methadone maintenance, therapeutic communities, outpatient drug-free treatments, outpatient detoxification clinics, and the comparison group, which was intake-only. The clients were also separated based on their addiction status, and divided into three categories: active addicts (those who used opioids daily for 2 months before the Drug Abuse Reporting Program), former addicts (who had a history of daily opioid use, but not during the 2 months before the Drug Abuse Reporting Program), and non-addicts (who had no history of daily opioid use). Outcomes examined at follow-up were: illicit drug use, criminality indicators, alcohol use, return to treatment, and employment. The main outcome measures were illicit drug use and criminality indicators. Highly favorable outcomes were defined as having no drug use and no arrests or incarcerations. Twenty-seven percent of clients in methadone maintenance met these standards, along with 28% in therapeutic communities, 24% in outpatient drug-free treatments, 15% in outpatient detoxification, and 14% in intake-only. Moderately favorable outcomes were defined as no daily drug use and no major criminality indicators, which were further defined as no crimes against persons or crimes of profit and no more than 30 days in jail or prison. Forty-one percent of clients from methadone maintenance met these standards, along with 40% in therapeutic communities, 33% in outpatient drug-free treatments, 25% in outpatient detoxification, and 27% in intake-only. More detailed results are found in Table 1.

The Drug Abuse Reporting Program follow-up results suggested that overall those clients in methadone maintenance, therapeutic communities, and outpatient drug-free treatments had better outcomes than those in the outpatient detoxification and intake-only groups. Long-term follow-up outcomes (i.e., those interviews conducted about 4 years after the Drug Abuse Reporting Program ended) continued with the same trend. Outcomes for clients in methadone maintenance, therapeutic communities, and drug-free treatments were more positive with an increased length of stay, with main results appearing between 90 days and 2 years. The outcomes for those who only stayed short term (less than 90 days) in these categories showed no significant difference between these clients and those who were in the outpatient detoxification and intake-only groups. Inspection of the follow-up records for 990 opioid addicts showed that 61% of that sample achieved opioid abstinence after the Drug Abuse Reporting Program treatment occurred. Throughout most of the Drug Abuse Reporting Program studies, the most important predictor variable was criminal history (arrests and incarcerations before entry into the Drug Abuse Reporting Program).

The Drug Abuse Reporting Program is still considered to be one of the great sources of information regarding client outcomes in community clinics. Some of the limitations of the

Table 1 Pretreatment and posttreatment outcomes for the drug abuse reporting program group treatments

	Therapeutic community (%)		Outpatient drug free (%)		Intake only (%)	
Outcome measures	Pre-trx.	Post- trx.	Pre-trx.	Post-trx.	Pre-trx.	Post-trx.

Adapted from data in Simpson and Sells [78]

Post-treatment data are for the first year after treatment, and persons included are black and white male opioid addicts

Drug Abuse Reporting Program studies include the fact that they were not controlled studies. There was no randomization of clients into the different treatments. This meant that equality among the groups for gender, age, or any other variables was not controlled. However, this could also be considered a strength, because the studies allowed a real look into how clients actually arrive into various treatments. Another limitation was the fact that outcome data relied mostly on retrospective self-report, although some of the variables, such as criminality indicators, could be verified through records. The findings from this study utilized pre- and post-treatment data, with no rigorous experimental controls, so these methods prevent firm conclusions regarding treatment efficacy and effectiveness. For example, one major limitation of pre-post treatment studies is that in a recurring disorder like substance use disorder, abstinence and other functional indicators of treatment success naturally fluctuate in their usual course. Individuals seek treatment when they are at their worst and thus may show improvement or success as the natural course of their chronic disorder continues, rather than as a direct causal result of treatment.

A major strength of the Drug Abuse Reporting Program studies was the huge breadth of the research. Treatment agencies that were included in the Drug Abuse Reporting Program were very diverse, both in location and treatment philosophy. The studies were very consistent and provided similar results throughout the course of the program. One of the interesting findings of the Drug Abuse Reporting Program was the fact that there were not any significant outcome differences between individual agencies or types of agencies. This could be considered a positive finding, showing more consistency than was necessarily expected. Overall, major Drug Abuse Reporting Program findings demonstrated positive outcomes for methadone maintenance, therapeutic community, and

outpatient drug-free treatments among daily opioid users who remained in treatment for more than 90 days.

Additional Treatment Models

Some group methods investigated through the National Institute on Drug Abuse's support include Relapse Prevention (some have utilized individual therapy), the Matrix Model, Community Reinforcement Approach Plus Vouchers, and Day Treatment with Abstinence Contingencies and Vouchers. All are reviewed in the National Institute on Drug Abuse's *Principles of Drug Addiction Treatment* [51], but this is not an exhaustive list of empirically based treatments. Numerous other substance abuse treatments, not listed include an eclectic mixture of methods, theoretically driven techniques, or variations of other treatment procedures. Some evidence-based group treatments have not been extensively evaluated, or have been found to be insufficiently efficacious or ineffective when rigorously evaluated in clinical settings. Still other substance use disorder treatments being utilized have been determined to be less effective than alternative evidence-based comparative treatments (for example, see Schumacher et al. [74]).

The Matrix Model

The Matrix Model [66, 76] is a multifaceted manualized approach aimed at helping stimulant abusers obtain abstinence. Group treatment incorporates educating clients and their family members about addiction and relapse as well as self-help techniques. Abstinence is monitored by regular urine testing. A therapist acts as a mentor by educating, guiding, and supporting clients during recovery. Treatment focus is on positively reinforcing progression towards abstinence. The relationship between the therapist and client is positive, promoting an open and honest dialog between the two, avoiding authoritative and confrontational interactions. The matrix emphasis is on building clients' self-worth and confidence, helping clients resist temptations for using, and increasing the importance of the self, while reducing potential harm that may ensue through using drugs.

Treatment procedures incorporate effective elements of other empirically supported treatments [67]. As summarized by the National Institute on Drug Abuse's *Principles of Drug Addiction Treatment* [63], specific techniques utilized in the Matrix Model include work sheets for individual sessions; group intervention components include family educational groups, early recovery skills groups, relapse prevention groups, conjoint sessions, 12-step programs, relapse analysis, and social support groups.

The Matrix Model has been shown in many studies to be effective at treating both drug and alcohol abuse as well as improving quality of life and reducing risky behaviors that may increase risk for acquiring HIV [76]. Matrix treatment has been found to be equally effective for methamphetamine and cocaine abusers as well as enhancing the effectiveness of naltrexone treatment of opiate abusers [36]. Recently the Matrix Model has incorporated abstinence contingency management based on Higgins et al.'s voucher approach [34].

Challenges to Community-Based Clinics

In the previous section a number of empirically supported community treatments utilizing group interventions for substance use disorder have been described. These interventions have been carefully designed and rigorously tested. However, substance use disorder is still a major national problem. For example, despite some reduction in the prevalence of cocaine use since its peak in the 1980s, the prevalence of heavy cocaine use has not diminished [72]. In rural communities, methamphetamine has come to replace cocaine use in recent surveys [81].

These alarming substance abuse trends have been observed despite a wealth of evidence documenting the detrimental cognitive and physical effects of these substances.

A recent review of substance use disorder community treatment programs revealed a 15% closure rate within the first year of operation. Among those programs that survive the first year, as many as 25% undergo a major shift in organization [51]. Most are taken over by a different administrative structure. The vast majority of programs report collecting more administrative data than clinically relevant information. Only 54% of programs perform on-site physical examinations at admission. A startling 28% of programs report no electronic information system, email, or even voice mail capabilities while only 30% (largely housed under hospital and university settings) had full access to advanced information technology. The remaining 40% only had an information system available for administrative duties (i.e., budgeting, payroll, and billing), but the technology was not available to staff members that interact face-to-face with clients [51].

It appears we are facing a paradox in the national effort to reduce substance use disorders. Health professionals have an increasing variety of effective interventions to treat persons with chemical dependencies, yet treatment programs in the community are struggling to remain open, let alone to address the rising population of persons with substance use disorders. Why is this? There are a number of barriers to the dissemination and maintenance of community addictions treatment programs. Most of these barriers can be categorized into one of three categories: (1) funding; (2) staffing, and (3) client-centered barriers.

Funding

Substance use disorder treatment programs have a myriad of funding sources to navigate. Each source has different eligibility requirements and payment mechanisms. The funding categories include: single state agencies, federal grants, local government, third-party reimbursements (e.g., private insurance and HMOs), private grants, client fees, and fundraising [86]. Community substance abuse treatment funding sources can be categorized as either the public or private sector. Funding sources, regardless of source, pose a number of barriers to substance use disorder treatment service delivery. The majority (more than 80%) of the nation's substance use disorder treatment programs are specialty care programs. Specialty care programs are small—typically treating fewer than 300 clients per year, community-based, outpatient, non-profit organizations. Most utilized group interventions of various types with mostly unknown effectiveness. They are rarely affiliated with large medical care facilities. As freestanding entities, specialty care substance use disorder programs operate outside the realm of the mainstream healthcare system. The majority of their funding is government mandated (e.g., Medicaid and Veterans Administration) or provided by state and/or local criminal justice systems [41]. In most cases, these resources are limited, and the documentation and procedural requirements can be very time consuming. This is despite the fact that cost-benefit analyses overwhelmingly support a move toward increased government support of substance use disorder treatment programs [79].

A few suggestions have been proposed to address the funding challenge facing substance use disorder treatment programs. A basic concern regarding program funding difficulties is the lack of information about available sources utilized by struggling agencies. This can be addressed by compiling a comprehensive list of available funding resources, such as the 1995 review by Zarkin and colleagues. Additionally, it may prove beneficial to provide program directors and administrative staff with basic budget and resource allocation training. The use or expansion of self-funding may help some substance use disorder treatment programs. Self-funding programs can operate by placing fees for specific products to fund services that address the detrimental effects of its consumption, like cigarette taxes being used to fund

cancer research [79]. In the case of illicit drug use, which, unlike alcohol and tobacco, is not commercially marketed, restitution payments from those convicted of drug charges could be used to fund rehabilitation centers. The idea of self-funding programs is still relatively new, but if it proves to be a viable option for mitigating the pubic harm caused by alcohol and nicotine, it may be useful to consider for substance use treatment.

Staffing

A number of staffing difficulties face substance use disorder treatment programs. Some of these issues include: clinical staff training, caseloads, and staff retention/stability. McClellan and colleagues' [51] sample of community treatment programs found that 15% of program directors had no college degree, 58% had a bachelor's degree, and 20% had a master's degree. Nearly 72% of the directors for these programs worked full-time. While 71% of the directors had worked within their program, most in a clinical position for more than a year, over half (54%) had been in the director position for less than a year. These statistics imply there is a problem of instability at the top administrative level of these programs.

If we look further at staff credentials, we find differences between private and public sector programs. The main difference is typically based on the program's funding source. Those who receive at least 50% of their funding through public grants and/or contracts can be considered public sector programs. By this definition, private sector programs receive the majority of their funding from affiliated institutions, direct client payments, and third party reimbursements [71]. One very notable distinction in staffing is that private sector programs, partially due to their hospital affiliations, are more likely to have a physician and master's level counselors available. This may have implications for these programs' viability, treatment quality, and success. Having higher educated staff allows more private sector programs to offer more innovative approaches, such as pharmacotherapy and other evidence-based psychosocial interventions—particularly those that require supervised training for implementation [45].

Staff caseloads often present challenges for these programs. A number of treatment programs have been described as "choking on data collection requirements" [51]. Administrative data reporting requirements are often time-consuming and cumbersome. This is particularly true for programs that hold contracts with multiple state agencies and managed care organizations. Each of these entities, for example, employment organizations, welfare departments, and criminal justice agencies, has unique requirements for record-keeping and billing. Case workers at many community programs report devoting 2–4 h to collecting administrative data alone for each admission. This time and effort appears not to contribute to actual clinical assessment or treatment planning. Nevertheless, staff members in most treatment facilities find themselves busy completing a sizeable amount of paperwork and still left with the task of providing client care, in many cases without access to computers, email, fax, or even voicemail capabilities.

The most salient staff-related barrier to community treatment vitality is staff retention. Data from the National Treatment Center Study reveal an average turnover rate of 18.5% among addiction counselors [45]. This is much greater than national annual rates for other occupations that traditionally have high turnovers, such as teachers (13%) and nurses (12%) [37]. Retention difficulties create numerous problems. In addition to recruiting costs, hiring, and training new counselors, high turnover rates compromise consistency of treatment and service delivery [45]. These staffing problems can have a variety of negative effects for clients such as increasing treatment drop-outs and exposing clients to rapidly changing staff—who may not be competent in delivering evidence-based, effective clinical interventions for their substance use disorders and other common comorbid mental disorders.

What can be done to address staff concerns? A survey of counselors and administrators in attendance at a 2003 training workshop yielded the following suggestions to address staff-related barriers to substance use disorder treatment programs: provide more relevant training, increase program support of staff, provide lighter workloads, and less redundancy in staff duties [5]. There is also a need to offer meaningful incentives to recruit physicians, nurses, psychologists, and counselors [51]. For instance, national educational loan forgiveness could help recruit health care professionals and make clinical careers in addiction treatment more valuable and rewarding if it were more accessible to community treatment programs. There is also a need to incorporate relevant continuing training opportunities, along with training for administrators in personnel management, accounting, budgeting, and other cornerstones of the small business industry. Administrators should streamline the amount of non-clinical data collection that is required [51]. Perhaps, by combining the administrative data with clinically pertinent information from admission, progress notes, and discharge assessments, the burden associated with required documentation can be partially alleviated.

Client-Centered Barriers

There are a number of barriers to substance use disorder program viability that are related to client-issues. One of the primary client-centered problems is motivation/treatment engagement. Client motivation has been shown to be a considerable predictor of treatment success [42]. This is even more evident when examining clients who do not enter treatment under criminal justice supervision. Surveys of substance use disorder programs have shown that clients are more likely to engage and remain motivated if they feel the staff has a vested interest in their recovery. This is especially true when clients feel a connection with their counselor. Good client-counselor rapport has been shown to be related to client engagement and subsequent success. A survey by Kirk and Amaranth [42] revealed a majority of clients preferred counselors with their own stories of recovery who are of the same gender, same cohort group, and with sensitivity to their client's culture.

In addition to client motivation/treatment engagement, many clients face practical obstacles that prevent their individual success, and when taken as a whole, become detrimental to the substance use disorder treatment program. Some of these challenges include transportation, child-care, and missed work. In order to address these issues, programs could offer incentives (e.g., meal and travel vouchers), day-care services, and vocational training to mitigate challenges, while maximizing the benefits of program attendance.

Opportunities to Expand Evidence-Based Substance Use Disorder Interventions

A great opportunity to expand program interventions is through university-affiliated translational research. Translational research emphasizes evaluations of treatments and interventions in clinically relevant settings. Continuing to increase knowledge about the efficacy and real-world implications of substance use disorder interventions is the first step toward increasing their availability. An additional way to improve substance use disorder program availability and effectiveness is with integrated mental health services. Despite barriers to prevent its occurrence, there remains a strong consensus to integrate mental health services with substance abuse treatment [17]. This is particularly important given that people with mental illness are 4–5 times as likely to develop a substance abuse disorder as the general population. Dual diagnosis significantly complicates treatment outcomes [26]. Drake and colleagues [25] concluded

Table 2 Key components of Davidson and White integrated substance abuse and mental health treatment approach

Domain	Mental illness Addiction
Goals of care	Assist people to reduce the interference, impairment, disability, and discrimination associated with the condition(s)
	Support person's own efforts to manage his or her condition(s) while pursuing a dignified and gratifying life in the community
Role of the person with the condition	Take ownership of his or her own recovery process
	Active involvement, including daily decision-making, for initiating and sustaining recovery
	Individual/family involvement, from policy development through service delivery and evaluation
Underlying values	Sustained health care partnership model (vs. expert model)
	Hope-based
	Person- and family-centered
	Culturally competent
	Choice philosophy
	Promotes growth
	Builds on strengths and interests
	Focuses on overall life, including wellness, health, and spirituality
	Recovery-focused outcome measures
Guiding principles	Recovery has multiple pathways and styles
	Recovery flourishes in supportive communities
	Recovery is enhanced by person–environment fit
	Recovery is voluntary
	Recovery outcomes vary across a heterogeneous population
	Recovery is a longitudinal, developmental process, and a continuum
	Recovery is nonlinear
	Family involvement in recovery is helpful
	Peer support in recovery may be crucial
	Spirituality may be a critical component of recovery
Strategies to facilitate recovery	Identify and engage early
	Carry and instill hope, offer role modeling
	Increase motivation for change (recovery priming)
	Offer information and education about the condition(s), recovery, available resources, and ways to self-manage the condition(s)
	Provide interventions effective in resolving crises, reducing or eliminating symptoms and/or impairments associated with condition(s), and improving health
	Provide opportunities, rehabilitation, and supports for persons to gain needed skills for occupying valued roles (e.g., student, spouse)
	Assertively connect person to other people in recovery, mutual support, recovery advocacy organizations, and indigenous recovery communities
	Provide post-treatment monitoring (recovery checkups) and support; active recovery coaching (stage-appropriate recovery education and advice); and, when necessary, early re-intervention
	Offer community supports to enable person to lead a self-determined and meaningful life in the communities of his or her choice (e.g., supported housing, supported employment, supported education)
	Legal advocacy to counter stigma and discrimination, ensure the person's rights, and enable the person to regain the status of being a contributing member of society

Table 2 (continued)

Domain	Mental illness	Addiction
Essential ingredients of recovery-oriented systems	Motivation-based outreach and engagement interventions	
	Basic (material and instrumental) support	
	Pre-treatment, in-treatment, and post-treatment recovery coaching/mentoring	
	Assessment processes that are global, continual, and strengths-based	
	Respite for people in recovery and families	
	Rehabilitation and ongoing provision of community supports	
	Peer support	
	Family education and support	
	Legal aid/advocacy	
	Intensive clinical services, including crisis prevention and response, pharmacological and psychosocial treatments	
	Acute inpatient care	Detox
	Illness management and recovery	Contingency management
	Assertive community treatment	Motivational interviewing

Adapted from an article by Davidson and White [17]
Note suggestions for how substance use disorder and mental health treatment can be structured to impact both disorders

that "treatment in parallel and separate mental health and substance abuse treatment systems is remarkably ineffective". An integrated approach would make recovery the focus of treatment and would address parallel challenges associated with addiction and mental illness. Davidson and White [17] provided a thoughtful conceptualization of integrated treatment. Their table (adapted here as Table 2) details the key components of their integrated substance abuse and mental health treatment approach and illustrates how an integrated substance use disorder and mental health treatment approach might be structured.

Introduction

The Institute of Medicine has provided a working definition of primary care:

> Primary care is the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients and practicing in the context of family and community [41].

This definition emphasizes several aspects of care that impact individuals who use alcohol, tobacco, and other drugs.

1) continuity of care over a "sustained" time period
2) responsibility for addressing the majority of health care needs, including behavioral or psychological problems
3) Coordination of "integrated" care that may include multiple consultants and groups
4) Inclusion of community and family issues that may challenge or promote health
5) Being "accountable" for care is meant to imply some regard for efficiency and cost effectiveness, and for long term outcomes across multiple conditions
6) Care is not in the sole purview of physicians: a team of nurses, counselors, physician's

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_42,

assistants, and others are the key to effective care.

The Institute of Medicine goes on to describe core functions of primary care relevant to substance users.

(1) Primary and secondary prevention, including screening for modifiable risk factors before they become problems
(2) Education of patients to help them live healthfully and to self-manage problems
(3) Initial evaluation and treatment of problems as they emerge

Primary care may be practiced by many medical professionals. Most readers will be familiar with general internists, family practitioners or pediatricians in this role, but gynecologists, and other subspecialists, such as those in infectious disease, nephrology or endocrinology, often provide primary care. In the United States, about half of the approximately one trillion doctor visits made in 2004 were to primary care clinicians (internal medicine, family medicine and pediatrics) [2].

Given primary care's ubiquity and the multiplicity of functions (particularly the "ownership" in the long run of a patient's care), primary care providers are poised optimally to help patients with chronic behavioral health problems, especially those that manifest with physical or emotional troubles that may cause someone to seek medical attention. Indeed, the setting for which the literature best supports the efficacy of brief interventions for alcohol is primary care practice. Problems that are accompanied by shame and secrecy may need a trusted relationship with a professional to catalyze healthy change. The primary care provider may be the only person in a patient's life who can fill that bill. Tobacco smoking, unhealthy alcohol use, and other drug and alcohol problems are common among patients seeing primary care practitioners. About one in five adults visiting primary care clinicians drink above recommended limits or have problems related to alcohol. Studies of primary care practices have demonstrated the success of care provided to people with substance use problems, but also the large gap between the prevalence of problems and the rates of screening, detection, and treatment of those problems.

This chapter addresses those gaps. Primary care providers are optimally positioned to identify, assess, manage and refer to specialty care as needed for drug and alcohol problems as well as psychiatric and medical problems that accompany or are caused by the substance use. The challenge to primary care in this arena is great; so too is the opportunity to make a profound difference in the lives of patients and their families [42].

Screening

Unhealthy alcohol and drug use are highly prevalent in the community and among primary care patients. They can result in physical and social deterioration and in increased use of costly medical resources. The primary care provider can detect preclinical at-risk or problem use, and intervene effectively prior to the development of a substance use disorder (i.e. abuse or dependence). This paradigm is best studied and supported for alcohol and tobacco, but weaker support exists for detection and intervention for other drugs. It is for conditions for which we know that early versus later intervention can delay or diminish disease severity, morbidity or mortality that a strong argument can be made for screening.

Screening for Alcohol Use

Surveys have found that screening is far from universal, and that only 13% of primary care providers use a validated instrument or tool to do so. When problems are identified, most primary care providers recommend self-help groups, but about a fifth of primary care providers offer no formal therapeutic intervention [34]. In a review of thousands of records, McGlynn et al found

that about one-half of recommended health services were provided to adult patients. Services for alcohol dependence were at the lowest level: only 10% of patients with alcohol dependence documented in the medical record had it addressed in any way [52].

The United States Preventive Services Task Force recommends screening and brief intervention for unhealthy alcohol use for adults and pregnant women. The United States Preventive Services Task Force found that screening and brief intervention improves important health outcomes and that benefits outweigh any risks. The recommendation is as strong as that for screening mammography for women aged 40–50, osteoporosis screening for women aged 65 or older, or cholesterol screening in young adults with other risk factors for coronary artery disease. One clear difference between screening and brief intervention for alcohol use and the other preventive services listed is that screening and brief intervention is a more time-consuming interaction with a patient than is ordering a radiologic or blood test. In a revenue-driven healthcare environment, test ordering may add revenue to an institution. Prevention of alcohol disorders and their consequences, in contrast, may slow down the primary care provider, decreasing volume-based-revenue, even with the prospect of downstream cost-savings. (This scenario may be mitigated in part by the current existence of a billing code for screening and brief-intervention for substance use). Indeed, screening and brief intervention is likely to be cost savings as well as cost-effective, at least from a societal perspective [76]. Screening and brief intervention for alcohol ranks in the top five of preventive services for cost-effectiveness [85].

Unhealthy Alcohol Use: Definitions

In the United States, about 70% of men and 60% of women over the age of 18 years drink alcohol [25]. While there is evidence that low-level consumption is low risk and may confer health benefits [77], higher amounts risk medical consequences. Thus, one dimension of screening for unhealthy alcohol use is solely based on quantity and frequency of intake. The other dimension that screening can address is alcohol consequences.

The National Institute on Alcohol Abuse and Alcoholism has defined cut-offs for unhealthy use that are empirically based in epidemiologic literature. Risky drinking amounts are those above these cut-offs. For men, this level is greater than 14 drinks/week or > 4 drinks on an occasion; for women this cutoff is >7 drinks/week or > 3 drinks on an occasion. For those over 65 years of age, the cut-off is that for women. A "drink" is defined, in the United States, as 12–14 g of ethanol (12 oz of beer, 5–6 oz of wine, and 1.5 oz of 80 proof spirits) (Table 1). Drinking risky amounts without associated consequences is risky drinking. If there are consequences/problems, patients may have problem alcohol use, alcohol abuse or alcohol dependence (the latter two are alcohol use disorders as defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition) [4]. An important exception to using consumption to define unhealthy use is when even low-level use risks consequences. Examples include pregnant women, people taking medications that interact with alcohol, and those with health conditions worsened by even small amounts (e.g. hepatitis C infection). The key distinction among those with unhealthy alcohol use is whether or not dependence is present. Identifying dependence is important because management differs, as discussed later in this chapter.

What is the best way to screen for unhealthy alcohol use? While we usually think about face-to-face discussions or questions in the clinical setting, screening runs the gamut from these to telephone or web-based instruments [49]. These should be considered and adapted as appropriate, with an eye to optimal efficiency and effectiveness, for system-based approaches.

Any interaction between the primary care provider and patient should serve to build the therapeutic relationship. Therefore even rote history-taking should be conducted in an empathic, nonjudgmental way. Embedding

Table 1 Alcohol use definitions

		Quantity	Alcohol-related problems/consequences
Lower risk use[a]		Below NIAAA-recommended limits cutoffs	None
Unhealthy use	Risky use	Above NIAAA-recommended limits	None
	Problem use	Not part of definition	Present but not meeting criteria for abuse or dependence
	Abuse	Not part of definition	Meets DSM-IV Abuse Criteria
	Dependence	Not part of definition	Meets DSM-IV Dependence Criteria

[a]The possible exceptions to the "lower risk" category are conditions in which any drinking may pose health risks. These include alcohol dependence (e.g., past), family history of alcohol dependence, pregnancy, use of medications that interact with alcohol, disorders or symptoms usually made worse by alcohol (e.g., for psychiatric symptoms or medical disorders such as hepatitis, peptic ulcer disease, or epilepsy)
Adapted from Refs. [4, 29, 56, 71]

questions about alcohol use among other routine medical history questions may serve to decrease resistance and improve both the tenor of the discussion and the quality of information generated.

The first order of business is to ascertain whether the patient drinks at all. The clearest question is: "Do you sometimes drink beer, wine or other alcoholic beverages?" If the patient does not drink at all, inquiring into the reasons may reveal that the patient is abstaining after prior problematic use. If the patient drinks at all, then quantity and frequency of drinking should be evaluated.

One wants to assess the average number of drinks in a week and whether there are any heavy drinking episodes, i.e. drinking in excess of the single-occasion cut-offs delineated by the National Institute on Alcohol Abuse and Alcoholism. This brief screen can be done with three questions [56]

- On average, how many days per week do you have an alcoholic drink?
- On a typical drinking day, how many drinks do you have?
- What is the maximum number of drinks you had on any given occasion during the past month?

With the first two responses, the number of drinks per week can be calculated, and if weekly cut-offs are exceeded, then there is risky drinking. Similarly, if limits per episode are exceeded, the patient is drinking at a risky level.

The most recent version of the National Institute on Alcohol Abuse and Alcoholism Clinician's Guide recommends a single question to screen people who drink for unhealthy alcohol use [56]:

> "How many times in the past year have you had X or more drinks in a day?" where X = 5 for men and 4 for women. A response ≥ 1 is considered positive. This single item is both sensitive and specific for detecting unhealthy alcohol use (from risky use through abuse and dependence) [75].

Vinson tested a similar single item for screening for risky drinking:

> When was the last time you had more than X drinks in a single day (where the value for X is 4 for a woman and 5 for a man)?

A "positive" response is anytime within the last three months [24].

These single-question instruments are brief, valid and therefore efficient.

The Alcohol Use Disorders Identification Test (see Fig. 1) is a ten-item instrument developed by the World Health Organization with good performance characteristics for identifying unhealthy alcohol use. It is scored from 0–40 with a score of 8 (for men) and 4 (for women and those over 60 years of age) considered positive. It requires scoring so may be better suited to a

PATIENT: Because alcohol use can affect your health and can interfere with certain medications and treatments, it is important that we ask some questions about your use of alcohol. Your answers will remain confidential, so please be honest.

Place an X in one box that best describes your answer to each question.

Questions	0	1	2	3	4	
1. How often do you have a drink containing alcohol?	Never	Monthly or less	2 to 4 times a month	2 to 3 times a week	4 or more times a week	
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 to 9	10 or more	
3. How often do you have 5 or more drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
5. How often during the last year have you failed to do what was normally expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
8. How often during the last year have you been unable to remember what happened the night before because of your drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
9. Have you or someone else been injured because of your drinking?	No		Yes, but not in the last year		Yes, during the last year	
10. Has a relative, friend, doctor, or other health care worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year	
					Total	

***Note*: This questionnaire (the AUDIT) is reprinted with permission from the World Health Organization. To reflect standard drink sizes in the United States, the number of drinks in question 3 was changed from 6 to 5. A free AUDIT manual with guidelines for use in primary care settings is available online at *www.who.org*.**

Fig. 1 The alcohol use disorders identification test. From Ref. [56]: NIAAA, "Helping patients who drink too much", NIAAA Publication No 07-3769; updated 2005 edition, printed May 2007

pen-and-paper or automated process than to verbal interview.

A briefer validated screening tool is the Alcohol Use Disorders Identification Test-C. It is comprised of the 3 quantity/frequency questions from the Alcohol Use Disorders Identification Test and also requires scoring [18, 68]. Using a score threshold (or cut-point) of 4 for males and 3 for females will identify unhealthy alcohol use while choosing 5 and 4 respectively is more useful for identifying alcohol use disorders.

If a patient is NOT drinking above recommended cutoffs and has no absolute contraindication to any drinking, then the patient should be congratulated on the healthy pattern, educated about the risks and benefits of moderate drinking (the best evidence being for an increased risk for breast cancer and decreased cardiovascular risk) and educated about optimal limits. If the screening is "positive," however, then further assessment is recommended for confirmation and to determine severity.

Screening for Tobacco Use

Evaluating the use of tobacco is by-and-large a simpler process than that for use of alcohol. The healthiest level of tobacco intake is none. Since efforts to make smoking a "vital sign," whether the patient smokes is now frequently recorded as a matter of routine at contacts with health care providers. Caution should be taken with patients who define smoking as regular or current use; they may report they are non-smokers despite sporadic or recent but not current regular use. Finally, the presence of past or current smoking may itself raise concern for concomitant unhealthy alcohol use [53].

Screening for Other Drug Use

The CAGE-AID is identical to the CAGE, one of the earliest validated alcohol screening questionnaires, with the exception that the clause ". . .or drug use" is appended to each of the four questions [21]. For example, the C question is: "Have you ever felt you should cut down on your drinking *or drug use*?" One affirmative response is a positive test. The CAGE-AID, like its source the CAGE, is limited in its focus on consequences, being less useful for identifying risky use.

THE DAST-10 is a screening questionnaire that asks about drug use and consequences. A score of 3 or more is positive. Its length, but particularly the lack of validation studies in primary care settings, limits its utility [74]. The ten questions probe for physical and social consequences (e.g. blackouts, withdrawal, relationship problems) and loss of control over use.

The Alcohol Smoking and Substance Involvement Screening Test is a complex instrument of 80 items yielding independent scores for each of multiple substances. A "positive" screening test can be defined as a score of 2 or greater (indicating any drug or alcohol use in the past 3 months), though the cutoff of 4 or greater is probably more clinically useful (indicating either weekly use or less frequent recent use accompanied by consequences of use). It has been validated internationally. Although there are 80 items, if no use of a specific substance is reported, only 10 items need to be answered. If the patient reports any use of a substance, then a series of questions are asked about that substance. Its complexity, length and need for scoring limit its utility in routine clinical primary care practice though where computers are integrated into clinical or research settings the test may be usable. Another major limitation of the Alcohol Smoking and Substance Involvement Screening Test is that the results do not directly identify use of risky alcohol amounts per se, a critical target of screening in primary care settings because of the prevalence and the proven value of brief intervention for such patients [88].

A shorter, more convenient screening test, but with limited validation, consists of two questions, the Two-Item Conjoint Screen [20]:

> "In the past year have you ever drunk or used drugs more than you meant to?"
>
> and
>
> "Have you felt you wanted to cut down on your drinking or drug use in the past year?"

Responses of 0, 1, and 2 positive answers indicated approximately 7, 35 and 70% chance of a current substance use disorder, respectively, in one clinical population. The sensitivity and specificity are both approximately 80%. The validation study for this test has not been replicated and the questions have not been studied for detecting drug use without abuse or dependence.

A Substance Abuse and Mental Health Services Administration [80] consensus agreed that the following would be a useful question for a single-question screening test. It has not been validated.

"Have you ever used street drugs more than five times in your life?"

While streamlined, "prescription" drugs will be missed as pharmaceuticals bought on the street (illegally) may not be detected. It is also not clear how a diverse sample of patients in primary care will respond to being asked about "street drug" use, and the "ever" time frame requires the primary care clinician to ask a series

of follow-up questions before deciding whether current use is present and needs to be addressed.

Assessment

For any patient with unhealthy alcohol or drug use, further assessment should delineate the role of the substance use in the patient's life. This runs the gamut among physical, emotional, interpersonal, and social/vocational functioning. Ultimately, ruling-in or –out the diagnosis of a substance use disorder, in particular dependence, is desirable, because management differs.

If the patient is screens positive for drinking above recommended limits, then there are several next steps: The primary objective of the evaluation is to determine if there is alcohol dependence. If there is no dependence, then brief counseling has proven efficacy and is indicated. If there is dependence, then the effectiveness of brief intervention is less certain, but brief counseling with a goal of further care by the primary care provider or via referral is desirable [70]. Dependence warrants an offer of pharmacotherapy, mutual help, and counseling. This can be provided by the primary care provider if expert, and time permits, and/or by referral to specialty care, generally the favored approach if available and the patient is willing to go. The other important objective of assessment here, whether or not dependence is diagnosed, is to gather information about the impact of alcohol in the patient's life, both positive and negative, to be able to counsel the patient appropriately. Such insight is necessary to enable use of motivational interviewing to assist with behavior change [54].

One approach to assessment (recommended by the National Institute on Alcohol Abuse and Alcoholism Clinician's Guide) [56] is to ask the patient about alcohol dependence symptoms. The cardinal elements of dependence are loss of control, use despite negative consequences, and significant negative impact of use. A patient meets criteria for the diagnosis of dependence if three or more of the following are present in a year, accompanied by significant impairment or distress:

1. Tolerance
2. Withdrawal
3. Use despite known consequences
4. Using more than intended
5. Inability to stop or cut-down
6. Spending substantial time getting, using and recovering from use
7. Giving up important activities

Abuse is more common and less severe. Criteria for abuse are one or more of the following in a year [4]:

1. Repeated use in hazardous situations
2. Use despite negative social consequences
3. Recurrent use despite interference with significant roles or function
4. Recurrent legal problems related to drinking.

Further assessment for psychiatric comorbidity is indicated when an alcohol use disorder is identified because it is common and needs to be addressed.

Some screening tests provide information regarding the presence of alcohol use disorders. While a detailed interview is recommended for assessment, primary care providers often will not have such time available, particularly at the same visit during which a patient screens positive. As such, screening tests that provide information about consequences can help suggest the presence of dependence.

Although not designed as an assessment tool, the 4-item CAGE questionnaire at a score of 2 or greater indicates a high likelihood of lifetime abuse or dependence. The four questions with which many primary care providers are already familiar, are:

Have you ever felt you should *Cut down* on your drinking?

Have people *Annoyed* you by criticizing your drinking?

Have you ever felt bad or *Guilty* about your drinking?

Have you ever taken a drink first thing in the morning (*Eye-opener*) to steady your nerves or get rid of a hangover?

A positive answer is worth one point, and a score of one is 85% sensitive and 78% specific for an alcohol use disorder; a score of two is 71% sensitive and 91% specific [1, 22].

Vinson and colleagues [87] tested two concepts to see if their presence or absence could separate those who screen positive into two groups—those with and without an alcohol use disorder (abuse or dependence),—to determine urgency of need for intervention and likely long-term management. The concepts (which came from several research studies that asked about them in slightly different ways) were summarized by these two questions:

1. In the past year, have you sometimes been under the influence of alcohol in situations were you might have caused an accident or gotten hurt? and
2. Have there often been times when you had a lot more to drink than you intended to have?

The test is considered positive if either question is answered affirmatively. The approach has promise though further validation will be important.

Management of Unhealthy Drug and Alcohol Use

Brief Intervention

Brief intervention is an essential part of the primary care provider's management of patients with unhealthy behaviors in general and unhealthy drug and alcohol use in particular. It is covered in detail in Chapter "Brief Interventions for the Treatment of Alcohol or Other Drug Addiction". Brief intervention is a brief, patient-centered counseling of no more than 40 but usually 10–15 min. Using a motivational interviewing approach, the primary care provider provides feedback to the patient about their substance use and any consequences (or risks thereof) of importance to the patient (e.g. social, occupational, legal, medical, psychological), and how their use compares to norms (Table 2). Along with the assessment should come clear advice about change. The patient's desires and understanding about and need to change should be elicited, as should their ability and readiness to change. Then with the patient's agreement, a menu of options for courses of action should be discussed. Their commitment, including an agreement about the next step and (long- and short-term) goals should be agreed upon and recorded. Finally, arrangement for follow-up should be made. The approach must be empathic, and must support the patient's self-efficacy.

More specifically, the clinician should determine the patient's perception of their use and need for change (e.g. "Do you think your drug use is a problem?") [70]. For those who are not ready to change, the goals are to increase problem awareness, express concern, and agree to disagree. Sometimes a trial of abstinence or cutting down can be useful. For those considering change, the goal is to tip the balance towards change by eliciting positive and negative aspects of drinking and not drinking, to demonstrate discrepancies between patients' values and actions. Once the patient has decided to change, working on motivation is not helpful but reviewing options is. The patient will need support and encouragement, and a reminder that the therapeutic relationship will continue regardless of continued unhealthy use or success in cutting down.

Management of Nondependent Unhealthy Alcohol and Drug Use

Brief intervention has been demonstrated to significantly improve drinking outcomes when delivered in many clinical settings and by varied clinical personnel, though the best controlled trial evidence is for screening and brief intervention in primary care settings by primary care providers [16, 31, 32]. Although they are

This table may be useful for helping patients understand how their level of drinking objectively compares to that of Americans of the same age and gender. For example, a 50 year old woman who drinks 2 drinks every day can be provided with the fact that she drinks more than 98% of American women her age

Reprinted from Ref. [25], with permission from Elsevier

less-well studied, brief interventions can also be written, phone, or computer/Web-based, and can be single or multiple contacts [49]. The best evidence for efficacy is for multi-contact interventions. Implementation depends on the particular practice setting.

Fleming and colleagues demonstrated in a randomized controlled trial of a multi-contact brief intervention, that significant effects on drinking and health care utilization and expenditures can be detected for up to four years [33]. One meta-analysis demonstrated brief intervention for alcohol decreases mortality [26]. Meta-analyses predict that on average alcohol intake will decline by 38 g per week (a 15% decrease) [15] and that the proportion of people drinking risky amounts decreases to 57% in brief intervention groups and 69% in controls [13].

The evidence supporting brief intervention for drugs other than alcohol and tobacco is more limited. Only three controlled trials have tested brief intervention for drugs after screening in outpatient settings. Bernstein and colleagues studied patients who used cocaine and or heroin presenting for care in outpatient (not primary care) settings. A single motivational brief intervention delivered by a trained health promotion advocate reduced cocaine and heroin use at 6 months more than written advice alone [14]. For example, more cocaine users who received brief intervention were abstinent than were controls (22% vs. 17%). One small trial (in 59

adolescents) demonstrated efficacy of brief intervention in primary care for marijuana and ecstasy use and problems [27]. Finally, the World Health Organization Alcohol Smoking and Substance Involvement Screening Test phase 3 trial found that brief intervention had efficacy (in 3 countries but not the United States) for decreasing a score on a screening test that reflected use and/or consequences [88].

Brief interventions can decrease substance use but even under the best circumstances (e.g. the evidence for alcohol brief intervention in primary care) many people continue to have unhealthy use. The effectiveness of repeated brief interventions is unknown, but primary care settings do provide the opportunity to address such behavior-change issues over time. Over the course of time, with repeated education and intervention, the case for change can build in breadth and depth. As the clinician learns more about the patient and their substance use, the advice and rationale may become more personally salient and effective. The key for clinicians delivering longitudinal care is to maintain an empathic alliance and continue to address substance use. Drinking despite known negative consequences is a *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criterion for dependence, so clinicians should remain alert to any consequences and the development of dependence.

If there is an important person in the patient's life, it may be effective to bring this person into the discussion, with the patient's consent. This person should be invited into a face-to-face visit with the patient. They may offer an important perspective, for instance by furnishing information about consequences of drinking or by assisting in the process of change. It may also be necessary for the behavior change to be a goal shared by the two people for success to take hold.

Once a patient has been able to reduce drinking to healthier levels, then the clinician should recognize and affirm this success, and monitor for any recurrence.

This discussion of management of nondependent drinking may be applied to non-dependent use of other drugs. It should be noted that in virtually all cases in the United States, the illegal activities involved in procuring illicit drugs is an obvious risk that can be used in motivational brief interventions. Several drugs, depending on route of administration, induce dependence at high rates, so non-dependent use will be rare; for instance, smoked free-base or crack cocaine is rarely a casual behavior over which there is robust control.

Management of Alcohol Dependence

Several approaches to alcohol dependence can be effective in primary care settings, namely, pharmacotherapy, counseling, and referrals.

Pharmacotherapy

For the management of alcohol dependence, acamprosate, naltrexone, and disulfiram have proven efficacy (see Chapter "Pharmacotherapy for Alcoholism and Some Related Psychiatric and Addictive Disorders: Scientific Basis and Clinical Findings") These medications, to be most effective, should be given along with counseling which can be done in primary care settings [78]. Medications for alcohol dependence are not magic bullets and should be considered as one of several effective approaches. Even with pharmacologic support, many patients find initiating and maintaining change to be challenging. We emphasize the importance of continued motivational counseling, mutual-help and peer support in the community and attention to relapse prevention with or without medication use. But no single approach is 100% effective for this chronic and serious condition so no known effective interventions should be excluded from consideration. As such, offering and discussing medications with patients should be routine and realistic, addressing efficacy without falsely raising hopes. Because medication adherence is one of the hardest challenges to overcome in primary

care for all chronic diseases, let alone for behavioral problems, minimizing and managing any side effects are critically important. Counseling designed to enhance medication adherence is also recommended.

Acamprosate has been approved for use in Europe since 1989 and in the United States since August 2004. It has generally been studied in patients abstaining from alcohol for at least five days. It is an oral medication that is taken three times a day (two capsules each time for a total of six capsules daily). A congener of homotaurine, it is active at the gamma-aminobutyric acid receptor and thought to modulate glutamatergic activity at the N-methyl-D-aspartate receptor. Its use is associated with an improvement in abstinence rates (15% in placebo vs. 23% for acamprosate treated patients at 12 months) time to first drink, and days of cumulative abstinence, with a number needed to treat of 7.5 to achieve a 13% absolute risk reduction in relapse at 12 months [17, 50, 69]. In one study, it was effective when administered for a full year, and also reduced relapse for an additional year of follow-up. It is relatively well tolerated, reflected by low drop out rates in clinical trials. The main side-effect is diarrhea. Renal insufficiency is a relative contraindication (dictates a dose reduction) [62, 63].

Oral naltrexone has been approved to treat alcohol dependence in the United States since 1994 and long-acting injectable naltrexone (monthly) since 2006. It is a mu opioid receptor antagonist that is considered to block central endorphins and to decrease levels of dopamine released in the nucleus accumbens, a key event in euphoria and reward. Naltrexone has also generally been studied in abstinent patients [79]. Orally it is taken daily usually at a dose of 50 mg. Most published studies are limited to a few months' duration, but there is support for its use up to six months [7]. Over weeks of ongoing treatment, measures of "craving" for alcohol diminish with time [73]. It may diminish craving and preoccupation with alcohol more than acamprosate [46]. There is good support for its role in decreasing rates of relapse to heavy drinking from 48% in controls to 37% in those on naltrexone, but weaker support for that of increasing continuous abstinence rates. Its effectiveness may be enhanced with cognitive behavioral therapy [6] but it has also been effective in protocols with minimal counseling components [60], making it well suited to the primary care setting. Other secondary outcomes are improved, including density of drinking and number of days without drinking. Medical outcomes, such as liver enzyme levels, improve with treatment as well [11]. It cannot be used in patients who require the use of opioids and should be withheld prior to elective procedures requiring opioid analgesia. Management of patients taking naltrexone with unanticipated need for opioid agonists, for example trauma victims, may be complex, requiring high doses and careful monitoring. It can be associated with gastrointestinal side effects but these are generally self-limited and minor [17, 64]. Despite the relative advantage of acamprosate with respect to its effect on abstinence, naltrexone has re-emerged in practice because of its significant superiority in a head-to-head trial versus acamprosate [5, 7]. The injectable long-acting form may help address the challenge of medication adherence [36].

Disulfiram is an inhibitor of aldehyde dehydrogenase, a step in the metabolism of alcohol. This causes the accumulation of acetaldehyde that causes a range of reactions from an uncomfortable flushing reaction and nausea, to more severe problems such as vomiting, dehydration, and death. It is used as an "aversive" treatment to heighten the negative consequences of drinking. In placebo-controlled trials it fails to show efficacy. In more structured settings, such as when a family member may supervise and witness administration of the medication, it may be efficacious. Several trials confirm that supervised administration is more effective than unsupervised dosing [71]. Because it has a high risk-to-benefit ratio, even in optimal settings, we do not typically choose this medication first. When it is prescribed, written informed consent should be obtained, reinforcing the supervisor's role as well as the possibly fatal consequences of co-administration with alcohol. Hepatitis is a feared side effect [28].

Counseling in Primary Care

Even within the time constraints of the primary care practice, there are models of counseling that can be adopted and adapted as feasible. Motivational interviewing is adapted as motivational enhancement therapy. Four sessions of motivational enhancement therapy was as effective as 12 sessions of cognitive behavioral therapy or 12-step-facilitation in one large randomized trial. Motivational enhancement therapy, while more extensive, has many parallels to motivational brief interventions done in primary care settings.

One model of adherence enhancing counseling with the acronym BRENDA has been tested with oral and injectable naltrexone. The elements of the model, described below, are individually or in combination supported by literature in depression and substance abuse management [78].

The acronym indicates that the model begins with a *Biopsychosocial* evaluation. This emphasizes that there is more to alcohol dependence than physical dependence. Providing feedback to the patient with a *Report* on this assessment is akin to brief intervention. *Empathic* understanding of the patient's situation as opposed to a confrontational style is a key element of interactions that fosters a strong therapeutic alliance. Rather than recommending one treatment to all patients, it is recommended that support and therapeutic interventions reflect the *Needs* collaboratively identified by the patient and the treatment provider. The many treatment types that have been demonstrated to improve drinking outcome with little evidence or clear superiority of any one, argue for acknowledgement of patient preferences. These first four BRENDA steps create a patient-centered, empathic alliance; they set the stage for and are recommended to precede the giving of *Direct* advice to the patient on how to meet the identified needs. Soliciting the patient's reaction to the advice and checking in as to the relevance and feasibility of the plan is key. This last step, to *Assess* reaction of the patient to advice and adjust as necessary for best care, permits the primary care provider and patient to arrive at a mutual plan. The patient role here may enhance self efficacy, motivation and ultimately behavior change.

An approach dubbed "medical management" tested in the "COMBINE" study calls for an initial discussion lasting 45 min and eight follow-up sessions of approximately 20 min over the ensuing 4 months, on average every two to three weeks. The sessions covered a review of drinking, medication use and effects, and global functioning [65]. In the COMBINE study, medical management as described here proved more efficacious in increasing the number of days of abstinence than a more intensive behavioral counseling intervention. While perhaps not a generalizable finding, this does reinforce the message of effectiveness of counseling that could be administered in the primary care setting [7]. Even if physician time is too limited for such counseling, health behavior change counselors in these settings could deliver it.

Primary care providers should adopt a proactive stance to supporting recovery activities. The counseling techniques described here are consistent with that general stance. It may be beneficial to discuss patient's participation in self-help groups in the community as a routine part of every visit. Exploring resistance to and benefits from meetings, suggesting active versus passive participation (e.g. working on "steps" or getting a sponsor) and recommending persistent and methodical attendance all promote engagement [40, 57].

Management of Tobacco Use

Brief interventions have been demonstrated to reduce smoking significantly. For patients who do not respond to brief counseling, the primary care provider should be familiar with medication and counseling approaches to tobacco cessation [10, 38, 44]. Chapter "Nicotine" contains a detailed guide to the use of nicotine replacement therapies, bupropion, and varenicline for

the treatment of nicotine dependence. The essential approach described for alcohol dependence is applicable to tobacco: focus on the patient's distress, maintain an empathic connection; support medication use by monitoring side effects and responses, and continue to work toward sustaining all positive behavior changes.

Management of Opioid Dependence: Pharmacotherapy

Rates of relapse to opioids are high when patients are not taking maintenance opioids for substitution therapy, so called opioid maintenance or opioid agonist therapy. A small minority of opioid dependent patients will be abstinent at one year if not receiving substitution therapy. From 30 to 60% of patients provided opioid maintenance with methadone or buprenorphine are not using illicit drugs at 6 months. Under the federal Drug Abuse Treatment Act of 2000 [84], specially qualified physicians may prescribe buprenorphine for sublingual administration for a limited number of opioid dependent patients. The management of opioid dependence with maintenance therapy, formerly legal only in methadone maintenance programs, has now begun to shift to outpatient clinicians outside of specialty settings and into the hands of primary care providers [82]. Qualifications for prescribing buprenorphine under the Drug Abuse Treatment Act of 2000 are listed in Table 3. With documentation of qualifications, application is made to the Food and Drug Administration for a special Drug Enforcement Administration number to use when prescribing buprenorphine. In the first year, qualified physicians can have 30 patients with active prescriptions at any one time. After a year of practice, application may be made to expand the allowed number of patients to 100.

Buprenorphine is a partial mu receptor agonist, meaning that it is active at the same receptor as morphine (and heroin, and oxycodone, etc.) but with only partial activation. It therefore produces a weaker drug effect than the "pure" agonists with less euphoria, less fatigue and fewer side effects such as respiratory depression or constipation (i.e. it has a ceiling with respect to these effects). It is more tightly bound to the receptor; therefore, agonists with stronger activity but weaker binding cannot occupy and activate the receptor. In fact it precipitates withdrawal from such substances. The only medication approved thus far for use under the Drug Abuse Treatment Act of 2000 is buprenorphine. It is available alone, or in combination with naloxone, the opioid antagonist that is usually administered intravenously. The buprenorphine and the buprenorphine/naloxone tablets are administered sublingually; via this route a negligible dose of naloxone is absorbed. The purpose of the addition of naloxone to the tablet

Table 3 Physician qualifications for prescribing buprenorphine for opiate dependence

Valid medical license (M.D. or D.O.)
Ability to refer to or provide appropriate psychosocial treatments
Must meet one or more of following:
+ Subspecialty board certification in addiction psychiatry from the American Board of Medical specialties
+ Subspecialty board certified in addiction medicine from the American Osteopathic Association (AOA)
+ Addiction certification by the American Society of Addiction Medicine
+ Successful completion of a qualifying 8-h educational offering by the American Academy of Addiction Psychiatry, American Medical Association, AOA, or any Department of Health and Human Services-approved organization
+ Physician is an investigator in a clinical trial that led to approval of buprenorphine
+ Training or experience as determined by a State Licensing Board
Adapted from Ref. [84]
U.S. Department of Health and Human Services Substance Abuse and Mental Health Services Administration Center for Substance Abuse Treatment Clinical Guidelines for the use of buprenorphine in the treatment of opioid addiction. Treatment Improvement Protocol (TIP) 40. Publication No. (SMA) 04-3939, 2004.

is to decrease the desirability of diversion of the medication to parenteral use: when the combination is injected, the naloxone is fully active and blocks the effects of any opioid at the mu receptor, causing an abrupt withdrawal in patients who have circulating or bound mu opioid agonists.

Patients meeting criteria for current opioid dependence (or in some cases those in remission but at high risk of relapse) may be managed with the use of buprenorphine. Detoxification or maintenance is possible, although relapse (and mortality) rates have been high after detoxification, and short-term outcomes of maintenance are superior. Patients who can do well in the relatively less-structured setting of the primary care provider's office generally can adhere to office procedures and protocols, and have no major comorbid psychiatric disorder and no dependence on a variety of other substances. The initial dosing of buprenorphine, evaluation, and follow up require assiduous attention and can be complicated. Physicians who have qualified and have obtained their special Drug Enforcement Administration number may receive ongoing advice and support through a Center for Substance Abuse Treatment-sponsored mentorship program, the Physician Clinical Support System (www.pcssmentor.org).

Referral to Specialty Care

For patients whose drinking or drug use meets the definition of dependence, the primary care provider may refer to and collaborate with specialty care clinicians, and should be familiar with available resources. Physicians should be familiar with how to refer to 12-step programs so that they can more effectively refer patients. Primary care providers should be aware of resources listing local meetings, and should attend meetings to be familiar with where they are sending patients. Many groups have representatives willing to come to physician offices or to meet patients to make referrals easier.

Primary care providers should also, as they would be for medical subspecialties, be familiar with local counseling resources, knowing what treatments are offered, how, if and which patients can access them. For patients with opioid dependence, referral for methadone (or buprenorphine) should be considered. Finally, the primary care provider should become aware of all local resources for referral of patients who exceed the clinician's expertise or available time for appropriate management.

Patients in Recovery

Primary care clinicians will care for many patients in recovery from dependence on drugs or alcohol [35]. Primary care providers who screen all patients will be aware of such personal history. Supportive discussions about recovery should be part of every routine visit. When situations that may increase risk for relapse are encountered, or anticipated, problem-solving and recovery enhancement discussions should ensue. Any significant change in routine can signal risk. If patients change housing, relationships, or jobs, discussing relapse potential may be prudent. If the patient or a relative is experiencing significant medical illness, or is diagnosed with a life-changing disease, the possibility of relapse should be discussed. If a patient with an active recovery routine, for example with regular participation in 12-step meetings, interrupts this practice, reasons should be explored, as such a change may herald relapse. And finally, when abstinent patients begin to experiment with "controlled" use of the problematic substance, empathic, clear concern should be expressed. If the patient is resistant to the notion that such use is itself problematic, it is good to discuss what warning signs would concern the patient. The sound of the patient's own voice describing such a scenario is sometimes enough to clarify the risk and catalyze improvement.

Patients newly achieving sobriety often feel shame and regret. This may extend to the maltreatment of their own bodies. Frequently patients worry about the state of the liver, heart, brain, immune system or kidneys after

a prolonged time using substances. This worry is often inaccurate or unrealistic. The primary care provider can support recovery by attending to such patients' concerns without being dismissive, but without augmenting the sense of urgency. It is normal for patients in early recovery to feel malaise or fatigue; these are probably not symptoms of underlying disease. Changing sleep patterns and appetite are part of recovery as well. It is acceptable practice to monitor patients closely over time rather than sending off batteries of tests. An exception to this approach of using the "test of time" would be for common infectious diseases that respond to treatment. Therefore repeated testing, for example, for exposure to HIV or hepatitis C would not be misplaced effort.

Treatment of Psychiatric Comorbidity

The details of the evaluation and management of comorbid psychiatric conditions are touched upon in various chapters throughout this book. There are higher rates of affective disorders among individuals who use alcohol, tobacco, and other drugs. There are several core principles that inform our practice and bear repeating for the primary care provider. First, the primary care provider should arrive at a mutual understanding with the patient about which symptoms are to be followed and evaluated as markers of the mental health condition. These may or may not be the most troubling for the patient. Those symptoms with higher frequency will be more sensitive bench marks than infrequent ones. Target symptoms should be clearly documented (e.g. sleep quality or quantity for people with depression; or numbers of episodes of tearfulness or guilty feelings). Second, patients should not titrate medications without speaking with the clinician. In part, substance dependence may be thought of as disordered self-pharmacotherapy. As such it may be counterproductive to ask the patient to focus on and respond with self-medication to perceived internal distress.

It can be useful to try to ascertain whether there is a psychiatric diagnosis independent of the substance use problem. It is helpful to elicit a history of psychiatric problems during periods of protracted abstinence, when they are less likely to be due solely to the substance use. Still, the diagnosis is usually tentative rather than definitive. Management of symptoms or treatment of possible diagnoses with medications does not establish an independent diagnosis. The patient may have substance-related symptoms or syndromes that respond to treatment but do not meet criteria for a diagnosis. Nonetheless, it is important to treat these symptoms as the approach will help management of the substance use disorder.

Consideration of withdrawal of the psychiatric medication when the patient is stable reduces the probability that patients without primary psychiatric problems will erroneously carry such a diagnosis long term. It is also important to remain vigilant about the emergence of new psychiatric problems. Recovery may have disparate effects on psychiatric symptoms. While in general recovery is associated with mitigation of psychologic distress and diminution of unpleasant psychiatric symptoms, abstinence may conversely elicit recrudescence or emergence of serious psychiatric distress, occasionally after months of seeming stability. Patients often discover persistence of guilt, poor sleep, or anxiety. Symptoms of post-traumatic stress disorder or mania may emerge in recovery. Moreover, there are well described prolonged abstinence syndromes, such as the depression-like anergia and anhedonia of protracted cocaine abstinence that not only create a high relapse risk, but may benefit from pharmacotherapy [37]. Finally, medications that themselves can be abused or induce dependence should generally be avoided. The risk of development of abuse or dependence is higher among those in early recovery or with current or past dependence [3]. Such medications are almost never to be the first choice, and it is a rare situation that demands the use of risky medications at all. Benzodiazepines and psychostimulants should be avoided.

When treating depression or depressive symptoms in the setting of drug or alcohol

dependence, the primary care provider needs to have a sense of how severe the symptoms are and how confident the patient can safely and effectively engage in outpatient treatment in the primary care setting. When there is doubt, bringing in expert consultation of a psychiatrist versed in addiction is warranted. Occasionally, when the patient or others is at risk of imminent harm, emergency referral for safety is warranted.

For patients within the primary care provider's comfort zone, management can be straightforward. The mainstays, as with the non-addicted, are psychotherapy and medication. Sometimes patients are resistant to a trial of medication for a variety of reasons, and their rationale should be discussed openly, though studies of depression management in primary care suggest patients are generally more willing to accept medication than counseling [86]. Often, the notion that depression, like addiction, is a chemical disorder of the brain can be what enables an individual to accept pharmacotherapy. The primary care provider may allay fears of dependence on a new drug or of stigmatization in abstinence-oriented therapy. Additionally, the evidence that treatment of depression in this setting has positive effects on addiction outcome should be reviewed [58]. Serotonin reuptake inhibitors such as citalopram or fluoxetine have demonstrated this dual efficacy in managing depression symptoms. Tricyclic antidepressants such as desipramine have been studied and supported in this setting as well, but may have a less favorable side effect profile.

Among the most distressing symptoms of early abstinence are disturbances of sleep. Hypersomnolence may be part of the "crash" from recovery from psychostimulants or the body's need to restore and heal itself after metabolic derangements associated with many drugs. It may also be one of several cardinal symptoms of depression. Other than treating depression if the diagnosis seems likely, we recommend no specific pharmacologic intervention here, other than to maintain good sleep hygiene and to avoid hazardous situations. Insomnia is also frequent. While patients often cite insomnia as a primary reason for relapse and persistence may be quite debilitating, randomized trials have not demonstrated an effect of insomnia treatment on abstinence rates. Nonetheless, many practitioners would use trazodone or a sedating antidepressant at least when depressive symptoms coexist. As with hypersomnolence, insomnia can be a symptom of affective disorders which should remain in the differential diagnosis, as they would guide pharmacotherapy. In the absence of affective disorder, the physician should review good sleep hygiene practices with the patient [55]. Among the mainstays of good sleep hygiene are: minimal or no caffeine; 30 min of sunshine in the morning; exercise early in the day; a light meal in the evening; using the bed for sleep only; relaxation before bed; and maintaining a regular schedule.

As with depression, anxiety is associated with substance use disorders, and for some the anxiety disorder is primary. For others, periods of relative or complete alcohol or other substance abstinence, associated with adrenergic drive, causes or exacerbates anxiety symptoms, complicating early recovery and risking relapse due to self-medication. Patients may struggle with intolerable symptoms that threaten sobriety. If the history is clear that anxiety symptoms abate during abstinence, supportive counseling and cognitive therapy may suffice. However, diagnosis can be challenging. Symptoms may be part of generalized anxiety disorder, specific phobias, or post-traumatic stress disorder. Primary management in all cases should include non-pharmacologic care. Support groups, cognitive therapy, and exposure based therapies (for desensitization and coping strategies) are all possibilities. Post-traumatic stress disorder presents a challenge as to timing of therapy, with experts advising delay of intensive therapy to periods of stability. Pharmacotherapy for generalized anxiety disorder or post-traumatic stress disorder should involve a selective serotonin reuptake inhibitor as the gold standard. Treatment with buspirone can also be effective for anxiety symptoms and may have beneficial effects on alcohol consumption [19, 48]. Benzodiazepines should

generally be avoided for this indication in the primary care setting.

It may be challenging to tease apart whether anxiety is a manifestation of mania or bipolar disorder, in which case an antidepressant as a sole agent may be contraindicated. When in doubt here, a mood stabilizer or sedating antipsychotic, such as quetiapine, may be preferable. Mood stabilizing agents (such as valproic acid and carbamazepine) may become more common in such situations as we witness the possible emergence of topiramate, an anticonvulsant and a second-line mood stabilizing agent, for use as a primary pharmacotherapy in alcohol dependence (controlled trials have demonstrated efficacy for alcohol dependence but it is not currently approved for this indication by the Food and Drug Administration) [43].

Management of Withdrawal from Alcohol and Other Drugs

"Withdrawal syndrome" refers to the physiologic and behavioral response to sudden cessation or abrupt decrease in the intake of a drug to which physiologic dependence has developed. In dependence, the brain becomes adapted to the presence of the drug and develops compensatory mechanisms to function. When the drug is withdrawn, those compensatory changes are no longer opposed by the drug, and the result is the withdrawal syndrome. A simple analogy would be driving an automobile with the hand-brake partially engaged. To maintain speed, supranormal acceleration is applied. If the brake is disengaged, the car will surge forward, until a new balance is achieved.

Different drugs are associated with different withdrawal syndromes. Some are outwardly noticeable, as with the tremor of alcohol withdrawal or the dilated pupils of opioid withdrawal, and others may be invisible, as with the mental slowing and depression of cocaine withdrawal. The rate of decrease in drug dosage, as well as conditions of the patient, will affect the severity and manifestations of withdrawal.

In the primary care setting, it is critical to be familiar with withdrawal syndromes and their management. In particular, there are situations where the likelihood of complicated or dangerous withdrawal necessitates admission to an inpatient service. For frail or elderly patients, or those with unstable medical conditions, such as recent myocardial infarction, then the risk of outpatient management is too great.

Even in otherwise healthy people, barbiturate and benzodiazepine withdrawal can be dangerous, as can severe alcohol withdrawal. Opioid withdrawal can lead to dehydration and metabolic abnormalities, but in healthy young people is usually tolerated. Psychostimulant, nicotine, and cannabis withdrawal are not typically dangerous, although they may be associated with subjective suffering that is real and significant. The management of withdrawal is termed "detoxification" and simply means supervised or medically treated withdrawal. Detoxification is not treatment of addiction per se; rather it is merely the process of ridding the body of the drug safely or with mitigated discomfort. As such, referral for detoxification should not be confused with addressing addiction treatment needs. In fact, in the United States, detoxification is most commonly not followed by effective addiction treatment.

Being aware of the withdrawal syndrome and attention to it are necessary to establish trust and to permit reasonable interactions with patients. It is inadvisable to engage in a long or complicated evaluation with a patient experiencing significant discomfort or craving because of withdrawal. Acknowledging and attending to a patient's comfort continuously to the extent possible is necessary. ("When did you last use? When will you need to again? Can we speak now?" are questions that may inaugurate all interactions with addicted patients seeking help).

There are other, non-"medical" features that will make admission advisable. If the patient does not have a safe place to go where temptation or access to the substance is limited, then outpatient management is less likely to succeed, and offering inpatient admission is indicated. If there is no-one to support the patient or to provide safe

transportation, then inpatient observation may be preferable. The American Society of Addiction Medicine has specific patient placement criteria that can help with such triage decisions [9]. Your office capabilities are also important in the decision to admit. Can you or staff see and evaluate the patient at sufficient frequency for safety? For moderate alcohol withdrawal, for example, evaluation daily with easy telephone availability throughout the first few days may be necessary.

In general, outpatient withdrawal can be achieved with reliable and motivated patients by advising them of safe symptom-driven and self-tapering schedules. Many patients will explain that they have done this on their own many times. Patients who are at low risk or using a low-risk drug may try this safely. Depending on the level of physiologic dependence, a typical recipe for self-tapering for short-acting opioids, benzodiazepines, and alcohol is to reduce the dose of the drug by 20% per day, achieving abstinence in about a week.

Many clinicians are reluctant to advise that a patient use the offending substance, even if it is part of a program to forestall withdrawal symptoms and to achieve abstinence. In this case, other medications can be prescribed. In principle, medications that are active at the same receptor or produce similar effects as the offending drug (i.e. cross-tolerance), have been demonstrated to help. Finally, patients may experience withdrawal from many substances simultaneously. It is often advisable to obtain objective identification of recently ingested drugs if possible, for instance with a urine toxicology panel or by confirming history with a trusted companion of the patient.

Alcohol Withdrawal

The primary care provider should be familiar with inpatient detoxification, and can adapt protocols to the outpatient setting [59]. We address this section to the clinician interested in providing ambulatory detoxification because it is a complicated and intensive process requiring a high level of commitment personally and programmatically. Alcohol withdrawal can be fatal or result in prolonged and complex hospitalization. Therefore the reflex may be to advise inpatient evaluation and management as a default. Most alcohol withdrawal, however, never comes to clinical attention and is not significant. Distinguishing cases that can be safely managed in the ambulatory arena from those requiring inpatient management can be challenging and may make the difference between life and death. Some patients will not be willing for myriad reasons to consider inpatient detoxification, so distinguishing those cases where admission is elective can be critically important [39].

In general, the severity of withdrawal can be predicted based on the severity of prior episodes. There is a loose relationship between intensity of drinking or blood alcohol level and severity of symptoms. But regardless, older patients, those with a history of head trauma or concomitant sedative use, and those with comorbid acute medical, surgical or psychiatric illness are at risk for more severe withdrawal. Outpatient management is generally safe in those who report their last drink over 36 h prior (since significant symptoms are unlikely to develop), have no other risk factors for severe withdrawal, and have a responsible other to accompany and monitor them. Inpatient detoxification should be considered when there is a history of seizure, other drug use, an anxiety disorder, multiple detoxifications, and a blood alcohol level over 150 mg/dL (the latter a sign of great tolerance and a risk for more severe withdrawal symptoms). Inpatient management is advisable for those over age 60, those who have concurrent acute illness, seizure, or moderate to severe symptoms (because of the risks for delirium) as measured by an objective assessment scale such as the revised Clinical Institute Withdrawal Assessment for Alcohol scale [81].

Patients who are uncomplicated may be advised to taper alcohol on their own at home. If instead, medications are to be used, several medications may be efficacious, including anticonvulsants. Despite the potential advantages of anticonvulsants that have fewer effects on cognition and alertness, we favor benzodiazepines because they are the only medications

proven to decrease the severe and fatal complications of withdrawal in placebo-controlled trials [51]. Chlordiazepoxide and diazepam are convenient, rapidly absorbed orally, have long half-lives of elimination, and are inexpensive. The half-life of diazepam is 33 h and that of desmethyl diazepam, its active metabolite, is 50 h. For patients with significant liver impairment (hypoalbuminemia or coagulopathy but not the more common mild transaminase elevation), benzodiazepines that are not hepatically metabolized are preferred. Oxazepam and lorazepam are frequent choices, having renal excretion. An objective measure of withdrawal should be used to monitor severity and response to treatment. For patients with moderate to moderate-severe withdrawal, that is a revised Clinical Institute Withdrawal Assessment for Alcohol scale score of 8–20, diazepam 20 mg orally should be given, and the patient reassessed after 2 h. If the revised Clinical Institute Withdrawal Assessment for Alcohol scale score has increased, then inpatient admission should be considered. If the score remains above 8–12 (i.e. severity is more than "mild,") another dose of 10 or 20 mg should be given. If after 2 more h, the revised Clinical Institute Withdrawal Assessment for Alcohol scale score has not decreased by two or more and /or remains above 15, admission should be advised. The median number of doses required for patients with moderate to severe uncomplicated withdrawal is three [72].

If the revised Clinical Institute Withdrawal Assessment for Alcohol scale score has decreased then the patient should be advised to take the same dose of benzodiazepine every 6–8 h for three to four doses and be re-evaluated within 48 h, preferably the next day. Patients may need additional doses between these scheduled doses to treat re-emergent symptoms. The revised Clinical Institute Withdrawal Assessment for Alcohol scale is administered at every clinical evaluation though patients and their significant others should be told which symptoms to follow themselves (e.g. tremor, anxiety, agitation). The tapering of benzodiazepine can occur over three to five days with clear follow-up and instructions to call for indications of over- or under-dosing but tapering is not necessary if the long-acting medications are used and given frequently until symptoms resolve.

Opioid Withdrawal

Like alcohol withdrawal, the intensity of opioid withdrawal syndromes is quite variable. Decisions about the choice between in- and outpatient detoxification, as with alcohol, depend on factors of social stability, comorbid illness, and the ability to resist illicit drug use as an outpatient. Unlike alcohol withdrawal, however, opioid withdrawal is less often life-threatening in the absence of underlying disease. The most effective class of drugs for relieving withdrawal symptoms are opioids themselves, and many inpatient detoxification programs use long-acting oral drugs such as methadone or sublingual drugs such as buprenorphine for this purpose. In the absence of a special license (such as that under the Drug Abuse Treatment Act of 2000 permitting use of buprenorphine), however, it is currently illegal in the outpatient setting to prescribe opioids for the treatment of drug dependence or detoxification. Specially qualified physicians may prescribe buprenorphine and no other opioid for this purpose. Anyone with prescriptive authority may treat opioid withdrawal with non-narcotics, however.

In general, all medications used for opioid withdrawal aim to attenuate the symptoms of withdrawal. Prominent symptoms or signs and the medications used to treat them are:

Anxiety—benzodiazepines, buspirone, sedating antipsychotics
Diarrhea or indigestion—hysocyamine
Insomnia—trazodone
Muscle and bone aches—nonsteroidal anti-inflammatory drugs such as ibuprofen.
Tachycardia, tremor—central alpha agonist clonidine either orally or transdermally.

Severity of withdrawal should be assessed using an objective scoring system such as the Clinical Opiate Withdrawal Scale or the Clinical Institute Narcotic Assessment Scale for Withdrawal Symptoms [84]. Treatment should match the pace of withdrawal. Therefore short

acting opioids that result in withdrawal syndromes that are themselves short will likely lead to a commensurately brief course of medication for withdrawal symptoms. Heroin withdrawal may gather intensity over 24–48 h, so the dose of medication may need to be higher on the second day of withdrawal than the first [47]. Similarly, protracted withdrawal from, for example, methadone, may require several days or weeks of treatment. The severity of withdrawal symptoms is most effectively reduced by opioid replacement (e.g. methadone or buprenorphine). But the outcome of short term detoxification alone, beyond symptom relief, is dismal with respect to relapse, unless the patient remains in a structured setting. As such, methadone or buprenorphine maintenance therapy is often indicated. This is best begun by referral for opioid agonist treatment of withdrawal followed by continuation as maintenance.

Medical Management (Including Preventive Care) of People with Unhealthy Alcohol and Drug Use

Regardless of whether or not substance use continues, a number of other health issues should be attended to. If use continues, driving habits should be assessed and clear advice given to abstain from driving when using alcohol or other drugs. For those who continue to use opioids by injection, safer sterile injection techniques should be discussed (e.g. use of new syringes, avoidance of sharing, bleach cleaning of needles, and needle exchange programs). For those with continued opioid dependence, provision of naloxone for use in the event of overdose can be lifesaving.

Preventive Care

Patients with unhealthy alcohol or drug use often do not receive routine preventive healthcare. They may not have a primary care physician or health insurance, and they may not seek this care in part as a result of substance use and related priorities and disorganization [42]. Furthermore, the physician-patient relationship may be less than optimal for people with addictions, leading to lower quality of care received. Thus, regardless of the status of the substance use, clinicians should make sure to offer such patients routine age- and gender-specific preventive care as is indicated for all adults (e.g. colon and cervical cancer screening, vaccines, cholesterol testing), and facilitate its receipt to the extent possible. In addition, clinicians should be alert for signs of interpersonal violence, and should ask about and recommend receipt of dental health care. On physical exam, cardiac auscultation is important for drug users who may have had endocarditis. Vaccination against hepatitis B should be considered in this high-risk population (particularly for those with a history of drug injection or risky sexual practices, or simply youth). Hepatitis A and B vaccination series are recommended when a patient is demonstrated to be non-immune and at-risk (e.g. injection drug use, unsafe sex). Pneumococcal vaccination is indicated for people with alcohol dependence. Risky sexual behavior is common in drug and alcohol using populations, so education and advice about risk, assuring access to condoms, and screening for sexually transmitted diseases, especially HIV (now recommended universally for all adults by the Centers for Disease Control), are prudent. Cervical cancer screening, also routine for adult sexually active women, is of particularly important in smokers and those with risky sex practices, who are at higher risk for the disease. Similarly breast cancer screening should be done, particularly in women with unhealthy alcohol use who are at greater risk. Osteoporosis screening (bone mineral density testing) is indicated for older women with risk factors, particularly smoking and heavy alcohol use. Consideration should also be given to screening for vitamin D deficiency because of poor diets and possible lack of sun exposure. Empirical recommendation of a multivitamin is another

approach. Folate should be recommended for women of childbearing age. Other routine tests for those with alcohol and other drug use include the serum creatinine, tuberculosis skin testing, and liver enzymes and tests of synthetic function. Patients maintained on methadone, as with any drug that may alter cardiac conduction, should have periodic electrocardiograms as indicated.

Managing Medical Consequences in the Face of Ongoing Substance Use

When patients are bothered enough by symptoms to bring them to the primary care provider's attention, an opportunity often arises to link the unhealthy substance use to the symptom. This link, when pointed out by the physician nonjudgmentally and recognized by the patient, can serve as a discrepancy that motivates the patient to change.

A recurrent practical dilemma will arise for which there is no strong evidence to assist the primary care provider in management. When a symptom or condition is likely related to the use of substances but can be treated with medication, primary care providers may be tempted to withhold medication, emphasizing instead the patient's responsibility to address the behavioral component (i.e. substance use). A common and representative scenario is hypertension related to excessive drinking of alcohol. An economical and healthy alternative to medication use is reduction of alcohol intake. The challenge to the primary care provider is to decide with the patient what the best course of action will be. The use of medication in this case may be reasonable, especially if the hypertension is severe. First, the reduction in the risk due to hypertension may be achieved more quickly with medication. Second, even if the blood pressure is only marginally elevated, the significance of the risk may be made more salient by the physician's prescription of a medication. The behavioral component of the problem may thus be helped more than if medication were withheld. Clearly neither response precludes the other, so pursuing both courses is often the best option. If and when the drinking improves, pharmacologic management may no longer be necessary. There are no hard and fast rules, here, however, and full and honest negotiation with the patient, while minimizing risk, is the optimal course. Prescription of known effective treatments even in the face of a behavioral etiology of or contributor to disease seems to be generally well accepted (e.g. medication for hypercholesterolemia in patients with poor diets; bypass surgery for people who smoke cigarettes).

The vast number of signs, symptoms and illnesses related to the entire spectrum of alcohol, tobacco and other drug use preclude detailing them here. But several highlights most relevant to primary care clinicians follow.

Because tobacco smoking is a well established risk factor for certain cancers and atherosclerotic disease, the primary care provider will interpret symptoms with this risk in mind. Whereas pain in the arm in a non-smoker may represent benign conditions, a Pancoast tumor or coronary insufficiency should be in the differential diagnosis for a smoker. Shortness of breath and fatigue, among the most common symptoms brought to the primary care provider's attention, may have serious causes in a smoker.

Heavy drinking is associated with disturbed sleep, gastro-esophageal reflux disease symptoms, hypertension, peripheral neuropathy, hepatitis and cognitive problems. It is sometimes not clear when and how intensively to investigate causes other than alcohol of a particular medical condition. When the condition does not improve with abstinence or moderation, then further testing is indicated, especially when these problems may be treatable or may represent important underlying conditions. Even when drinking is ongoing, however, it is prudent to rule out common, treatable problems and not simply attribute a sign, symptom or condition to alcohol use. In the case of hepatitis, it is prudent to test for viral hepatitis or iron excess. If hypertension is refractory or severe, one may screen for

secondary causes. Chronic esophagitis symptoms, refractory to proton pump inhibitors, may be an indication for endoscopy, even if drinking is ongoing. Cytopenias may represent a primary marrow dyscrasia. Neuropathy may be caused by a paraprotein (e.g. in multiple myeloma), diabetes, toxins or other primary problems. Fatigue, tremor, and insomnia may all be referable to thyroid dysfunction. Cognitive decline, coordination problems, seizures or confusion may represent a subdural hematoma, cerebrovascular accident, or other central process.

Hypertension or cardiac ischemia may be an acute presentation of cocaine use. If there are electrocardiographic changes consistent with ischemia, the patient needs to be observed. In the presence of enhanced beta- and alpha-adrenergic tone that results from cocaine use, beta-blockers can cause unopposed alpha-adrenergic effects, such as vasoconstriction and hypertension, that can be dangerous if not fatal. Anxiolytics and calcium channel blockers are preferred treatments.

Patients using parenteral drugs often present with skin problems caused by the needle use. Abscesses, ulcers and cellulitis are common. Some ulcers are ischemic rather than infectious, typically when cocaine or other vasoconstrictive agents are injected subcutaneously or into muscle (e.g. when "skin-popping," the preferred route when veins become sclerosed and unusable after chronic intravenous administration). Needle use is also a risk for systemic infection. Viral infections include HIV and hepatitis. Fever in a parenteral drug user should always raise the possibility of systemic viral or bacterial infection. The venous system or right side is more likely affected than the arterial or left side, thus endocarditis is more often of the pulmonic or tricuspid valve. Pulmonary infiltrates may represent embolization of bacteria to the lung.

Viral hepatitis is common in injection drug users. Hepatitis C, usually leads to chronic infection, and in a minority leads to cirrhosis, liver failure or hepatocellular carcinoma. Effective treatments can result in permanent viral suppression. Current treatment involves prolonged administration of interferon, often three times per week. While the side effects are variable, the majority of patients experience a flu-like syndrome that may mimic opioid withdrawal and lead patients to relapse. Interferon therapy often causes or rekindles depression. The primary care provider can help the patient to manage both risks. In general, the primary care provider should delay hepatitis C treatment until recovery is stable, evaluate for depression, treat if present, and prevent the depression that can accompany the interferon treatment (often with *prophylactic* selective serotonin reuptake inhibitors), and augment recovery activities and support during treatment.

Pain Management

Among the most challenging problems for people with addictions is that of pain management. Perhaps because of the riskier lifestyles of people who use drugs and alcohol, trauma and pain are common. And pain thresholds are altered as either a cause or consequences of substance dependence. Use of opioids for analgesia or other drugs as muscle relaxants can lead either to abuse of the prescribed drugs or relapse to the original drug of abuse [67]. There is a higher incidence of problems among chronic pain patients who have addictions than among those without [89]. But pain can also be a trigger for relapse, and when necessary, opioids may be prescribed. The key to navigating the difficult course here is to engage the patient in honest collaborative planning with the dual goal of minimizing both pain and the risk for relapse.

Clear enunciation of the risk of relapse may help the patient embrace, along with the primary care provider, protocols that minimize such risk. Primary care providers might be wise to adopt some of these processes as "universal precautions" irrespective of a patients' prior history of addiction. Medications should be prescribed in small amounts, e.g. for days or weeks at a time, rather than for longer periods. Face-to-face visits should be frequent; initially prescriptions should

be refilled only at visits. While assuring adequate analgesia, clinicians should prescribe alternatives that have a lower street value, less abrupt onset of action, and longer half life; such choices reduce the likelihood of misuse of prescribed drugs. It may be the case, paradoxically, that more aggressive pharmacologic management to ablate pain may spare the patient the stress of discomfort and thus lower the likelihood of relapse, so long as the provider and patient both keep the specter of relapse on the discussion agenda, and mutually agree to maintain tight control over drug quantities.

Discussion about perception of the drug effect may reveal that the patient is experiencing a high or euphoria or that the drug entrains preoccupation with the next dose or illicit drugs. Conversely, withdrawal may be experienced as pain. It may be impossible to distinguish the two; patient trust in the expertise and benevolence of the primary care provider in these cases may permit trials of changes in drug or dose. For patients with chronic pain, whatever the cause, it is useful to identify measures other than the perceived severity of pain to monitor as the benchmarks for successful analgesia. It may be difficult for some patients to distinguish drug-hunger from somatic pain. Thus, objective measures, such as duration of performance of an activity or distance walked, are preferable to severity of pain.

Two commonly adopted protocols for the management of chronic pain with opioids in patients with addiction are contracts and urine toxicology testing. Neither is well supported in objective literature, so the primary care provider needs to think through the risks, benefits and costs of either [8]. Many contracts specify expectations and the consequences of failing to meet them. Many of the behaviors that contracts seek to minimize are those that often accompany the development of pathologic dependence. Requests for early refills, lost medication, requests for brand name narcotics and other behaviors may represent inadequate pain control. Diversion of medication for use in ways not prescribed (e.g. chewing or snorting rather than swallowing whole sustained-release oxycodone), buying illicit drugs, or clandestinely obtaining medication from many prescribers, however, are clearer signs of addiction, although none of these is itself a reliable indicator. It is the pattern, intensity and persistence of these behaviors that ought to raise suspicion of problems. As soon as the use of or desire for the drug on the patient's part becomes highly preoccupying, then the strategy ought to change. The existence of a clear contract may make changes in management easier.

Contracts may present certain risks as well. If they are not utilized universally, they may stigmatize one group more than another and raise fairness or discrimination issues. They may undermine trust. If not adhered to by the provider, they appear to point out poor-quality care, as the primary care provider is failing to adhere to a self-professed and written standard. This internal contradiction could raise the risk of litigation.

Written agreements might outline routines for monitoring urine toxicology tests [23] expectations about non-pharmacologic therapy (e.g. physical therapy), the prescribing physician(s), designation of a single pharmacy, provisions for replacement medication for lost prescriptions or medication, the frequency of face-to-face visits, and the option of random call-in for pill counts and/or toxicologic screening [9, 30]. Sample contracts can be reviewed online [61]. Office protocols for coverage and shared responsibility should also be established to facilitate good continuity and communication. The checking of urine toxicology tests for the presence of illicit drugs (or the absence of prescribed drugs), although a common element of patient management, is complex, yielding false positives and false negatives. It has not been demonstrated to improve outcomes of management of pain [45]. Nonetheless it can be useful in certain situations (e.g. to confirm that the patient is taking any of a prescribed controlled substance).

Because drug and alcohol dependence have both genetic and environmental causes, one should expect that family members of patients in recovery are at risk of addiction themselves. Thus it is wise to discuss openly the risk of diversion of medications that may not be securely

stored. Clear explanation of the patient's responsibility to protect medications and close monitoring of the rate of medication use are advisable. Primary care providers should know that some seemingly innocuous medications have abuse liability or a street value, either because of their direct euphorogenic effects or their role as adjunctive medications to augment euphoria. A partial list of such adjuncts includes: quetiapine, gabapentin, carisoprodol, cyclobenzaprine, clonidine, baclofen, hydroxyzine, and promethazine [12, 66].

Other Challenging Medical Situations

Situations likely to be encountered by primary care physicians in the care of patients with drug or alcohol problems include problems related to medications and medical procedures. For example, some patients report that opioids and anxiolytics prescribed for procedures, such as for colonoscopy, may lead to craving for illicit drugs. Similarly, use of needles for phlebotomy or medication injection may trigger craving. Anticipating this problem may prevent a relapse. Discussing it with the patient, having plans of patient action in place and for an increased intensity of supportive services may be indicated.

Confidentiality

The primary care provider may not be familiar with laws concerning medical records and confidentiality of patients with substance abuse issues. Patients may be ashamed of their problems with drugs or alcohol, and explaining the confidential nature of discussions can be reassuring. Indeed such assurance may be necessary for good communication, though the assurance may not be enough as patients are often concerned that those with legal access to medical records (e.g. health insurers, employers, others to whom patients often must release information), will find out about their substance use (as is also true for cancer, diabetes and other health problems). The sharing of general medical records and information broadly comes under the Health Insurance Portability and Accountability Act of 1996 [83]. By this federal law, providers who share the care of a patient may communicate with one another about the patient. Such communication is critical for high quality patient care and safety. This does not, however, apply to certain types of information or treatment settings. Notably, drug and alcohol dependence and psychiatric issues *sometimes* come under a *more stringent* set of Federal regulations (42 CFR Part 2 revised in 1987) [83]. Under these statutes, there are very few situations in which information can be released to institutions, health care providers, or others *without express and detailed written permission from the patient*. Not only does such written consent need to be obtained, but it must describe the purpose of communication and the duration of permission. When *covered* information about drug or alcohol problems is communicated, written notice that this information cannot be re-communicated should be provided to the recipient. Information covered under CFR 42 Part 2 is highly protected and patients can be reassured it will not be released without their permission barring a court order (though patients can be required to sign such releases for various purposes, and insurers have access).

There are, however, a few important *exceptions* to the inviolability of this privacy. In a *medical emergency*, all relevant information should be shared. Many states have *mandatory reporting laws* with which primary care providers should be familiar. States vary, but in general primary care providers are required to report to the relevant state authority certain high-risk situations when reason to suspect harm or risk of harm is substantial. Among these situations is suspected abuse or neglect of an elder or child, or specific intent to harm another person. Under some state mandatory reporting laws, it is illegal *not* to breach confidentiality and report the suspected risk to the mandated authority. Primary care providers need to know these laws so as to be clear with patients about the bounds of

confidentiality. It may be helpful to let patients know that, barring an emergency, the primary care provider will inform the patient *before* reporting a dangerous situation. In general, the situations requiring reporting are ones from which patients themselves would want to be protected, and knowing that the primary care provider will intercede, with warning, may be welcome.

Because many have misconceptions about alcohol and drug use health information privacy laws, the most important information for primary care providers to know about CFR 42 Part 2 is when it does not apply. In general it does *not* apply to primary care settings. CFR 42 Part 2 applies only to federally assisted individuals, entities, or identified units in medical facilities who hold themselves out as providing, and provide, alcohol or drug abuse diagnosis, treatment or referral for treatment, or to healthcare personnel whose primary function is to do this and who are identified as such. Primary care settings generally do not fall under this definition, though there may be exceptions.

Summary and Conclusions

The primary care provider is ideally positioned to identify patients with unhealthy alcohol or drug use. The primary care provider should be able to assess the severity of the substance use, to identify dependence, and perform brief interventions as appropriate. While identifying and managing comorbid problems, be they medical or psychiatric, incorporating the assistance of consultants and substance abuse specialists when needed can augment the quality of care. In addition to treating and referring, primary care providers have a critical role for patients with addictions who often need medical, mental health, and addictions services, as they coordinate and integrate care across these disparate and often poorly connected systems. Primary care providers can prescribe pharmacotherapy or refer to specialists who can prescribe, for alcohol and opioid dependence, and be the source of primary or adjunctive counseling. They can also treat comorbid psychiatric symptoms and syndromes. Finally, primary care providers should be familiar with treating medical problems, managing pain, and delivering preventive care to patients with substance related diagnoses. With this knowledge and skill, primary care clinicians can make a difference for patients suffering from substance use conditions by doing the right thing at the right time. Such practice is among the most rewarding activities in primary care settings.

Criminal Justice System and Addiction Treatment

Karen L. Cropsey, Galen J. Hale, Faye S. Taxman, and Gloria D. Eldridge

Contents

Introduction

Compared with other nations, the United States incarcerates the largest percentage of its citizens, with over 8 million adults and 650,000 youth under some form of criminal justice supervision, including prison, jail, and probation or parole supervision in the community [70, 79]. Incarceration in the United States costs nearly $65 billion each year and 40–60% of prison intakes result from failures in community supervision related to drug relapse [30, 46, 62]. Research consistently demonstrates the close connection between drug use and criminal justice involvement, with over 70% of offenders involved with drugs or alcohol at some point in their lifetimes [80]. About 36% of violent crimes involve alcohol and 40% of criminal offenders reported using alcohol at the time of their offense [34]. Many offenders are caught in a cycle of drug use, crime, arrest and reincarceration [4, 31, 75]. Drug charges account for about one-third of re-arrests following release from prison or jail. About one-third of offenders are re-arrested within 6 months of release and over two-thirds are rearrested within 3 years of release [78]. Numerous studies have shown that involvement in community alcohol and drug treatment services delays re-arrest and re-incarceration. The purpose of this chapter is to provide an overview of the drug and alcohol treatment needs of offenders and the mechanisms available in the criminal justice system to address these needs.

Prevalence of Substance Abuse and Dependence

Substance abuse is four times greater in the offender population than in the general population; 37% of offenders are estimated to have a substance abuse disorder, compared with 9% of the general population [63]. Over 80% of

K.L. Cropsey (✉)

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_43,

state prisoners reported a lifetime history of drug use [54] and 95% of state prison inmates met *Diagnostic and Statistical Manual of Mental Disorders* criteria for at least one form of substance abuse or dependence [44].

Compared with the non-offender populations, offenders are more likely to abuse illicit and prescribed substances [26]. For example, about 11.3% of male and 20.8% of female prisoners reported daily opioid use in the 6 months preceding incarceration; 10% had a history of lifetime opioid dependence and 8% met criteria for current opioid dependence [8]. Abuse of prescribed opiates is a recent phenomenon and, according to the 2008 National Survey on Drug Use and Health, an estimated 5.2 million Americans aged 12 or older used prescription opiates non-medically in the past month, an increase from 4.7 million in 2005. Among individuals aged 18 and older who were arrested between 2002 and 2004, almost 30% had used prescription drugs non-medically in the past year [63]. A recent study of prescription drug abuse among a large sample of prisoners found that 34% of males and 62% of females reported nonmedical use of prescription opiates [92]. Individuals who abused prescription opiates were more likely to have been involved in criminal activity and reported more drug charges, shoplifting, forgery, disorderly conduct, charges resulting in convictions, number of convictions, months incarcerated, and days incarcerated within the last month than individuals who had never abused prescription opiates [92].

A recent study concluded that 58% of county jail inmates had a lifetime history of drug dependence and 51% met criteria for current dependence, suggesting a large need for substance abuse services in facilities that are not equipped to offer such services. Since almost all arrestees are initially housed in jails while awaiting trial or sentencing, it is left to the jail facilities to treat the acute effects of drug use and withdrawal. For example, one-quarter (25%) of inmates reported withdrawal symptoms from active drug or alcohol use upon entering jail, but only 16% reported receiving medication for relief of withdrawal symptoms [8].

Substance Abuse Comorbidities

Smoking

Smoking is the leading preventable cause of death in the United States, resulting in over 440,000 premature deaths each year and implicated as a causal agent in an increasing range of cancers [76, 77]. Prisoners, as a class, are especially vulnerable to the negative health consequences of smoking. Smoking rates are 3-4 times higher among prisoners than among individuals in the general population and smoking is normative and non-stigmatized within the correctional environment [17–19]. Among male prisoners, smoking prevalence is 70–80% [13, 14, 17, 18]. Smoking rates among incarcerated women range from 42 to 91%—two to four times greater than among women in the general population [16, 17].

Ninety percent of prisons prohibit smoking in medical, chapel, and vocational and educational areas; however, about 40% allow unrestricted smoking in common areas, housing units and cells, or in prison yards [42, 84]. Cigarettes and other tobacco products are readily available in prison and tobacco products are sold in prison commissaries. Some prisoners may receive wages and thus, have money to spend on tobacco products. Other prisoners rely on impoverished families and friends to provide money for tobacco products [16]. Tobacco products are bartered among prisoners and employees and function as a form of prison currency [47, 56]. Because of the high cost of cigarettes in prison, many prisoners purchase loose tobacco that they roll into non-filtered cigarettes [16, 17]. Thus, smoking inside a correctional environment may present higher risk for tobacco-related diseases than smoking in the community.

In contrast to the enormous literature focusing on smoking prevalence, prevention, cessation, and policies in other populations, smoking among prisoners remains virtually ignored, despite the enormous human, health, and economic costs [2, 16]. Only three published studies have examined smoking interventions for

prisoners [17, 25, 58]. All three suggest that prisoners are interested in smoking cessation and able to achieve smoking abstinence, despite pressures within the correctional environment to continue smoking. In the largest study to date of smoking cessation in a correctional setting, Cropsey and colleagues conducted a randomized controlled trial of a combined nicotine replacement and 10-week group smoking cessation intervention for female prisoners. Sustained cessation rates were comparable to cessation rates following smoking cessation interventions in the community [17].

Psychiatric Disorders

According to a recent Report to Congress by the National Commission on Correctional Healthcare and National Institute on Justice on the health status of soon-to-be released inmates, rates of psychiatric disorders in United States prisons and jails dramatically exceed general population rates [55]. A meta-analysis of 62 studies from 12 western countries estimated that one in seven prisoners has a psychotic or major depressive disorder [27]. Prevalence estimates for psychiatric disorders among state *prison* inmates are schizophrenia (2–4%), major depression (13–19%), bipolar disorder (2–5%), dysthymia (8–14%), anxiety disorder (22–30%), and posttraumatic stress disorder (6–12%). Prevalence estimates for psychiatric disorders among *jail* inmates are similar: schizophrenia (1%), major depression (8–15%), bipolar disorder (1–3%), dysthymia (2–5%), anxiety disorder (14–20%) and post-traumatic stress disorder (4–9%) [86]. Approximately 50% of female inmates suffer from mental illness [22]. A national study estimated rates of mental illness ranging from 3 to 23% for probationers and 1–11% for parolees [7]. Finally, 6% of male and 15% of female jail inmates have acute psychiatric symptoms in need of treatment at time of initial booking [72, 73].

Inmates with comorbid substance use and mental health problems report more numerous and serious past year and lifetime medical conditions and consume more medical services during incarceration and in the community [38]—underscoring the importance of psychiatric treatment in correctional settings. With the number of prisoners with serious psychiatric disorders exceeding the number of patients in psychiatric hospitals, jails and prisons have become "America's new mental hospitals" (p. 1612) [74]. For many individuals with severe mental illness, most psychiatric care is provided in jails and prisons [45]. The high prevalence of psychiatric disorders in correctional populations is due, in part, to deinstitutionalization of mentally ill persons, lack of access to community mental health services [49] and the criminalization of the mentally ill [45]. Unfortunately, most prisoners with psychiatric and substance use disorders do not receive adequate care during incarceration [27]. Although data are limited, most prisons and jails fail to conform to community standards for screening and treatment of mental disorders [55, 85]. For example, 83% of jails offer screening, 60% offer mental health evaluations, 42% provide psychiatric medications, 43% offer crisis intervention, and 72% offer access to inpatient psychiatric treatment [61]. Jails and prisons differ in the type and range of mental health services; jails may provide management of acute symptoms and suicide prevention, while prisons may offer a range of services including long-term support and treatment. Medical and psychiatric treatment in criminal justice systems varies from state to state; some contract with independent companies to provide psychiatric and medical services for their populations. Often facilities offer specialized services such psychiatric or sex offender treatment units [87] although little is known about the types and effectiveness of treatment programs offered.

HIV/AIDS and Sexually Transmitted Infections

The HIV/AIDS epidemic in the United States coincided with a sharp rise in incarceration

related to the "war on drugs," mandatory minimum sentencing, and "truth in sentencing" legislation in the 1980s and 1990s. As a result, many substance-abusing individuals at high risk for HIV/AIDS are also at high risk for criminal justice involvement. In 1997, 16% of individuals with AIDS and 22–31% of individuals with HIV passed through a United States correctional facility [35]. Between 1989 and 1999, 32.9% of positive HIV tests in Rhode Island came from the state correctional institution [21]. Between 1995 and 2004, the percentage of known HIV+ prisoners decreased from 2.3 to 1.9% of the prison population. Despite that decline, the rate of confirmed AIDS in state and federal prisons was three times higher than in the overall United States population—0.49% for prisoners and 0.14% for the United States population [78].

Offenders have histories of high-risk sexual behavior and high rates of sexually transmitted infections [39, 40]. High-risk sexual behavior includes inconsistent condom use with multiple sexual partners, history of sexually transmitted infections, exchanging sex for money or drugs, and engaging in sexual intercourse with an injection drug user or under the influence of drugs or alcohol [15, 52]. Rates of chlamydia and gonorrhea are 18–50 times higher in adult prisoners compared with adults in the general population [10]. Left untreated, chlamydia and gonorrhea may result in infertility, pelvic inflammatory disease, cervicitis, and ectopic pregnancy [10]. Rates of syphilis are also high among correctional populations; with 3.7% of male and 5.2% of female inmates testing positive for syphilis, compared with less than 0.001% of adults in the general population [10]. High rates of untreated sexually transmitted infections enhance risk for HIV transmission or infection [10]—suggesting the importance of addressing high-risk sexual behavior in the context of drug and alcohol abuse among criminal justice populations.

Other Infectious Diseases

Active or latent tuberculosis infections are higher among correctional populations than the general population, with 20–25% of prisoners testing positive for tuberculosis compared with 0.0048% of the general population [3, 11, 12]. Multi-drug-resistant tuberculosis has become epidemic in prison institutions around the world, where high rates of HIV facilitate transmission of multi-drug-resistant tuberculosis [89]. About one-third of prisoners test positive for hepatitis C, compared with general population rates of 2% [9]. The convergence of high rates of sexually transmitted infections, hepatitis C, HIV/AIDS, and tuberculosis among prisoners is not a coincidence; these diseases act synergistically in their infection rates and disease progression, making them more challenging to treat [89] and highlighting the importance of addressing them in the context of alcohol and drug abuse among correctional populations.

Pharmacotherapies for Substance Use

A review of the literature shows a dearth of research on pharmacological treatments for substance abuse among criminal justice populations, particularly in the United States [20]. Providing effective treatment for opioid dependence decreases relapse to active substance use upon release from prison and prevents recidivism [23]. Despite this, very few correctional facilities provide methadone or other detoxification or maintenance for opioid-dependent prisoners [19, 43, 51]. A recent study demonstrated that initiating methadone maintenance therapy for prisoners with histories of opioid dependence prior to release facilitated entry into community treatment [43]. However, a primary disadvantage of methadone maintenance therapy is that the individual has to be treated at a methadone maintenance clinic after release from prison and waiting lists for such treatments in the community are long [51], providing the opportunity for a recently released offender to "fall between the cracks" and miss the opportunity for immediate entry into methadone maintenance therapy upon release from prison.

An alternative treatment, oral naltrexone, an opiate antagonist, has been available for 20 years but has not been widely used, primarily due to problems with medication compliance. One review noted that fewer than 20% of recipients continued to take oral naltrexone 4 months after treatment was initiated [57]. Depot naltrexone has recently received Food and Drug Administration approval for use in treating alcohol dependence, but does not have an indication for treating opioid dependence and is unlikely to be adopted by criminal justice authorities until Food and Drug Administration approval is obtained. However, studies are under way to investigate the use of depot naltrexone with individuals in community corrections, which may provide another option for pharmacotherapy for individuals under criminal justice supervision in the community.

Buprenorphine, a thebaine derivative, is a mu opioid partial agonist with a pharmacological profile that makes it attractive as a pharmacotherapy for the treatment of opioid dependence. Buprenorphine, like other full mu agonists, produces opioid-associated subjective and physiological effects, but its maximal effects are less than those of a full agonist such as morphine [6]. This property contributes to its utility in the treatment of opioid dependence in that buprenorphine is effective in preventing the onset of the opioid abstinence syndrome in opioid-dependent individuals. With escalating doses, buprenorphine produces less effect than full mu agonists and exhibits a "ceiling" effect at which further dose increases produce no additional effects [88]. In addition, buprenorphine has high affinity for the mu receptor, a property that produces blockade of the effects of full mu agonists, should these be administered during buprenorphine maintenance.

The safety of buprenorphine in non-tolerant individuals (such as those exiting a controlled environment) was demonstrated by Walsh and colleagues [88], where a plateau on subjective and respiratory dose-effects resulted in sublingual doses up to 32 mg (2–4 times the recommended treatment dose) being well tolerated. Thus, the ceiling effect associated with buprenorphine administration provides a wide margin of safety. Buprenorphine has fewer restrictions on its use for treatment of opioid addiction and provides an attractive alternative to methadone. In comparison with methadone and oral naltrexone, buprenorphine treatment demonstrated lower overall mortality related to its use [29]. Thus, buprenorphine appears to have advantages over other opioid therapies, including better acceptance and compliance, a favorable safety profile, and the ability to deliver the medication by prescription in a general clinic practice after release from prison. A recent review concluded that the efficacy of buprenorphine has been firmly established for treatment of opioid dependence [48]. A cost-effectiveness study embedded in a randomized controlled trial of buprenorphine versus methadone concluded that buprenorphine is no more expensive than methadone maintenance therapy [24]. Buprenorphine has not been widely investigated with a corrections population, and adoption of this medication by criminal justice administrators has been non-existent, despite the well-demonstrated efficacy of buprenorphine in non-criminal justice populations.

Community Corrections

The community corrections population has quadrupled over the past 25 years (1.12 million in 1980 to 6 million in 2006) [70, 79] and comprises the largest segment of the criminal justice population. The increase in criminal justice sanctions has been attributed to a change in United States policy in the 1980s to "get tough on crime" and led to the "war on drugs" that continues today, with drug-related arrests skyrocketing over the past 35 years (322,300 drug arrests in 1970 to 1.65 mil in 2005) [79]; driving under the influence continues to be the largest arrest category in the United States, with over 1.8 million arrests a year [79].

Probation and Parole

At the end of 2006, there were over 6 million offenders on probation or parole in the

United States (about 5,237,000 on probation and 798,200 on parole). Over half of these offenders have orders for substance abuse treatment services in the community, and providing care to these offenders is a challenge given the dearth of treatment services available in the community. For example, a recent survey of correctional agencies in the United States found that less than 10% of the offender population can participate in treatment services on a daily basis, due to the size of the population, and the lack of availability of treatment services for offenders [67]. The majority of treatment services available to offenders are drug and alcohol education (53.1%), group counseling for less than 4 h a week (47.1%), substance abuse counseling 5 or more hours a week (21.2%), and therapeutic community or residential services (3.7%) (see Table 1). Even more revealing is that the most commonly offered services do not incorporate evidence based treatment strategies such as cognitive behavioral therapy, motivational interviewing, and therapeutic communities [67].

Over the last three decades, different strategies have been used to address the large percentage of offenders that are in need of treatment services. Most community correctional agencies use referrals to existing programs and services in the community to provide treatment for offenders. The referral process, generally referred to as the brokerage model, relies upon the probation/parole officer giving a referral to the offender for a public health clinic(s) or a specific program. The success of the model relies on the offender obtaining services. Other variations to bridge the correctional and drug treatment systems have evolved over the past two decades to provide more direct access to treatment services by offenders. These variations include the Treatment Alternatives to Street Crime (now called Treatment Accountability for Safer Communities), drug treatment courts, "break the cycle" or seamless systems of care, or on-site treatment services [1, 65, 71, 91]. Studies vary considerably on these different mechanisms but generally research demonstrates that more offenders have access to treatment services and increased participation in treatment services when these options are available [66, 71].

Another model is to train the probation/parole officer in a new role which involves engaging

Table 1 Substance abuse treatment services in community supervision agencies

			Specialized facilities		Generic prisons	
Type of service	% with service	Estimated # of offenders	% of ADP (median)	% of programs >90 days	% of ADP (median)	% of programs >90 days
Drug/alcohol education	53.1	190,906	7.7	78	8.6	56.9
Substance abuse group counseling: up to 4 h/week	47.1	141,263	4.8	90.9	3.3	62.8
Substance abuse group counseling: 5–25 h/week	21.2	37,090	1	87.9	2.7	92.9

the offender in the change process [71] by utilizing clinical skills such as motivational interviewing and addressing the offender's ambivalence towards involvement in treatment services. Studies of this approach have demonstrated that the altered role of the probation officer reduces technical violations compared with traditional intensive supervision programs where the parole officer's focus is solely on monitoring the offender after release [28, 71].

Drug Court

The drug court, a post-adjudication sentencing program, was first established in 1989 and designed to reduce criminal involvement among drug-addicted offenders. By 2007 there were over 890 drug courts operating in the United States [82]. The theory that led to the formation of drug courts is that many drug-addicted offenders engage in criminal behavior as a means to acquire drugs; therefore, to reduce crime among drug-addicted offenders, the addiction must be treated [32]. The basic components of most drug courts include assessment of substance abuse disorder, assimilation of substance abuse treatment and criminal justice supervision through case management and weekly status hearings with judicial oversight, a continuum of care in which offenders have access to multiple services, frequent drug and alcohol screening, and continuous interactions between the offender and the criminal justice system (e.g., judges, case managers, etc.) [91]. Drug treatment courts have revolutionized treatment for the criminal justice offender in that they provide a mechanism to ensure that monitoring, supervision, and treatment are intertwined. However, only about 3% of substance-abusing offenders have access to drug treatment courts [67].

A number of studies have been conducted to determine the effectiveness of drug courts; findings are generally positive but mixed. Several studies have shown that participants in drug courts show diminished drug use and criminal activity and higher treatment retention rates compared with offenders in traditional treatment settings [32, 33, 67, 91]. Belenko [5] reviewed evaluations of 37 drug courts nationwide and found that 47% of participants graduated successfully and that drug use and recidivism were low while clients were enrolled in drug court. However, most studies did not include long term follow-up data, making post-program outcomes unclear [5]. An empirical study of drug treatment courts found that treatment participation (29–88%) and program graduation rates (29–50%) varied considerably [64].

A recent meta-analysis by Wilson, Mitchell, and Mackenzie revealed that while individuals graduating from drug court have significantly lower arrest rates than non-participants, most drug court participants did not attend the minimum number of required treatment sessions and more than half were not given the minimum number of drug tests [91]. Taxman and colleagues report treatment participation varied from 35% to 80% across drug courts [64]. In addition, none of the programs reviewed by Wilson and colleagues was based on a formal theory of the causes of addiction and most were using a "mixed bag" of therapeutic approaches without focusing on any one treatment method [66, 81]. For example, some programs used 12-step approaches, which require addicts to turn over their addiction to a higher power in conjunction with cognitive-behavioral therapy, which focuses on thoughts and feelings and emphasizes learning new skills to change addictive behaviors. Unfortunately, these two therapeutic approaches are incompatible in their views on the origins of addiction. In addition, while cognitive-behavioral therapy is widely considered one of the best approaches for treating substance abuse, it was used in only about 22% of therapy sessions [64].

There also appears to be a dearth in family involvement and minority or culture-specific treatment in drug courts, all of which are important treatment components [81]. Many researchers have suggested that the lack of evidence- and theory-based practices in substance abuse treatment contributes significantly to rates of relapse and recidivism among

offenders receiving treatment through drug courts [81]. Overall, it appears that the longer an offender is in treatment, the greater their chances are of succeeding in a drug court program—a finding consistent with research on all substance abuse treatment programs [59, 67].

Treatment Accountability for Safer Communities

Treatment Accountability for Safer Communities was developed in 1972 as a strategy to provide case management to bridge the gap between the criminal justice system and community substance abuse treatment. Treatment Accountability for Safer Communities models operate under the assumptions that drug addiction is prevalent among offenders, that there is a cycle of crime, incarceration, release, and relapse among drug-dependent individuals, and that this cycle provides frequent opportunities for treatment interventions [41]. Most Treatment Accountability for Safer Communities programs provide screening for program eligibility, assessment of treatment needs, referrals for treatment outside of Treatment Accountability for Safer Communities, and client-centered case management. Many programs emphasize a continuum of care and provide regular drug screens and correspondence with the criminal justice system regarding the client's progress. Treatment Accountability for Safer Communities currently operates in almost 40 states and about 100 organizations use the Treatment Accountability for Safer Communities model.

Anglin and colleagues assessed Treatment Accountability for Safer Communities programs at five sites in the United States across three domains: service delivery, drug use, and recidivism. Compared with individuals receiving the standard strategy of referral to community treatment services, offenders participating in Treatment Accountability for Safer Communities had access to significantly more services at four of the five sites (drug counseling, urinalysis, and/or AIDS/HIV education). At three of the five sites, drug use decreased for Treatment Accountability for Safer Communities participants. However, there were no significant differences in recidivism (as assessed by re-arrest rates) among control and Treatment Accountability for Safer Communities groups. In fact, at two of the sites there were indications that Treatment Accountability for Safer Communities participants were more likely to be re-arrested than control group participants. More positive findings occurred in sites where the Treatment Accountability for Safer Communities services included group counseling and offenders did not have to go to another agency to acquire the needed treatment clinical services. Similar findings for intensive supervision programs (i.e., the probation officer monitors the offender through more frequent contact) suggest that increased monitoring leads to easier detection of criminal behavior among participants. Thus, the increase in arrests among Treatment Accountability for Safer Communities participants can be seen as a success from a viewpoint of community safety, even though it increases technical violations and re-incarcerations [1]. Other researchers have postulated that the case management approach taken by Treatment Accountability for Safer Communities programs does not decrease recidivism because it does not lead to increased participation in substance abuse treatment, treatment is usually of a short duration, and there are often no provisions in place for non-compliance (e.g., positive drug tests or missed treatment sessions) [68].

A more recent study revealed that jurisdictions with Treatment Accountability for Safer Communities had increased use of motivational interviewing, continuum of care policies, and services for offenders with co-occurring disorders [93]. Additionally, the survey found that Treatment Accountability for Safer Communities administrators were stronger supporters of training initiatives likely to enhance cooperation among criminal justice organizations. A general survey of treatment services offered in correctional settings found that innovations tended to be

clustered. Treatment Accountability for Safer Communities organizations are more likely to offer this clustering of innovative practices than program and parole agencies [37]. This finding allows a better understanding of implementation issues based on how organizations such as Treatment Accountability for Safer Communities, jails, and community correctional agencies affect the treatment delivery system. Overall, the survey findings suggest that communities that have Treatment Accountability for Safer Communities or Treatment Accountability for Safer Communities-like organizations have made greater gains in improving service delivery for offenders in measurable ways, but that there is also considerable room for improvement in access to services and treatment and supervision outcomes.

Institutional Corrections

The availability of substance abuse treatment in correctional environments has decreased in the past two decades. In 1991, one-third of inmates who reported using drugs in the month prior to arrest received substance abuse treatment; in 1997, only 15% received treatment [54]. A recent survey of drug treatment services in the correctional setting found that less than 10% of the eligible inmate population receive drug treatment services in prison and that offenders in specialized treatment programs such as segregated therapeutic communities are more likely to be offered treatment services that are consistent with evidence-based practices [67]. Substance abuse treatment programs for inmates during and after incarceration are effective in reducing drug use and subsequent recidivism [4, 31, 60]. About one-quarter of inmates who participated in therapeutic community substance abuse treatment in prison and after release returned to prison compared with 75% of prisoners who did not receive treatment or who received treatment in prison but no treatment after release [50, 60]. The Washington State Institute for Public Policy noted that drug treatment in prison yields a benefit of $1.91 and $2.69 for every dollar invested in treatment. Drug treatment outside prison yielded a benefit of $8.87 for every dollar spent on treatment [83]. Thus, substance abuse treatment programs in and out of prison are successful in reducing substance abuse and recidivism and are cost effective [36].

Prisons and Jails

Despite the potential benefits associated with delivery of drug treatment in correctional facilities, drug treatment is increasingly unavailable for drug-dependent offenders during incarceration and the services provided are often not of sufficient duration or intensity and do not incorporate evidence-based practices. The National Criminal Justice Treatment Practices survey provided data on the availability of different types and intensities of drug treatment services offered in prisons and jails in the United States (see Tables 2 and 3) [69]. Substance abuse education and awareness is offered in 74% of prisons and 61% of jails and, as such, is the most prevalent form of drug treatment service provided. Group substance abuse counseling ($\leq$4 h/week) is available in 55% of prisons and 60% of jails; group counseling 5–25 h/week is available in 46% of prisons and 23% of jails; and group counseling $\geq$26 h/week is available in 11% of prisons and 1% of jails. Counseling programs within prisons and jails incorporate various combinations of 12-step work, cognitive-behavioral skills training, life skills training, and drug education [53], although less than 20% of sessions use cognitive or cognitive behavioral therapies [69]. Segregated therapeutic communities are available in 20% of prisons and 26% of jails; 45% of prisons and 51% of jails provide access to relapse prevention groups [69].

Although therapeutic communities are available in only a minority of prisons and jails in the United States, the aim of therapeutic communities goes beyond abstinence from drugs to complete lifestyle change for individuals involved in the therapeutic community, including

Table 2 Prevalence of substance abuse services in prisons

Type of service	% with service	Estimated # of offenders	Specialized facilities		Generic prisons	
			% of ADP (median)	% of programs >90 days	% of ADP (median)	% of programs >90 days

development of prosocial attitudes and values and elimination of antisocial behaviors and attitudes. Therapeutic community members live with one another, ideally segregated from the general correctional population, and take responsibility for recovery through individual and group counseling, peer pressure, confrontation, and incentives and sanctions [53, 90].

Despite the apparent availability of drug treatment services in prisons and jails, less than 10% of prison and jail inmates have daily access to drug treatment services [69]. One way of assessing the quality and appropriateness of services offered is to examine the proportion of prisons and jails that use evidence-based practices in their drug treatment programs. Fewer than 60% of available evidence-based practices were used in treatment programs for drug-involved adult offenders, suggesting that services available for drug-involved offenders in prisons and jails may be far from optimal [28]. Interestingly, clusters of evidence-based practices tend to occur together, suggesting that some facilities may have overcome resource and philosophical barriers to the adoption of evidence-based practices—once one evidence-based practice is adopted, others may be adopted in the same setting with less difficulty [37].

The effectiveness of drug treatment programs offered in prisons and jails can be evaluated in terms of reductions in post-release drug use and in post-release reoffending. A meta-analysis of 66 published and unpublished evaluations of incarceration-based drug treatment programs [53] provided support for the effectiveness of therapeutic communities in reducing post-release drug use and reoffending. In contrast, other incarceration-based residential substance abuse treatment programs and group counseling programs reduced re-offending but were less effective in reducing drug use after release.

Conclusion

Research reviewed for this chapter documents the relationship between drug and alcohol abuse and dependence and criminal justice involvement, the relationship between drug and alcohol relapse and re-arrest and recidivism, the need for greater availability of drug and alcohol treatment within the criminal justice system, the need for strengthening treatment services by the inclusion of evidence-based practices and alternative forms of service delivery (such as drug courts and Treatment Accountability for Safer Communities or Treatment Accountability for Safer Communities-like programs), the need for a coordinated system of care that bridges the gap between incarceration and return to the community, the need to introduce pharmacotherapy for addictions into drug treatment for criminal justice populations, and the urgent need for research into effective models of service delivery.

On one hand, it is possible to look with horror at the system of drug treatment available for individuals under criminal justice supervision in the United States – as rates of incarceration and recidivism increase and comorbid conditions such as psychiatric disorders and infectious diseases become more prevalent, resources available to provide drug treatment become increasingly scarce. On the other hand, the association between criminal behavior and drug and alcohol abuse suggests a way out of the repeating cycle of drug abuse, criminal activity, incarceration, release, relapse, and re-arrest. Drug treatment reduces drug use and relapse and may reduce re-offense and re-arrest. Research is urgently needed to improve both access to and quality of drug treatment services for individuals under criminal justice supervision.

Adolescent Neurocognitive Development and School-Based Drug Abuse Prevention and Treatment

Contents

Introduction

Schools are an efficient and convenient choice of setting for intervention programs targeting adolescents. Schools provide access to a large number of adolescents in a learning environment in which adolescents are more likely to be receptive toward instructions involved in an intervention. Moreover, monitoring fidelity of program implementation and assessing program effectiveness in a school setting are relatively easy [67]. In addition, the typical 4-year structure of school systems is conducive to tracking down students in order to obtain long-term follow-up data.

Prevention programming attempts to reach adolescents prior to the expected occurrence of certain problematic behavior, such as drug abuse. The central focus of prevention is on the antecedents of problem behavior. Program participants are taught how to anticipate the impacts of these antecedents (e.g., such as desiring to feel good, cognitive exposure to drug-related cues, social influence, or cultural norms) and to counteract their potential impacts with instruction of protective cognitions, behaviors, or access to protective social units (e.g., drug-free communities). Among these strategies are "selective" or "indicated" approaches that attempt to prevent individuals who are either currently at-risk for drug use behavior, by virtue of their membership in certain segments of the population, or who are already demonstrating early signs of drug use behavior, from developing clinically diagnosed drug use disorders [45]. Some researchers tend to refer both indicated and selective programs as "targeted" programs [70].

Cessation (treatment) programs are designed to assist in stopping drug use, given that youth were either not exposed or did not respond to prevention efforts. Cessation programs provide participants with strategies to cope with psychological dependence (emotional reliance) on and physiological withdrawal from a drug

(e.g., what types of withdrawal symptoms to expect, how long one will experience these symptoms, and how to cope with these symptoms without relapsing). Cessation programs focus on stopping a current behavior from continuing to arrest ongoing consequences and permit recovery of health. The goal may also involve teaching one how to live with permanent changes (e.g., drug-related injury).

In the school setting, prevention efforts are generally delivered school-wide (i.e., universal prevention), whereas cessation programs are usually delivered outside of the classroom (e.g., with student assistance programs, in clinics, or perhaps involving the school nurse, possibly involving self-help support groups which meet during lunchtime or after school). Exposure to early prevention programming could potentially provide proactive interference against later drug-facilitative-type information, resulting in protection against drug misuse. These prevention efforts may inhibit, delay, or halt addiction, which is what makes cessation so difficult. For older adolescents who are caught up in cycles of drug misuse or abuse, prevention programming could help minimize the time spent in a using cycle.

A recent focus of adolescent school-based drug abuse prevention and cessation programming involves applying models of neurobiology/neuropsychology as potential influences on program outcomes. This chapter will provide a brief overview on the application of neuroscience to adolescent development, indicate current school-based prevention and cessation strategies that may impact neuroscience-relevant adolescent functioning, and suggest new directions for the development and implementation of drug use prevention and cessation programs.

Brief Overview: Neuroscience and Adolescents

Adolescent vulnerability to substance use has been associated with the protracted morphological development of the neural systems responsible for self-control and regulation, in conjunction with a heightened tendency to seek novel experiences (e.g., [7, 66]). The regions of the human brain linked to self-control and self-regulation are not fully developed until late adolescence. However, an increase in novelty-seeking behavior is evident when children transition into early adolescence. Thus, increases in risk-taking and sensation-seeking tendencies among adolescents seem to precede the development of self-regulatory competencies [66].

Several animal as well as human studies suggest that novelty-seeking behavior increases rapidly during adolescence [7], which has been attributed to the changes that occur in the pro-motivational dopamine systems during this stage in ontological development [7]. The level of dopamine turnover among adolescents is likely to be higher than among children and adults [7, 64]. Dopamine in the ventral striatum, which includes the nucleus accumbens, is believed to modulate the conversion of thoughts and emotions into motivated actions [30]. Dopamine release in the nucleus accumbens appears to filter and gate the motivational signals received from the cortical and limbic systems that are to be processed by the downstream motor systems [7, 30].

Several motivational stimuli have been associated with dopamine stimulation in the nucleus accumbens, including the drugs of misuse and agents of natural reward (e.g., food, sex). Further, novel experiences tend to cause higher levels of dopamine stimulation compared with previously learned behaviors that have expected outcomes [7]. Hence, the same mesolimbic dopamine systems appear to mediate both drug- and novelty-seeking behaviors [1]. Conversely, concentrations of inhibitory motivation neurotransmitters such as serotonin appear to be lower in adolescent cerebrospinal fluid, which has been associated with higher impulsivity [7]. A greater tendency to "act" along with decreased inhibitory tendencies for self-destructive action could contribute to drug use experimentation.

Adolescents' vulnerability to drug use due to developmental changes in the dopaminergic

system is further exacerbated by the relatively underdeveloped prefrontal cortex. Brain structure and function undergo significant changes throughout adolescence, notably in the forebrain regions which comprise the prefrontal cortex. The prefrontal cortex is one of the last cortical structures to reach full ontogenetic development and may not achieve complete maturation until the third decade of a person's life [15]. This region of the brain is responsible for the spatiotemporal organization of goal-directed actions, which involve the carrying out of relevant actions in response to internal (e.g., memory) or external (e.g., environmental context) cues [15, 29]. In other words, the principal function of the prefrontal cortex is to perform executive function. Executive function represents a complex set of interrelated functions that make the temporal organization of goal-directed behavior, language, and reasoning possible [15]. Methodologically, brain researchers find it difficult to separate the interrelated components of the executive system into discrete units (e.g., attention, working memory, decision-making) and localize them to specific areas of the prefrontal cortex [15]. For example, the functional contribution of a specific prefrontal cortex area is difficult to measure after a discrete lesion, for such a lesion is likely to functionally affect the entire executive system [15]. Nonetheless, researchers have linked deficiencies in executive function to abnormalities related to attention, working memory, long-term memory retrieval, planning, temporal integration of memory and goal, decision-making, monitoring, and inhibitory control [15].

Ability to exert sustained attention or manipulate the focus of one's attention is necessary to formulate a goal-directed thought or bring an action to completion. In turn, one needs to control distracting or interfering urges, both internal (e.g., thoughts, memory, instinctual) and external (e.g., environmental), in order to maintain sustained attention [15]. Working memory refers to the ability to retain information and utilize the information to execute a related action. Like most executive functions, working memory and sustained attention are interrelated and are essential for task perseverance. Further, execution of actions involves foresight and planning. Planning represents the ability to utilize information obtained from selective retrieval of long-term memory, such as memory of past actions, for the anticipation of future events. Planning provides a conceptual scheme for the execution of a goal-directed behavior, and based on the anticipation of consequences, lays out the order of prospective actions. Individuals often have to choose among competing actions. The executive function of decision-making involves choosing an action after rationally evaluating the potential risks and rewards associated with its outcomes. Successful execution of goal-directed behaviors also depends largely on the ability to self-monitor. Monitoring enables one to assess the discrepancies between one's actions and one's goals, thus creating feedback which allows one to correct subsequent actions.

Inhibitory control involves controlling an impulse by inhibiting a response. According to Barkley [2], response inhibition involves three processes: (1) inhibition of the prepotent response (i.e., a response linked in associational memory to immediate reinforcement), (2) stopping of an ongoing response in order to delay the final decision to respond, and (3) protecting this decision-making time interval from being interfered with by other competing stimuli and responses (i.e., interference control). Primary response inhibition partially aids the functioning of working memory, regulation of motivation, verbal internalization, and behavioral analyses.

Hence, executive functions make the self-regulation of thoughts, emotion, and behavior possible. Conversely, deficiencies in executive function may result in poor impulse control, poor judgment, and disinhibited behavior [2]. Among adolescents, poor executive functioning has been consistently associated with higher rates of drug use (e.g., [22, 38, 73, 84]. Further, early adolescent deficiencies in executive function have been found to predict later drug use disorders [17, 71]. For example, Habeych et al. [24] found that attenuated amplitude of the P300 wave, an indicator of executive cognitive function, in late childhood predicted substance use disorders in late adolescent males.

Research suggests that executive function develops in sophistication at the same rate as the structural maturation of the prefrontal cortex; and age-related social and cognitive maturation during adolescence may be attributed to the concomitant structural changes in the brain [15, 66]. For example, improvements in planning and decision-making have been linked with the structural developments in the dorsolateral and ventrolateral prefrontal cortex, respectively [66]. Most notable developmental changes in the forebrain region have been observed as changes in grey and white matter volumes. Recent neuroimaging studies suggest that there occurs a continuous increase in the brain white matter volume during adolescence [19, 49]. For example, a significant growth is noticed in the posterior corpus callosum, the collection of over 200 million nerve-fibers that allow communication between right and left hemispheres of the brain [19, 49]. In addition, the grey matter volume, which increases substantially during childhood, appears to decrease during adolescence in certain cortical structures (e.g., the prefrontal cortex [18]).

Reduction in cortical gray matter volume might occur due to increased intra-cortical myelination and/or due to synaptic pruning [49]. Increased myelination of neurons results in a more efficient propagation of action potentials. Synaptic pruning involves selective removal of synapses that "do not efficiently transmit information pertaining to accumulating experience" [7]. Synaptic pruning appears to serve a number of functions that facilitate cognitive development. For example, the process appears to stabilize the firing patterns of cortical neurons, which in turn is thought to enhance working memory performance [7]. In general, both myelination and synaptic pruning are believed to enhance the efficiency of cortical information processing as well as the connectivity between cortical and subcortical regions [7, 49, 64, 66].

Thus, since adolescent prefrontal cortex is not yet fully developed, the associated executive functions are expected to be inadequately developed. As a result, adolescents tend to have lower regulatory competence, which makes them highly susceptible to drug use risk factors such as rash impulsiveness and poor decision-making [72]. For example, adolescents tend to be poor judges of the harmful consequences of drug use, yield easily to peer pressure, and seek immediate gratification [72]. Therefore, it is not surprising that most adult drug users are likely to have initiated drug use in the period between early to mid-adolescence, before the brain regions associated with self-regulation are optimally developed [72].

In summary, evidence suggests that the developmental upsurge in novelty seeking coupled with suboptimal brain development makes adolescents vulnerable to drug use. Thus, to some extent, adolescent experimentation with drugs appears to be a normative behavior [72]. However, it should be noted that individual differences exist among adolescents with respect to both novelty seeking and executive functioning; some adolescents are always at a higher risk for developing substance use disorders than others [1, 72].

Negative Consequences of Drug Use on Teen Cognitive Function

Early onset of drug use, escalation of use, and possible dependence might subject adolescents to the risks of developing mental health disorders and experiencing social, academic, and legal consequences. The developing adolescent brain appears to be highly vulnerable to the neurotoxic effects of drugs, including those of licit drugs such as tobacco and alcohol and the so-called "soft" drugs such as marijuana. Prolonged exposure to drugs during adolescence may result in neuropsychological deficiencies and structural brain damage, especially in areas associated with memory and executive functions [32, 33]. Brown et al. [6] have reported that compared with a matched group of healthy youth, alcohol-dependent young adolescents (in the third week of abstinence) were found to perform poorly on verbal and visuospatial tasks, suggesting that

protracted exposure to alcohol might have enduring adverse effects on the brain's functional ability involving memory and information processing. In fact, magnetic resonance imaging results indicate that youth with alcohol use disorders tend to show smaller hippocampal and white matter volumes [8, 10, 43] and smaller prefrontal cortices [10]. De Bellis et al. [8] further found that the total hippocampal volume among adolescents with alcohol use disorder increased with the age of onset and decreased with the duration of disorder.

Although, taken together, the relatively limited extant neuroimaging studies fail to conclude whether chronic marijuana use is related to structural abnormalities in the brain (for review, see [53]), some of the findings (e.g., [82]) suggest a relationship between age of first onset and decreased total brain volume. Further, it appears that early marijuana use initiators (e.g., before the age of 17) tend to show significant later cognitive deficits (e.g., indicated by verbal IQ; visual scanning tasks) in comparison with non-users and late-onset users [12, 51]. Nicotine-dependent adolescents have been suggested to perform normally on working memory tasks following nicotine intake but poorly while on withdrawal [25, 26]. One neuroimaging study indicated that despite poor task performance, nicotine-dependent adolescents on withdrawal exhibited increased activities in the prefrontal cortex regions (e.g., dorsolateral prefrontal cortex) associated with working memory [26]. As an optimal level of dopamine action is essential for normal working memory functioning, the adverse effects of tobacco use cessation on working memory suggests that regular nicotine use causes abnormal adaptations of the dopaminergic circuitries [26]. In fact, research on rodents has shown that the normal development of catecholaminergic systems during adolescence might be disrupted by protracted exposure to nicotine [74–76]. These studies have linked adolescent nicotine exposure with hippocampal damage and impairments in the midbrain catecholaminergic systems that play important roles in mood regulation and addiction development [74–76].

By adversely affecting the normal development of the cortical and limbic brain structures associated with risk and reward calibration, decision-making, and inhibitory control, drug use not only exacerbates the loss-of-control due to incentive-sensitization [56] but also undermines the cognitive ability to stop using drugs voluntarily [85]. Evidence suggests that drug addiction might be related to impairments in ventromedial prefrontal and anterior cingulate cortices, brain regions associated with decision-making and inhibitory control [85]. Further, acute withdrawal of drug use seems to affect the anterior cingulate cortex, consequently weakening inhibitory control [85].

However, it should be noted that most of the research linking adolescent drug use, drug use withdrawal, and neuropsychological deficiencies have been cross-sectional, which makes any conclusion on their causal relationships open for debate [85]. Nonetheless, it seems that deficient neuropsychological functioning and adolescent drug use share a reciprocal relationship. For example, neuropsychological deficiencies in preteen years tend to predict drug use disorders (e.g., [73]), and, similarly, early drug use onset or abuse seems also to predict neuropsychological deficiencies [85]. Such bidirectional relationships imply that adolescents with impaired neuropsychological functioning face the additional risk of drug use-mediated further neuropsychological deterioration [85].

Thus, there appears to be at least three important reasons why prevention or treatment targeting adolescent drug misuse should address motivation, decision-making, and inhibitory control. First, adolescents normally tend to show suboptimal development of regulatory competence [9, 66]. Second, this regulatory competence is likely to be markedly lower among drug-misusing adolescents due to possible impairments in certain brain regions such as the prefrontal cortex, anterior cingulate cortex, and hippocampus [8, 10, 85]. Poor regulatory competence may not only make it difficult for these high-risk adolescents to stop using drugs but also cause them to relapse easily in case of temporary

successful cessation [85]. Third, adolescents at high risk for using drugs or developing drug use disorders are already likely to rank low on neurobehavioral inhibition [73], which might additionally indicate that their executive functions have trait-based deficiencies [2]. Thus, drug-abusing adolescents and adolescents at risk for developing drug dependence would benefit greatly from supplemental programming that promotes adaptive coping, impulse control, problem solving, and self-monitoring.

Brain Development and School-Based Drug Use Prevention and Treatment

It has become increasingly important for prevention researchers to take into account the findings made in neuroscience to guide their approach in designing drug use prevention programs for youth. In particular, researchers are interested in knowing whether developmental neurobiological and neurocognitive variables moderate and/or mediate prevention effects [20, 54]. Currently, the research attempting to answer these questions seems to be at a preliminary stage [20]. For example, there is some evidence that adolescents' neurocognitive skills moderate their response to preventive intervention materials. In a study dealing with social competency skills training, adolescents with poor executive cognitive abilities were less likely to respond positively to the prevention curriculum [13, 14]. Hence, not all youth may be equally able to process prevention messages and instructions, and program materials may need to be individualized to address differential neurocognitive skills.

Alternatively, prevention or treatment programs may aim to enhance adolescent neurocognitive skills in order to counteract drug use behavior. Recent evidence suggests that practice in tasks requiring regulatory skills may enhance one's executive functioning and this alteration appears to correspond to practice-induced structural changes in the brain (e.g., [27, 45]). Hence, one might argue that repeated practice of skills and tasks demanding the use of executive functions (e.g., attention control, working memory) during childhood and adolescence, when cortical structures are likely to be most malleable, may assist the age-related development of executive functions, and in turn protect adolescents from engaging in risky behaviors.

Need for Tailoring Prevention and Treatment Programs

To promote program efficacy, prevention and treatment programming may need to be tailored to participants' personality characteristics. For example, outcomes may be enhanced a great deal if programs are designed to permit maximum processing of information by sensation-seeking recipients with neurocognitive processing that prefers presentations of rapidly changing stimuli [50]. As noted by Bardo et al. [1], novelty exposure tends to activate the same neural substrates that mediate the rewarding effects of drugs of abuse. The reinforcing effects of drugs play a key role in promoting continued drug use behavior, especially among those more susceptible to drug effects (e.g., sensation-seeking or novelty-seeking individuals). Initial positive or neutral physical responses to drugs may encourage subsequent use, whereas initial aversive physical reactions may discourage subsequent use behavior. One suggestion for prevention is to consider that at-risk youth (e.g., sensation-seeking youth) may process information differently than lower risk youth, and therefore prevention materials should be tailored accordingly.

Given the evidence that individuals higher in sensation seeking may have a neurobiologically based need for stimulation, it seems reasonable to assume that they need drug abuse prevention messages that are novel and exciting enough to grab their attention and pique their curiosity (e.g., see [50]). In fact, Palmgreen et al. [48] found that high-sensation-seeking value-type public service announcements may have influenced higher sensation seekers' drug

intake for several months following a media campaign. Fast-paced, novel, and stimulating media-type programs that grab or increase adolescents' attention and learning may more effectively influence sensation-seeking individuals with lower baseline dopamine turnover [48].

Staiger et al. [65] have recently stated the need for tailoring drug abuse treatment programs with respect to three specific personality-based drug use risk factors, namely reward sensitivity, behavior disinhibition (or rash impulsivity), and anxiety proneness. For example, contingency management could be used as a possible tactic for someone with high levels of reward sensitivity, as to replace drug-related reward with a prosocial alternative [65]. Similarly, treatment strategies such as meditation and mindfulness-based practices could be used to promote attention control and relaxation in order to address impulsiveness and anxiety proneness, respectively [65].

Current School-Based Prevention Practices and Executive Functions

School-based programs designed for young children often focus on improving social-emotional competence (e.g., [21, 61, 62]). Temperament characteristics such as emotionality predict adolescent problem behavior, including drug use behavior [80]. Wills and colleagues [79, 81] argue that a person's childhood temperament characteristics and socialization affect his or her ability to self-regulate during adolescence, and in turn, his or her drug use behavior [79, 81]. "Promoting Alternative Thinking Strategies" is a school-based prevention program which attempts to assist young children in social and emotional learning through the teaching and practice of executive function skills [21]. The Promoting Alternative Thinking Strategies curriculum is based on the affective-behavioral-cognitive-dynamic model of development [20, 21]. The assumption underlying the affective-behavioral-cognitive-dynamic model is that due to delayed development of the neurocircuitry connecting cortical and limbic structures children's cognitive and linguistic development tends to be inadequate when required to regulate complex emotional experiences. Thus, children appear to have difficulty verbally internalizing emotional experience and managing related behavioral response. The Promoting Alternative Thinking Strategies curriculum uses the concepts of vertical control and horizontal communication to assist children's age-related neurocognitive development. Vertical control refers to the exertion of control by higher-order cognitive processes on the lower-order limbic impulses, and horizontal communication refers to mediated communication between the two hemispheres of the brain, a process integral to the internal verbalization of affect [20, 55].

Results demonstrate that Promoting Alternative Thinking Strategies can improve vertical control and horizontal communication. Vertical control is addressed though the combined use of curriculum lessons and the Control Signals Poster which teach strategies for self-control such as "self-talk" that facilitate inhibitory control and planning [20]. The control signals poster uses a traffic-signal to guide goal-directed behaviors (e.g., red light signaling to stop and calm down, yellow light to slow down and think, and green light to try out the plan [55]). Horizontal communication is addressed through the identification and labeling of emotions and feelings through the combined use of curricular lessons and Feeling Face cards, which include color-coded facial images of affective states [55].

A Promoting Alternative Thinking Strategies trial involving 7–9 year olds recently found that the curriculum was effective in reducing externalizing and internalizing behaviors at 1-year follow-up, that Promoting Alternative Thinking Strategies had significant positive effects on verbal fluency and inhibitory control nine month posttest, that both inhibitory control and verbal fluency partially mediated internalizing behaviors, and that inhibitory control partially mediated the program effects on externalizing behaviors [55].

Another example of a program for young children that focuses on social and emotional learning is the "I Can Problem Solve" program [61, 62]. This program has been implemented on preschooler through 6th graders and provides children with language and critical thinking skills that help them successfully resolve interpersonal problems with peers and adults through effective decision-making. The program is recommended to be implemented as a daily 20-min classroom session for 15 months. All sessions are designed to foster interpersonal cognitive problem solving through dialogues, games, and group discussions that involve the use of words, pictures, puppets, and role playing. For example, students are taught to identify words that are precursors to understanding behavioral consequences and problem solving, and teacher-initiated interpersonal cognitive problem-solving dialogue is used to solve actual interpersonal problems among children. The program has been successful in reducing impulsivity and social inhibition (e.g., fear and timidity of others), which are related to the development of drug use and mental health disorders [62].

Although it is common for prevention programs to include cognitive-behavioral skills training as a major component (e.g., "life skills training") [4, 5], executive function variables are not often directly measured as mediators of program effects [55]. However, in essence, such studies attempt to enhance the rate and quality of age-related cortical development. Several developmentally tailored life skills training trials have been successfully implemented in elementary, middle, and high schools to develop social and personal skills among youth [58]. The skills-building component of the program focuses on developing regulatory competence among youth necessary to counteract the social influences of drug use through training on, for example, coping and anxiety management (e.g., vertical control), and effective communication and assertiveness (e.g., horizontal communication) [58].

Recently, mindfulness-based interventions have emerged as having promising implications for executive function enhancement. Mindfulness refers to attaining a mental state in which attention is sustainably focused on the non-judgmental awareness of thoughts and sensations passing through one at the given moment. Interestingly, mindfulness-based programs are also starting to be practiced children and adolescent populations. An investigation carried out by the Garrison Institute [16] on the mindfulness practices of kindergarten to 12th grade students found that nearly 20 school and community-based organizations have established mindfulness programs, and several more use elements of mindfulness as part of other social and educational programs.

Mindfulness-based interventions typically use a simple sitting technique that teaches participants to focus on the breath, image, or mantra for as little as 10 min per session. In a sample of 194 1st–3rd graders, Napoli et al. [44] found that a mindfulness intervention increased selective attention as measured by a visual task. Moreover, several studies have replicated evidence that mindfulness can decrease externalizing and problem behaviors in adolescents [3, 31, 60].

Studies are just beginning to examine the effects of mindfulness on neurocognitive variables. A randomized control trial of school-based "mindful awareness practices" involving 44 4–5 year olds found that children in the treatment condition showed significant increases in executive functioning as indicated by improved working memory and planning skills [59]. The treatment program consisted of implementing a 30-min session, twice a week, over 8 weeks. Interestingly, further analyses of the program effects suggested that mindful awareness practices may have stronger effects on children with executive function difficulties.

Clearly, further studies are required to better understand the potential protective effects of mindfulness-based interventions on adolescent drug use. However, preliminary evidence seem promising, to the extent that some of the known outcomes of mindfulness-based interventions such as increased self-awareness, emotional intelligence, and lowered externalizing

problems are known to be protective against adolescent drug use behavior [3, 16, 31, 44, 60].

It appears that prevention programming would benefit additionally from the inclusion of a motivation component. Sussman et al. [70] evaluated 29 evidence-based, targeted drug abuse prevention programs for their effects on drug use or other problem behavior among high-risk youth. Eighteen of these programs involved school as a setting in some way. Of the 18, 12 involved some motivation aspect, generally motivation enhancement, but sometimes they included extrinsic reinforcement strategies (i.e., reinforcement by manipulating environmental consequences of behavior such as by being paid contingent on performance). Sixteen of the 18 programs provided skills training, and 11 programs provided instruction in decision-making.

Taken together, these programs appear to define a type of programming referred to as the Motivation-Skills-Decision-making Model [70]. According to this model, targeted programming needs to: (1) motivate the at-risk recipients, who might have higher reward sensitivity [65] to not desire to misuse drugs, (2) teach skills to enhance regulatory competence (e.g., self-control strategies [37]) and form prosocial bonds; and (3) facilitate decision-making and goal-directed behaviors. The Motivation-Skills-Decision-making Model tends to appear in a majority of the 18 programs; however, all three components were included together in only 5 of the programs.

The Reconnecting Youth program was one of the five programs and was implemented to youth at risk for school dropout [11]. The program involved 90 sessions within a comprehensive high school class, delivered generally over one semester, with small student groups and highly trained teachers. Instruction included use of group support and providing life skills training (norm setting, self-esteem enhancement, mood management, communication skills, self-monitoring, monitoring goals, school bonding and social activities), with feedback to parents. Program goals were achieved through use of a quasi-experimental design, showing effects for school performance (18% improvement in grades), drug use (54% decrease in hard drug use), and suicide risk (32% decline in perceived stress). This program involved all three components of the Motivation-Skills-Decision-making Model, except that motivation was provided through peer group support, not through provision in motivational enhancement strategies. In essence, these targeted programs for high-risk populations could be interpreted as modifying phenotypical expressions of suboptimal neurobiological development. However, future integrative research will be needed to examine the reality of this speculation.

Schools as a Modality for Implementation of Cessation Programming

School-based interventions have been recognized as one of the most effective community-based means of delivering drug use treatment services to adolescents [77]. Empirical evidence indicates that most school-based drug use treatment programs tend to yield treatment outcomes that are, in terms of success, similar to outcomes of programs targeting adults [77]. Treatment services in schools can be delivered either through school clinics (i.e., clinics located within schools), classroom-level interventions, or a combination of both [68, 77].

Traditionally, treatment services have been delivered to youth drug users by trained health professions in clinics located outside schools, such as in hospitals and universities [77]. In regard to adolescents, school-based treatment delivery options seem to have clear advantages over the traditional modes of service delivery, in terms of both identifying the need for treatment and access to treatment [77]. Adolescents are not only less likely to recognize their own drug use problems but also less likely to make an effort to seek treatment services voluntarily [77]. Hence, unless concerned adults guide them to treatment facilities, which is less likely to happen if the problems have not yet become serious,

most adolescents requiring treatment might not receive any treatment at all. Moreover, visiting clinics situated in institutions other than schools might exact potentially deterring efforts from adults and adolescents alike, such as spending money and one's free time, and making appointments [77]. Ethnic minorities and individuals of lower socioeconomic status in particular might fail to take advantage of treatment opportunities offered outside schools [77].

In a review of 66 adolescent tobacco use cessation programs, Sussman [68] found that 28 (i.e., 43% of the studies) of the programs used school-based clinics to deliver services and 9 programs used classroom-based programming, while the remaining involved system-wide efforts (e.g., mass-media campaigns, policy, or statewide), computer-based self-help, medical or recovery clinics, and family-based interventions. The review suggested that a school clinic is located within school premises and generally delivers services to students in non-classroom sessions that usually address groups of 5 to 15 students during school-hours [68]. On the other hand, classroom-based programs make use of course curricula to deliver services in classroom settings [68]. These programs often combine prevention and cessation components together [68]. Although school clinics are supposed to address subjects' individual needs and thus be more effective, among the studies reviewed by Sussman [68], classroom-based programs showed higher quit rates (i.e., 17%) compared with school clinics (12%). In fact, classroom-based programs showed the highest rates of cessation among all channels of program delivery [68].

However, it seems unclear whether school clinics and classroom-based treatment programs function similarly for alcohol or illicit drug use problems. Most of the Motivation-Skills-Decision-making Model-based classroom programs that combine prevention and treatment objectives seem to target all drug use [68]. However, school-based interventions that only target alcohol or illicit drug use disorders seem to rely more on problem identification, referral (e.g., referring problem users or suspected users to outside facilities for treatment or screening) or group counseling (e.g., Student Assistance Programs) [77]. Moreover, the efficaciousness of these interventions has not been rigorously researched [78].

Treatment Strategies and Executive Function Skills

As with prevention programming, treatment programming for adolescent drug users is likely to benefit a great deal from motivational enhancement and skills training. Preparedness to change one's drug-using behavior (e.g., motivation) and drug use outcome expectancies are considered to be important cognitive mediators of drug abuse treatment [83]. Treatment efforts are successful when drug abusers are receptive toward treatment, understand the risks of abusing drugs, and identify the benefits of stopping [83]. In other words, treatment efforts are more likely to be successful when subjects are adequately motivated to change their behaviors.

However, compared with adult drug abusers, adolescent abusers might be less motivated to change their behaviors and less likely to accept that they have drug abuse problems [63]. For example, a study on high school alcohol users found 49% of the sample at the "precontemplation" stage [52] of behavior change [39]. Hence, treatment programs targeting adolescents need to be able to motivate them to seek treatment and comply by treatment protocol [46]. A large number of adolescents with less serious problems miss treatment opportunities because of lack of motivation [46]. In other words, motivation is a prerequisite for the success of other treatment strategies, such as cognitive-behavioral skills training, which includes self-control, planning, self-monitoring, and decision-making treatment strategies.

Smith and Anderson [63] argue that much of adolescent alcohol-related problem behaviors

can be explained in terms of an interplay between personality factors such as behavioral disinhibition and learned or acquired pro-alcohol outcome expectancies. According to their model, over time, disinhibited adolescents learn to yield more readily to positive outcome expectancies of alcohol than negative [63]. Teaching adolescents cognitive skills such as self-instruction [36] to allocate attention on negative consequences of drug use rather than positive would be one way to treat biased outcome expectancies [63]. For example, an intervention could train adolescent drug users on mentally reviewing and countering the positive consequences of drug use with negative ones [63]. Another treatment strategy that Smith and Anderson [63] recommend deals with restructuring memory associations such as replacing incentives associated with drug use in memory with deterrents. For example, metamemory techniques can be used to train adolescents on selectively retrieving negative experiences of past drug use episodes when confronted with a new drug use situation [34, 63]. Treatment components should also include additional cognitive-behavioral strategies, particularly those dealing with self-control, stress management, and coping, which are especially important in helping individuals sustain through recovery. For example, meditation and mindfulness techniques, which are not commonly used in adolescent drug use treatment, can be implemented to improve attention and stress management [27] and reduce withdrawal-related symptoms.

Interventions based on motivational interviewing combine motivational enhancement with cognitive-behavioral therapy [46]. Brief motivational interviewing interventions have been found to be effective in reducing drug use among adults and young adults. Sussman's [68] review of youth tobacco use cessation programs found that most school-related programs tend to use cognitive-behavioral strategies compared with very few that use motivational enhancement, even though programs that use motivational enhancement tend to have higher quit rates.

Motivation Enhancement and Motivational Interviewing

Motivation enhancement techniques serve to clarify desire for change and reduce ambivalence toward change. This may include, but is not restricted to, a specific strategy such as motivational interviewing [40]. Motivation enhancement helps participants to clarify their direction of change and increases their willingness to change. Motivation enhancement may also include use of response-contingent reinforcement which reinforces quit-behavior with the chance for extrinsic rewards such as money or prizes [68]. In one of the largest controlled field trials of a school-based teen smoking cessation program that uses various motivating activities (e.g., games, talk-shows), Sussman et al. [69] found 17% adolescents who received the treatment to have stopped smoking at 3-month follow-up compared with 8% of the control adolescents. The clinic curriculum, of Project EX, consisted of eight sessions spread over 6 weeks [69]. The motivation component in the first session was represented by a talk show where family and friends confront smokers about their habits. In session three, adolescent smokers were involved in a game which intended to teach them about the negative effects on one's body of the harmful substances in tobacco [69].

Motivational interviewing is a type of brief intervention (i.e., comprising of one to five sessions), based on the theoretical principles of stages of change model (the transtheoretical model) [52], client-centered therapy [57], and cognitive behavioral therapy. As advocated by the client-centered therapy, motivational-interviewing attempts to motivate individuals to change their health risk behaviors through a non-judgmental and non-confrontational form of counseling [40]. In order to assist individuals to take action and maintain the behavior change, motivational interviewing programs usually intend to help individuals toward building self-regulatory skills that are essential in coping with stress and solving personal as well as interpersonal problems [46].

As a treatment and harm-reduction technique, motivational interviewing has a relatively long history of effectiveness among alcohol-dependent adults [46]. More recently, researchers have begun to apply the technique on adolescent drug users too (e.g., [41]). In a systematic review of motivation interviewing trials on adolescents and emerging adults, Grenard et al. [23] located 17 treatment studies that dealt with alcohol use, tobacco use, multiple drug use, and injury-related outcomes. These interventions, five of which reported successful outcomes, were set in hospital outpatient clinics and emergency rooms (e.g., a youth visiting an emergency room after a drinking-related incident), colleges and universities, psychiatric hospitals, and other outpatient clinics. Evidently, most interventions tended to target adolescents with relatively serious drug use problems and none of them were school-based. Further, majority of the studies (i.e., 9 out of 17) dealt with alcohol use only [23].

Providing one-to-one motivational interviewing sessions in school-based settings might be a daunting effort but certainly not impossible. Methods used by alcohol abuse interventions among young adults in college settings (e.g., [35]) could perhaps be applied to adolescents in high schools. For example, drug-using adolescents could be screened and referred to school clinics, where they would be assisted by trained motivational interviewers [42]. Another possible way of utilizing motivational interviewing in school-based prevention or treatment practices is to combine it with a longer intervention. In an ongoing school-based intervention study Sussman and colleagues are testing the effects of adding telephone-based motivational interviewing component to an existing teen drug abuse prevention curriculum. Motivational interviewing has a prospect of proving effective in treating adolescent drug abuse in a school setting.

Conclusions and Future Directions

Table 1 lists examples of strategies that could possibly be used to alter children or adolescents' executive functioning with the aim of preventing or treating drug abuse. Novel techniques that might help assist age-related development of executive functioning are being increasingly tested (e.g., [28, 47]) and seem to have relevance to school-based prevention and cessation programming. To implement these strategies, school-based drug use prevention and cessation programming should consider important findings from the field of neuroscience. First, programs should be tailored to meet the appropriate developmental stage of youth considering both age and the special needs of certain subgroups (e.g., students raised in poverty or abuse). Treatments that require a certain level

Table 1 Potential intervention strategies to improve adolescent executive function skills

Executive functions	Strategies
Attention	Attentional control skills instruction (e.g., self-instruction strategies to help shift attention); mindfulness training
Memory	Training on metamemory (e.g., selective memory retrieval)
Working memory	Task practice (e.g., backward digit span task); mindfulness training
Inhibitory control	Self-control skills instruction (e.g. practice "control signals poster"; self-instruction; delay of gratification strategies)
Planning	Self-regulation skills instruction (e.g., making action plans; practice "control signals poster"); motivational interviewing
Decision-making	Social and emotional problem-solving skills instruction (e.g., dialoguing; internal verbalization of speech); motivational interviewing
Monitoring	Self-regulation skills instruction (e.g., practice behavioral and emotional analyses; "Feeling Face cards"; life skills training)

of emotional and cognitive processing should make sure that the psycho-physiological skills have been developed by participants. Second, the neurocognitive mediators acting between the intervention and drug outcome need to be carefully measured. Third, the social environment must be considered since resources, support systems, and messages delivered in the intervention may not be available in the general community (i.e., lack of community or family support not to use drugs, lack of financial resources to quit smoking such as the nicotine replacement patch). Thus it is important to assist youth to develop executive functioning skills to plan and obtain resources from their environment (identify treatment centers, plan transportation, consider options of treatment centers). Lastly, much more research is needed in order to substantiate and improve the application of neuropsychological models to school-based drug use prevention and research.

The Therapeutic Community for Drug Abuse Treatment: A Journey Yet Unfolding in the Recovery Movement

David A. Deitch and Liliane Drago

Contents

Origins

It is wrong to assume that there has always been a specific and widely accepted understanding of what is meant by a "therapeutic community." The designation has an ancient pedigree and an historic association with diseases of appetite and the concept of mutual help. By the late twentieth century, it had come to identify a specific mode of treatment for substance misuse, addiction, and other behavioral disorders based on the power of the treatment community to change attitudes and behavior through mutual help and a regimen of structured activities and expectations. This is a regimen designed to promote compassion and responsibility, foster self-awareness, enable social learning, and make possible the acquisition of social capital.

At the dawn of the Christian era, in 25 A.D., Philo Judaeus wrote, "They are called communitae therapeutrides . . . because they profess an art . . . more excellent than in general use . . . for medicine only heals the bodies but [these] heal the souls which are under the mastery of terrible . . . incurable diseases of pleasures and appetites" [21]. (Curiously, the term "appetitive" became a neurobehavioral declaration regarding addictive behavior in the late twentieth and early twenty first centuries—as supported by neuroimaging techniques that became available in the late twentieth century.) Thus, it appears that the struggle with uncontrolled appetite behavior was a challenge then, as it is now, and the ancients embraced an approach not unlike the therapeutic communities of today [11].

We can presume that Philo, writing in Alexandria early in the first century, was describing the early Essene communities, where according to the Qumran Community rules of order and duty, life was meant to conform to the following principles: concern for the state of our soul and our physical survival; search for meaning

(transcending truths); challenge and admonish with love; be invasive—accountable to the community; public disclosure of acts, fears, hopes, guilt; public expiation for wrongs done; banishment is possible—done with concern for survival; and leadership by elders—by models.

These same principles have been present in mutual help communities from early monastic splinter groups to the much later Methodist congregations that espoused a "return to first principles" and morphed into the early Oxford movement [48]. It may well be that combining two sets of rules—one imposing rigid moral and behavioral standards and the other promoting humanizing compassion and forgiveness—is why these principles have so often and so successfully been brought to bear on delinquent or deviant behavior, problems of social maladaptation, and finally on addictive behavior and other problems of appetite.

This can be seen in the spread of religiously based mutual help societies in Western Europe during the seventeenth and eighteenth centuries. Responding to the widespread overuse of alcohol, they launched temperance efforts in Europe which spread to America. Many of these early attempts at "appetite control" included temporary residential support and "pledges" of abstinence [48]. Key principles embraced by these mutual help groups included disclosure (confession), admonition, commitment, and conversion of others. By the 1800s, the spread of these principles had influenced development of the Washingtonian and numerous other small groups.

Before World War II, however, the term therapeutic community recurs only once, when it was applied to the care of orphans in eighteenth century Russia. It was next revived in wartime England at Northfield Hospital, a facility dedicated to the treatment of traumatized British troops. There, two psychiatric innovators, Maxwell Jones and Tom Maine, sought to reapportion authority and decision making between staff and patients [1, 7].

They began referring to the "democratic therapy" they introduced at Northfield Hospital as a "therapeutic community," designed to reverse the dynamics of the traditional psychiatric hospital, which many had come to believe infantilized patients, exacerbating their disability, and rendering them incapable of functioning outside the hospital environment. Patients in Northfield psychiatric units became the active decision makers, taking on increasing responsibility for ward management. Early discussions among these pioneers resulted in five basic assumptions: two-way communication at all levels; decision making at all levels; shared leadership; consensus in decision making, and social learning by social interaction with emphasis on the "here and now" [26].

The horizontal, open system of communication, based on those five principles, was itself assumed to result in healing. It did, in fact, produce marked improvement among community members, and such success made the need for individualized treatment plans seem unnecessary (a notion that would later become doctrine in American drug treatment therapeutic communities). Maxwell Jones went on to become a teacher of this method in Europe and the United States throughout the 1950s and 1960s, influencing younger psychiatrists, particularly at state psychiatric hospitals in Washington, Oregon, New Mexico, and other Southwestern states [27]. However, not until the late 1970s did Jones become aware of and engaged with the American drug treatment therapeutic community movement [40].

The drug treatment therapeutic community was not introduced by any of the nurses or psychiatrists who, inspired by Jones, sought to develop similar treatment models. Its origin is attributed to a group that emerged in Venice Beach, California, in 1958, when an Alcoholics Anonymous member, Charles E. (Chuck) Dederich, started an organization he called Synanon, embodying mutual help principles of Alcoholics Anonymous and characterized by hierarchical structure, a semi-open communication system, and small group interactions focusing on behavior change.

Not unlike other charismatic and gifted figures, Dederich brought his own background—corporate, Midwestern, and

Depression-influenced—to the organization he founded. As is often the case when strong leading theoreticians mount efforts designed to alter human behavior, the organization took on the personality of its founder. Imitation of the leader—in dress, language, and general demeanor—became a defining characteristic of Synanon and an influence on subsequent therapeutic communities.

Dederich launched Synanon by breaking away from the Alcoholics Anonymous group he had been attending. Within the tradition of Alcoholics Anonymous anyone can pick up the "Big Book" and start his own meeting. When Dederich and the few members who followed him started their meeting in Venice Beach in 1958, the community was loaded with "alkies", "pill-heads", and a few "junkies". These people, living on the edge of society, in the pleasant, hospitable, Southern California beach community, were sleeping on the beach, begging for money, making drug deals, and essentially staying intoxicated with the drug of their choice or whatever else they could get. It was a setting ripe for an evangelical salvation-oriented mission.

With the help of a dedicated few, Dederich and his followers obtained funds to open a "club" and, in a tradition easily traced back 200 years, encouraged folks to drop in for conversation in hopes of gaining sobriety. Dederich began holding long meetings in which his innate verbal talents and wide range of interests—from corporate structures to Zen and Transcendental philosophies—drew growing audiences and proved a powerful magnet for membership.

Hearing of these meetings, the availability of food and rumors of easy sex, a few heroin users recently released from the California prison system dropped in. Contrary to their expectations, they were immediately confronted by a loud, bombastic host, who assured them they were welcome, but only if they were willing to help out. "There's no free lunch," Dederich told them, and this proved an attractive challenge to some, since it was such a departure from the traditional social work style they anticipated [3].

A nascent community came into being made up of Dederich's Alcoholics Anonymous cadre, former prisoners, quasi-homeless addicts from the beach, and an upscale contingent of musicians and other artists. Core members from outside the area began moving in, renting the readily available small cabin rooms along Venice Beach. Later in that first year, the group acquired an armory on the beach in Santa Monica, which gave members a chance to live together, pool their funds, share meals, and begin to "hustle" in the community, soliciting donations of cash, foodstuffs, and other living supplies. It also challenged Dederich to organize, preside over, and control community life.

A large man, highly verbose and partially deaf, Dederich spoke at length and high volume. He loved to argue and debate, inspiring heated confrontation among members. These confrontations became a common style of interaction within the group, valued for the relief that many members claimed such abrasive exchanges brought them. Soon formalized, this mechanism was first called "The Synanon" after the name of their organization. By 1964 "The Synanon" began to be referred to as the "game" [3].

It is from the Synanon "game" that the therapeutic community "encounter" evolved. What Dederich added to the fundamental Alcoholics Anonymous mechanism of self-disclosure was the muscle of confrontation. Alcoholics Anonymous rejects both invasiveness and cross-talking. While no one at an Alcoholics Anonymous meeting interrupts, questions, or challenges a speaker, the "game" encouraged this kind of spirited exchange.

As the "game" developed, so did the ethical demands of mutual responsibility. Although "no drug use" was an early requirement of the group, many members continued to use. A troubling question arose: "What then is the responsibility of others in the group? Are they obliged to expose their drug-using fellow members?"

The issue came to a head at what later became known as the "Night of the Big Cop-Out", when a number of drug users were "outed" and others "copped to" their use. At this point, the role of the community as monitor was established along with the principle of expulsion from the group for drug use [3].

As a daily schedule took shape, work tasks necessary to operation of the community were assigned and a schedule of daily seminars established to broaden the intellectual horizon and knowledge base of members. A distinct corporate-like hierarchy was formed, with a top-down structure based on coercion ("our way or the highway") and leadership determined and rewarded by Dederich. The early rewards included special living quarters, special food, access to vehicles, and the ability to acquire girlfriends or boyfriends and sleep with them. (The euphemisms were "courting" and "steady dating").

Early on Synanon began organizing the process of drug treatment into a series of phases. Phase One was live in and work in; Phase Two, work out and live in; and Phase Three, live out, work out, and maintain membership. But very soon, by 1960, Phase One had grown from 2 to 6 months in response to relapse among members in Phases Two and Three [19]. By 1962, during a period of rapid membership growth, Phase One was extended to at least 1 year. Nevertheless, relapse continued to occur in Phases Two and Three. As a result, the work out and live out phases were entirely eliminated in 1964, with Dederich rationalizing that "Our members remain healthy and drug free while with us—so that we are obviously a healthier community than is the greater society" [14]. At this point, the effort once labeled by *Life Magazine* as a "Miracle on the Beach" began its drift into increasingly wilder utopian community fantasies and ultimately into a cult capable of criminal behavior (pleading "no contest" to charges of soliciting an assault and conspiracy to murder).

Early Expansion

Not surprisingly, and consistent with the experience of other psychosocial movements, there were breakaways from Synanon by 1964. These breakaways, while troubled by the Synanon's flaws, still took with them a deep belief in the essential elements of a treatment model that had made it possible for them to achieve and sustain abstinence. They also, however, carried with them a vision of treatment as "redemption" and the Synanon belief that they had the right and the only right answer. Theirs was a point of view that perceived addiction, if not as a moral weakness and sin, then as a disorder of character [3]. Thus, they were not only entitled to, but charged with, correcting such flaws by whatever means necessary within the limits of the law.

It was at this moment that new opportunities were created by growing demand for a response to the seemingly intractable problem of addiction to heroin and other illicit drugs. By the early 1960s, heroin use was expanding, particularly in urban America. The accompanying increase in crime brought to the surface public frustration with the failure of stern anti-addiction measures to effect change. Longer and longer minimum mandatory sentences for drug law offenses and civil commitment of addicts for treatment with lengthy stays in federal hospitals did not produce abstinence outcomes.

The notion that abstinence might not be a rational expectation had surfaced back in the early 1950s when Victor Vogel, M.D., who then oversaw addiction treatment at the United States Public Health Hospital at Lexington, Kentucky, wrote that "If treatment results are compared with those in other chronic or recurrent diseases such as TB… arthritis… hypertension … diabetes … or cancer—results in this field (drug treatment) are good" [36]. But this early glimpse of addiction as a chronic disease was ignored. Both the public and the afflicted either hoped for or wanted an answer called "cure." Synanon had promised such a miracle and so did the first spin-off, Daytop Lodge in New York.

Daytop Lodge was a research project based on Synanon. It was supervised by Brooklyn's Chief of Probation Joseph Shelly and his lead psychologist Alex Bassin. The acronym stood for Drug Addicts Treated on Probation. The population consisted of 35 male felons who accepted treatment at Daytop under probation supervision rather than prison sentences [42]. This marked a serious departure from the mutual help

members involved in volitional recovery. Money in the past was begged or provided as charity. Now it was underwritten by government and administered by a criminal justice agency. It should be noted that this was the first step in what came to be known as therapeutic community institutionalization, and a new term, "ex-addict" came into use. The project had a shaky start with a rapid turnover of leadership. In October 1964, under a new and more experienced leadership team and with increased financial support from New York City, the program was reorganized, and Daytop Lodge morphed into Daytop Village.

Probation was no longer a requirement for admission, and the program now accepted women. A board of directors was formed, chaired by co-founder Monsignor William B. O'Brien, a Bronx priest with strong ties to the New York archdiocese [41]. Alex Bassin joined the board. Daniel Casriel, M.D., a psychiatrist who had written the first book about Synanon, So Fair a House, was now psychiatric director and David Deitch clinical and program leader [5]. Soon, a growing number of candidates sought admission and by the end of 1965, there were 100 "members/residents" in a larger facility [12].

In 1966, New York City's mayor, John V. Lindsay, recruited Efren Ramirez, M.D., a psychiatrist from San Juan, Puerto Rico, to coordinate the City's narcotic treatment programs as commissioner of the city's new Addiction Services Agency. Dr. Ramirez had already developed systems of community engagement, protracted client induction processes and treatment approaches similar to those of Daytop Village ("Daytop"). Ramirez developed a close working relationship with the program, and Daytop staff became a resource for him as he set out to expand the City's response to a growing heroin epidemic. It was Ramirez, trained in the Max Jones model, who persuaded Daytop, which had been calling itself a "humanizing community," to adopt the term "therapeutic community" to better describe its approach.

Dr. Ramirez was soon joined by Mitchell S. Rosenthal, M.D., a psychiatrist who had developed an alcohol and drug treatment hospital unit at the Oak Knoll Naval Hospital in Oakland, California. There, he had introduced many of structural and group characteristics he had observed at a Synanon facility in San Francisco. Ultimately, Ramirez made him deputy commissioner for rehabilitation.

Commissioner Ramirez was also reaching out to other young psychiatrists in hopes of expanding addiction treatment. He created a weekly get-together of Deitch, Rosenthal, and a young psychiatrist still in residency training, Judy Densen-Gerber Baden. These meetings provided the impetus for an explosive growth of the model in New York City. Rosenthal developed Phoenix House, and Judy Densen-Gerber created Odyssey House [18]. Daytop lent staff to each of these projects, and help also came from other former Synanon members [41].

In short order, these projects spun off other new starts: Samaritan Village and Project Return in New York City; Gaudenzia in Philadelphia; Village South in Miami; and Gateway in Chicago. All of them shared many similar beliefs, hierarchical structures, group activities, and goals.

There was also a significant role in the expansion of the therapeutic community played by the young psychiatrists who finished their training and served in the United States Public Health Service. The earliest concentrations of addiction treatment were located at the United States Narcotic Farm in Lexington, Kentucky, run jointly by the Public Health Service and the United States Prison Service, and a similar facility in Fort Worth, Texas. These facilities accepted voluntary admissions as well as addicts convicted in federal territories or found guilty of federal offenses [2].

Three of these psychiatrists emerged as leaders in addiction research and treatment. Jerry Jaffe, who was to become the first White House director of the Special Action Office for Drug Abuse Prevention, currently referred to as the Office of National Drug Control Policy, became familiar with therapeutic community methods at Daytop while at Albert Einstein Hospital in at New York City. Recruited by the Department of Psychiatry at the University of Chicago to serve as the director of drug abuse treatment

programs for the State of Illinois, he subsequently recruited two Daytop staff members who helped him to further develop Illinois' first therapeutic community, Gateway Foundation. In order to secure a facility for Gateway, Jaffe took a lien against his own home so that the therapeutic community model would be part of the broad array of programs, from outpatient detoxification through methadone maintenance, he created in Chicago.

A second United States Public Health Service psychiatrist, Herbert D. Kleber, had his introduction to addictions at the Lexington Hospital and went on to the Department of Psychiatry at Yale's medical school. There, he recruited Daytop staff to develop a separate Daytop Connecticut in New Haven. Kleber was subsequently tapped to become the Office of National Drug Control Policy's first deputy director for demand reduction. Another United States Public Health Service Hospital psychiatrist, Fred Glaser, helped bring the therapeutic community program Gaudenzia to Philadelphia while teaching at Temple University.

This rapid spread of therapeutic communities was made possible by program members seeking a cure and communities in search of new and better ways to confront addiction. Unlike the Alcoholics Anonymous movement which holds that "members are in recovery not recovered," the therapeutic communities believed that cure was possible [12]. This belief was reinforced when peers were seen to succeed. Use of the term "ex-addict" grew, and the expansion of the therapeutic community was now fueled not only by former Synanon members, but by "graduates" of these new and exciting programs.

Proliferation of the therapeutic community was carried on a wave of optimism characteristic of the era—a period of seemingly infinite possibilities, before the war in Vietnam clouded the political landscape. The climate of the times made possible the spread of therapeutic community doctrine by outsiders, for here was a treatment model with no academic provenance or research history that essentially invented itself. Pioneering psychiatrists who embraced the model did not come from the medical or mental health mainstream, and few of those first-generation program leaders had any professional credentials at all. What they did have was an ideology. The concept of "giving to get"—the notion of helping others to facilitate one's own recovery—was a philosophical cornerstone, as was the belief that healing was possible only when one was part of something greater and more important than oneself. The men and women who staffed the early therapeutic communities strived to submerge their separate identities. To them, the golden word was "we." Many of these early staffers—formerly gone astray, isolated and addicted themselves—needed that merged identity to heal themselves before they could help others heal.

As Deitch wrote many years later [51], "These outsiders ... created humanizing communities that espoused dignity of all people, equality between races and sexes, nonviolence and peace, heightened consciousness and spirituality, and action as the road to personal and social change. These first-generation ideologists committed themselves to a way of life that provided health, safety, caring, and honesty—sometimes brutal honesty. They censured deception, cheating, and gain at others' expense. The original version of these early crusaders—a vision that still holds true today—was a commitment to live and act as agents of positive social transformation. We believed that what goes around comes around."

The Formative Years

Admissions

The mind set of first-generation United States therapeutic communities was shaped by the realities of the heroin epidemics of the 1950s and 1960s and the lack of much in the way of alternative treatment resources. Candidates for admission were not then greeted with open arms—admission, it was felt, had to be earned. One had to prove oneself ready for treatment. In some programs this meant demonstrating that one had "hit bottom."

Therapeutic community membership was then, as it is now, deemed to be voluntary. But few candidates at any time have sought admission without some form of suasion, generally from family, employers, or the legal system. The pressure on addicts to seek therapeutic community treatment was particularly strong in the 1960s, when there was great threat of arrest or civil commitment, particularly in New York, which held the greatest concentration of first-generation therapeutic communities.

Admission to most therapeutic community programs then generally involved heavy doses of dissonance. These ranged from the demand that applicants demonstrate commitment by daily telephone calls to the program and long waits in the interviewee chair. Interviews could be conducted by three or four program members who would challenge the applicants' candor, belittle their claims of sincerity, and demand they drop their drug user's "street" facade and adopt new language and behavior [50]. Clearly, this type of challenge and the levels of dissonance discouraged many applicants and prompted others to leave soon after admission, feeling both angry and confused or compromised. For those who stayed, however, many would subsequently claim that the dissonance experience left them more invested in the process that followed.

The Role of Family

Then as now, the pressure that brought many applicants to treatment came from their families. This posed something of a problem for the therapeutic communities, which wanted to keep families engaged but distant. They needed families to understand that they were vulnerable to manipulation and exploitation and must to learn to resist pleas for help from their addicted children—particularly for money.

A favored practice for dealing with families that remained committed to their addicted children was bringing a group of families together to discuss their concerns and answer their questions. These sessions led to the creation of an education program that dealt not only with therapeutic community goals, structure, and methods but also with the stages and nature of addiction. This practice was, in many ways, an innovation that was adapted by other groups to help family members deal with such other disorders as mental illness, autism, and alcoholism.

Families were taught, as were their loved ones in the program, the concept of "responsible concern," the notion that when you care about someone, you must set limits on their behavior, which may, at times, mean denying them money, shelter, and other benefits that might "enable" addicts to keep using without facing the natural consequences of their behavior. This later evolved into the "tough love" philosophy, one that would become a central theme to a self-help movement for parents and others intimately involved with addicts and others with problem behavior.

Eventually, many therapeutic communities formed small groups for family members, where the staff would lead discussions about their attitudes, behaviors, and values. This was considered a way to explore conflicts that potentially abetted their loved one's drug use. The preferred means of encouraging frank discussion was the encounter group which aimed at revealing differences between stated goals or needs and actual behavior. The intensity of interaction at these family groups, however, did not rise to the level practiced in the treatment community, and there was little acceptance or use of harsh confrontation [21].

The Hierarchy of Roles

Once admitted to the residential setting, the new member was introduced to the community's elaborate and hierarchical structure, much of which remains as a cornerstone in the American therapeutic communities to this day. Rank and status were based on work assignment, and newcomers were assigned to what was considered a "bottom" function, such as cleaning the toilets or washing dishes. These jobs were meant

to make clear to the client his position at the bottom in status, and the need to do the job well in order to gain status and move up in the hierarchy (which was often called "growing up"). But work was only one element on which moving up was based. Attitude, change, and commitment to the treatment community were also considered. The theme constantly reinforced by leaders to those beneath them was "You can have my job;" "You can be in charge," but "You must earn it!"

Each of these work assignments was real and necessary to the actual functioning of the community. Facilities needed to be cleaned, food prepared and cooked, cars oiled, gassed, and repaired, walls painted, and rooms renovated. Household needs had to be met, and effort was made to solicit contributions of everything from milk to gasoline from the greater community.

All donations were accepted: used clothing; slightly stale bread; fruit and vegetables; old dishes; and cookware. It was all needed. There were also cash gifts and, by incorporating as non-profit organizations, therapeutic communities were able to add the inducement of a tax deduction to the selling points of personal recovery and self-reliance.

Much also had to be done to run what was, in reality, a small business—write the letters; answer the phones; make agendas; ensure positive behavior, coordinate between departments, and represent the therapeutic community in the outside world. Each task was the responsibility of a specific department. Each department had its place within the hierarchy, and one's status depended upon one's role within the department and the department's place within the community. One gained status first by moving up within a department and then by moving on to a department with a more complex or demanding function.

Over time, each member, depending on his investment in treatment (judged to be doing well by peers and elders) was promoted upward. The promotions were done with drama and praise and were part of the reward system. Each promotion was discussed internally and was used as an example to guests and visitors to show how the therapeutic community structure rewarded one with increasing amounts of responsibility for areas of work, productiveness, and oversight of others.

During this time, youth and adults were mixed together, as were genders. All were treated with the same methods, expectations, and accountability demands. There was then no consciousness of a need for formal education for this predominantly adult population, and vocational training was "on the job," in the classic apprenticeship tradition. The need for supervision and oversight within the departments and within the community created an interesting tension between trust and scrutiny.

The Interactive Healing Life

Group processes were then and still are the lifeblood of the therapeutic community. Every day, every member, staff or client, and even steady visitors and friends, became involved in one group process or another [12].

The community began the day with a morning community meeting where concerns were expressed, and problems were solved. These meetings always began with a prayer or a statement of the program philosophy. Each therapeutic community group strove to be unique, creating its own language and terms to describe shared activities common to all other therapeutic community groups. Program philosophies became a critical means of identification and morale building. Many were created by the members themselves and reflect the spirit of the times and the intense need for affiliation, membership, and family. Indeed, the greeting, "Good morning, family," permeated most American therapeutic communities and (at least until the mid-1970s) most therapeutic communities outside the United States.

During these early formative years, the problems that came up at morning meetings often dealt with issues of survival, such as getting food for the table. Others were more mundane, like dealing with laundry, announcing

visitors that day, or welcoming new members. Some were personal disclosures, making the community aware of some member's personal distress. These morning meeting public disclosures were greeted with "reach-outs," expressions of concern and support from others. There were "pull-ups" for tasks left undone and also "push-ups", applause and recognition for tasks accomplished. These activities generated positive feelings—laughter and energy to start the day. The meetings usually ended with mutual hugs.

Intellectual Exchange

There was usually a break in the workday in mid-afternoon for lunch followed by the "daily seminar". Participation was mandatory for all, including the leadership. The goal of the seminar was to broaden the intellectual vista of community members. It was an opportunity to make them familiar with ideas and concepts that they had perhaps never heard of before. Everyone became a tutor or mentor, reading up on subjects so it could be brought to the group. There, members were encouraged, cajoled, and sometimes coerced into taking part in discussion of matters that ranged across vast subject areas. Philosophy was discussed, along with science, and literature. Sessions might focus on the works of Nietzsche or Freud or the writing of Hemingway or Faulkner. The seminar was an important part of daily life, not only for its content, but as a means of helping members learn to conceptualize and verbalize.

Small Group Interventions

Generally, every evening was reserved for small group process. These sessions were at first called "encounters," although some used the language of Synanon and called them the "game". One dimension of the encounter was its formation, for the makeup of each group was usually decided by elders in the program drawing on information they had received from various members. No less than twice weekly, when the call went out "encounter-time," every member experienced a moment of tension and anxiety. One never knew until that moment who might be in their group and how they might be perceived or challenged about their behavior, attitude, or social contribution to learning to live drug free. Encounters involved challenge, and often exaggerated elaboration of a person's behavior would be used to elicit truth, the admission of error, and acceptance of corrective action [6].

In 1968, the psychologist O. Horbart Mowrer, who visited Daytop frequently and was certainly in the behavioral therapy camp, made a unique contribution to the encounter group by adding a new aspect—promise-making. Members would now make a commitment to another (or many others) in the group to change or adapt some specific behavior. One did not necessarily have to believe in the need for or use of this behavior, one merely had to practice it. Subsequently, such phrases as "act as if" or "go through a motion" became a commonplace part of early therapeutic community life.

Also in 1964, Deitch and Casriel began experimenting with groups lasting 18–30 h. This was not a physically impractical notion at a time when all community members, including the directors, paid staff, and program elders, all lived either in the same facility or one close by. Therapy was an ongoing process, 24 h a day, and interactive dialogues were primary aspects of community life [6].

These long-lasting groups became known as marathons, and a set of methods and procedures slowly evolved. The staff who selected marathon participants would consider how the process could be the most useful for the member. However, common to all was the expectation of going deep toward the past, toward unresolved guilt and unrevealed strengths to discover, in the process, that one could be vulnerable in the face of fears and, by doing so, gain strength. The format began with autobiography, particularly aimed at early feelings of fear, shame, and defenses that became self-defeating [6].

As hours passed and intimacy grew, an atmosphere of caring emerged with expressions of compassion, and attempts at resolution became key. This experience was heightened by the combination of sleep deprivation, limited external stimuli, and selected stimuli to provoke moods (usually music, mirrors, drawing supplies, and occasional props such as photographs). Usually, by 24 h, all had experienced a sense of catharsis and acceptance by the others over conflicts, guilt, and regrets.

This marathon session would be followed by a break during which each participant was asked to be alone and reflect on the experience. They were usually escorted by a non-participating member who had experience with the process to a quiet, private space to sleep, eat, and think. After this 6-h break, participants reconvened for feedback. This process became very carefully regulated after the first few years, with the participants asking for feedback being given a scribe to record those portions of the feedback they requested. After feedback the members would talk about their "commitments" to the group.

Considering the regressive possibilities of this type of group, there was a safety net provided by the fact that they all lived together in a larger community of others equally committed to being there for each other. Most often, this experience resulted in peaks of love and compassion and group bonding. At this point a follow-up plan could be developed to monitor the keeping of commitments made during the marathon [6].

These marathons and shorter versions, with fixed targets of inquiry known as probes, ultimately morphed into a static group that met weekly and where the emphasis was on maintaining the intimacy created by the marathon or probe for further deep work. By 1979, static groups were created for members regardless of marathon participation.

The General Meeting: A Response to Crisis and Bad Behaviors

Unlike the daily morning meeting, when one heard the announcement "general meeting" therapeutic community members immediately headed for the meeting space knowing something big or bad had happened. Here, unlike at traditional meetings, the chairs were not arranged in a circle, but rather in a classroom format, with the front reserved for standing elders who had a message to deliver. These meetings did not occur often. When they did occur, it had to do with a serious threat (usually by a member's behavior) to the community's two principal taboos—no violence or even the threat of violence, and no drugs or alcohol. (Cigarettes were used by all members, and smoking was considered normative.) Such violations usually called for banishment of the offender. The meeting was to bring focus to the event, generate anger toward the offender, challenge the offender's right to remain, and vent fury at the threat to the community. The decision about whether an offender stayed or was banished was made as a result of the group's assessment of the offender's display of regret, seeking of forgiveness, and pleas to stay. Such a visible display and catharsis for the entire community was considered necessary for safety and the community's drug-free goals [4].

Public acts of contrition also permeated normal daily life. Signs were hung around member's necks describing their failures to be honest, their propensity for manipulation, or some other set of behaviors requiring a high level of focus and embarrassment to the person. These signs were often quite creative and developed for a specific individual and the particular offense. Others signs for more common offenses were used routinely and could be kept in a closet until needed [12].

Treatment Duration

All of the New York therapeutic communities and many others maintained a phase system with an average prescribed length of stay, in order to complete all phases, of two to two-and-a-half years. The early therapeutic communities believed in a full character makeover and the creation of a new pro-social role in society. Indeed,

such roles were made possible by becoming "change agents" and taking on careerist roles of therapeutic community staff which were in high demand [11].

Understandably, considering the length of prescribed stay, the problem of sexual needs and interaction was always present. Many attempts were made to resolve this dilemma. At first, permission to have sex was given if the heterosexual couple were behaving well in their community life, presented as stable in courting, and had been in treatment long enough to presume greater stability. This approach varied from program to program and often within the same programs.

The tradition at that time was to insist on couples' education groups, followed by encounter groups for couples meant to explore feelings and conflicts. When such couples demonstrated that the relationship was not compromising their positive treatment engagement, they were permitted a designated space and privacy for a given time period. This ranged from 2 h for beginners to an overnight visit for residents who had been in treatment for a considerable time.

By the early 1970s, the controversy and complexity of permitting, condoning, monitoring safety, public relations, and couples' conflict resolution soon gave way to exhaustion and brought about an official end to this era. Henceforth, sexual identity and romance could be discussed, but sanctioned sexual interactions were no longer permitted. The admonishment "You are here to get better; those other aspects are off the table and impede your personal recovery" eliminated the conversation but not the problem. However, sexual interactions between staff and clients continue to plague the recovery and mental health communities to this day.

The Therapeutic Community's Coming of Age

Therapeutic community treatment spread throughout country as well as to Europe and the Philippines (where there were new heroin epidemics). Expansion to Europe followed the visits of medical and psychiatric professionals to New York, then a hub of heroin use and treatment. Daytop (and later Phoenix House and Odyssey House) had a tradition of welcoming overseas visitors and enjoyed displaying their accomplishments. By 1970, this exposure had led Dr. Griffith Edwards, a leading addiction specialist in Britain, to sponsor Phoenix House London. Daytop sent staff to Sweden (1972) and Canada (1973). In 1972 Community Emiliehoefe in the Netherlands began shifting from a democratic (Jones) therapeutic community model to a United States model therapeutic community. In 1976, the first world federation conference of therapeutic communities took place in Sweden. There was to be continued growth in Europe, where expansion, which had initially involved the American therapeutic communities, was soon undertaken by the Europeans themselves [32].

In the United States, a national conference was organized by the National Institute on Drug Abuse and a very newly formed Therapeutic Communities of America in January 1976. Prominent among participants were the New York City therapeutic communities, but also represented were therapeutic communities from Florida, Canada, Pennsylvania, New Jersey, Washington, DC, Illinois, Washington, California, Ohio, Arizona, Rhode Island, Maryland, and Wisconsin [40].

However, the majority of the incorporators of the Therapeutic Communities of America remained in steady stable roles as chief executive officers, and their organizations grew in numbers of people treated and locations throughout the United States.

A key finding of the 1976 conference was that ". . . the therapeutic community is now determined to succeed in the public arena. In part this choice is a reflex to survive, but the therapeutic community is aware that it is an evolving institution!" Certainly there was prescient truth of what continues to this day. In 1974 there were 15,000 people in therapeutic community treatment . . . and major new drug-taking trends of type, method, and user populations [40].

The proceedings of the 1976 conference were sensitive to vulnerabilities of the past, noting that

"the communities are still dependent upon the emergent sanctioned leader. Despite an ostensible peer dynamic, individual therapeutic communities and the therapeutic community movement as a whole are very hierarchical in their internal process particularly in the selection, cultivation, and acceptance of their leaders. . ." [40]. This, however, proved no bar to expansion. Although the majority of the incorporators of the Therapeutic Communities of America remained in steady stable roles as chief executive officers, their organizations thrived, growing in size and spreading to new locations throughout the country.

Therapeutic Community Research

The 1976 conference proceedings also called for more research on both process and outcomes. Three major outcomes "researchers"—George DeLeon hired by Phoenix House [16], followed a few years later by Vincent Biase, hired by Daytop and Sherry Holland hired by Gateway—began to publish a set of promising outcome studies attesting to efficacy of the therapeutic community model.

The most prolific outcome spokesman for the therapeutic community movement was George DeLeon, who completed a series of 5-year follow-ups that revealed an important term for the entire drug abuse field. Time in program showed that any dose of drug treatment—regardless of type—of less than 3 months' duration did not appear helpful.

By 1984, DeLeon had published five papers, first describing the socio-demographics of New York Phoenix House therapeutic community members, then the signs or types of pathology and differences between men and women at Phoenix House. But it was the 1984 paper on a study of effectiveness which found that therapeutic community graduates had significant improvements in areas of drug use, criminality, and employment, which became the rallying point used by all therapeutic communities. These positive outcomes, with observable effect beginning after 90 days of treatment, were found to increase with the amount of time spent in treatment. The success rate at 2 years' post-treatment was approximately 90% for graduates (members who both completed residential care and achieved 6 months or more of aftercare in good status), 50% for completers, and 25% for dropouts who remain more than 6 months and less than 1 year [15]. The relationship between time in program and post-treatment success was found by other researchers as well [23, 43].

While there were critics then as even now, all of DeLeon's publications gave the entire field a sense of accomplishment, a right to brag (sometimes boast) that this was a model that produced drug-free cures, and regardless of cure, helped reclaim lives.

Early Therapeutic Community Studies

Outcome research by De Leon and others continued to demonstrate the value of therapeutic community treatment. In 1988, in another study at Phoenix House, DeLeon found that over 75% of Phoenix House graduates were both drug and crime free 5–7 years after completing treatment. In contrast, dropouts in DeLeon's sample were 31% drug and crime free, and only 25% of individuals who received less than 1 year of treatment were drug and crime free.

Following the Drug Abuse Reporting Program studies [43], a series of national studies in the 1990s with large samples of clients continued to demonstrate the efficacy of therapeutic community treatment. In the Treatment Outcomes Prospective Study, it was found that the longer clients spent in therapeutic communities, the less likely they were to use heroin, cocaine, marijuana, and psychotherapeutic drugs, and the more likely they were to be employed full-time and to have committed no predatory crimes during the follow-up year [9].

In four large-scale follow-up studies interviewing samples of more than 1,000 clients—the California Drug and Alcohol Treatment

Assessment [20], the Services Research Outcomes Study, the National Treatment Improvement Evaluation Study and the Drug Abuse Treatment Outcomes Study [44]—long-term therapeutic community treatment was found to produce greater reductions in marijuana, cocaine, and crack use 1 year after treatment than any other modality. Heroin use was reduced nearly as much as by methadone maintenance. Similar effects were shown for reductions in arrests and in drug selling. The Drug Abuse Treatment Outcomes Study also reported that full-time employment following long-term residential treatment was more than 250% greater than for any other modality. The National Treatment Improvement Evaluation Study found employment among former participants in long-term residential treatment nearly 200% the rate for any other treatment modality.

Dropout rates early in therapeutic community treatment are high, but similar to those across all substance abuse treatment modalities [15, 43, 23]. In his early studies, DeLeon reported completion rates from 10 to 20%, and 1-year retention was from 15 to 30%, with the highest dropout within the first 30 days. In the mid-1980s, DeLeon and psychologist Steven Schwartz reported 12-month retention rates ranging from 4 to 21% at seven therapeutic communities, with the dropout rate highest in the first 14 days and declining thereafter.

The Treatment of Adolescents and Findings

The Drug Abuse Reporting Program and Treatment Outcomes Prospective studies of the effectiveness of the therapeutic community when adolescents were treated with adults in the same programs yielded mixed but disappointing results on the reduction of substance abuse, particularly alcohol and marijuana. Positive outcomes were found on employment and criminal involvement. Retention of adolescents was similar to that found for adults, as was the time-in-program correlation with post-treatment improvement.

However, as the 1970s witnessed an explosion in adolescent drug use and a significant decrease in the average age of onset of drug dependency, calls were being made to treat adolescents separately from adults. Therapeutic communities developed adolescent day and outpatient programs, as well as residential therapeutic communities for teens only [13]. The regimens of these programs were designed to be responsive to the developmental tasks of adolescents.

Many of the programs incorporated educational programs. In the case of some of the larger residential therapeutic communities, these were at times annexes of local high schools that offered a full range of academic courses and services.

School attendance and homework took the traditional place of job functions in the therapeutic community regimen for adolescents, with job assignments relegated to after-school hours and weekends, similar to the balance of work and school responsibilities of most adolescents in the community at large [17].

Recreation was also more prominent in the therapeutic community regimens of adolescent facilities compared to those for adults, predicated on the notion that teens needed a physical outlet for their energies that otherwise would be channeled into misbehavior and that they needed to find ways of amusing themselves that did not involve the use of intoxicants.

Work with the adolescent population also necessitated working with their families. At Phoenix House, the use of multi-family therapy was pioneered with adolescent clients and their families [28]. This treatment approach capitalized on the strengths of group therapy, helping parents and other family members reduce their sense of shame and guilt with the help of similar peers, and built upon the merits of the therapeutic community by creating a sense of belonging, social support, and collective identification. Subsequently, multiple studies have demonstrated improved outcomes for clients whose families are included in the treatment process and have demonstrated support for the use group approaches for families [28].

In a RAND study by Andrew Morral et al., teens randomly assigned to a therapeutic community residential program and other types of residential settings were compared [38]. The adolescents who were in the therapeutic community program had superior outcomes on measures of drug use, criminal activity, and measures of psychological dysfunction. These findings were substantiated in a study of adolescents in six different therapeutic communities, whose members were found to have significant reductions in alcohol, marijuana, and other illicit drug use, as well as criminal and other deviant behavior [25].

The holistic therapeutic community approach for adolescents proved especially useful, with its emphasis on the broader range of developmental tasks instead of exclusive focus on drug taking, given that some drug and alcohol use and risk taking behavior is normative for young people in their late teens and early twenties. If abstinence is achieved in the months they are in the treatment setting, and gains are made in educational achievement and psychosocial development and functioning, adolescents may well reap significant and valuable therapeutic benefit, avoiding the high likelihood of intransigent addiction known to be the trajectory for youngsters who initiate substance abuse in early adolescence [17].

To the Twenty First Century

Responding to two decades of remarkable advances in our understanding of the addicted brain, therapeutic communities slowly modified the early treatment methods that were predicated upon a view of addicts as they presented in the 1950s. As is true for most diseases, it was the grossest manifestations of addiction that first came to the attention of therapeutic community workers. This reflected more than the severity of their drug involvement. Because of the illegal nature of heroin (opiate) abuse, most addicts of the 1950s were stereotyped, marginalized, and imprisoned with all kinds of other criminals. As a result, they developed the competencies necessary to survive as outsiders. They may have wished they wanted to quit, but they continued to use because they had very little, if any, other identity.

The heroin epidemic continued through the 1960s, but with the 1970s came widespread misuse of such other drugs as amphetamines, hallucinogens, and cocaine, and a new and more diverse population of drug users. They came from all social strata and had a broader range of education and economic resources.

The image of the addict as an end-stage user with concomitant social and psychological disorders began to change with the emergence of the 1970s users, predominantly white and middle class, and included numbers of college age users of hallucinogens.

While the 1960s had seen an expansion of methadone maintenance and therapeutic community treatment for heroin addiction, a new model of treatment, neither residential nor pharmacological, was developed for the drug abusers of the 1970s. The introduction of ambulatory care, labeled "outpatient drug-free" [44], swelled the ranks of behavioral healthcare professionals engaged in the treatment of drug misuse. They were quite unlike the men and women who provided most Alcoholics Anonymous and therapeutic community-based treatments, whose role was as much a commitment as a calling and who themselves suffered from the disorder, learned the lore of the model that had helped them, and presented the same with zeal and deep belief.

The outpatient drug-free community drew psychologists, social workers, and others from the helping professions. This new work force brought with it standards of practice based on the delivery of care during set hours and in discreet units of either individual counseling or group therapy. This was quite different from what was being practiced in the therapeutic community and 12-step world of full-time recovery engagement and constant involvement (albeit with sloppy boundaries). It was, however, this "professional" model that soon came to influence all of drug treatment, particularly that which was funded directly or indirectly by government.

Changing Therapeutic Community Practices

As federal and state substance abuse agencies were created in 1969 in response to President Nixon's "War on Drugs," the influence of new regulatory demands and the increased demand for practices that closely resembled hospital and medical clinics markedly changed therapeutic community practices.

Basic to the therapeutic community was the concept of clients and staff belonging to a single community in which therapy was an ongoing process, interactive dialogues were a primary aspect of community life, and counselors were fully engaged in this process, regardless of the time it took. Imposition of a strict 40-h work week in which at least 10 h was needed for paperwork (case notes, group notes, counseling notes, treatment plans, and revisions) played havoc with this concept.

Regulation and credentialization raised therapeutic community costs. The early therapeutic communities, built upon adult care paradigms, utilized a client (resident) workforce to perform all the many tasks necessary to maintain the community—food services, cleaning and repairs, auto maintenance, escort service, and administrative chores. Residents, as they rose in the hierarchy, also undertook supervisory functions. Moreover, the early therapeutic community was also predicated on a long-term care model which gave the population a substantial group of more mature members who were actualizing recovery skills in their daily lives. Regulations now barred residents from certain tasks. Since counselors now spent substantially less time with clients and there were fewer senior residents (the "elders" of the early years) to serve as role models and monitors, staff needs increased. Whereas once a ratio of one counselor for 20 or even 30 residents was sufficient, regulations now called for ratios closer to 1:15.

Funding sources responded to increased costs with demands for shorter lengths of stay, and therapeutic community programs attempted to control expenditures by creating economies of scale, developing treatment settings capable of housing a client population in excess of—often far in excess of—150 residents. While these settings were often able to reduce fixed costs for food and building supplies, they created issues of clinical management that also limited the time and quality of client interactions. One must consider Bill White's admonition regarding threats to viability: "The twin threats of professionalism (preoccupation with power or status) and commercialism (preoccupation with money or property) have often proved fatal to advocacy movements" [49].

The nature of therapeutic community treatment also reflected a changing treatment population. This was due, in part, to the criminal justice system's widespread acceptance of treatment as an alternative to incarceration for most nonviolent drug law offenders. The courts, probation, and parole authorities became, for most therapeutic community programs in the United States, a major if not the sole source of referrals.

The therapeutic community client base had, over the decades, come to display a rising level of pathology as seen in multi-generational use of drugs, with new court referrals often reflecting three or four generations of family use. These clients were quite different from addicts of the 1950s, who were most often adults, usually the first in their families to use drugs, and who accepted the view that something was wrong with them because of their drug use. This view eroded in the 1980s as a growing number of addicts came to reject the social view of drug-taking as deviant. They considered their drug-taking normative and the laws as deviant and blindly prejudiced against them. Unlike the burned-out residents of the past, who arrived exhausted by their jail experiences and addiction lifestyle, these court referrals arrived resenting their mandated treatment. Rather than viewing treatment staff as helpers who cared deeply about them, they tended to view program staff as "jailers".

Added to the forces reshaping therapeutic community treatment was the competition for clients. The days when therapeutic communities were "the only game in town" and clients

needed to demonstrate their commitment to be admitted were long gone. Since few addicts were now eager to submit to the therapeutic community's demanding regimen, the programs became increasingly reliant on court referrals, who lacked any real choice.

At this point a further challenge emerged from academics and federal researchers who challenged therapeutic community claims of effectiveness. The landmark, long-term, follow-up studies of George DeLeon and others that had demonstrated the pivotal role of time in program were faulted for lacking random assignment and the control groups that make up the gold standard of experimental design. These critical voices reinforced a jaundiced view of therapeutic communities taken by a number of academically trained professionals entering the field, who not only challenged the utility of the therapeutic community, but raised as an issue the potential harmfulness of therapeutic community practices [37]. This came at a time when many researchers, particularly those studying the treatment of other life-threatening disorders, were adopting new and more rigorous experimental design [39]. The call for more credible studies and more evidence-supported practices extended throughout the field of medicine and behavioral health.

Buffeted by these forces therapeutic community credibility began to wane. Some therapeutic communities faced these doubts by digging in their heels and becoming more rigid and orthodox. Others began to modify methods and incorporate new clinical practices into the therapeutic community regimen. However, the stereotype of shame-based, attack therapy which humiliated its members, screamed and yelled at them, and broke them down to build them back up was kept alive by those who questioned the validity of the therapeutic communities. Although the overwhelming majority of therapeutic communities had long ago abandoned such primitive practices, the field was demoralized in the late 1980s by its failure to shake off the stereotypes.

In 1992, however, a new and more favorable light was cast on therapeutic communities with the publication of studies that documented the effectiveness of therapeutic communities in prison settings to reduce recidivism and/or increase the length of time between release and re-incarceration. New York's Stay'n Out program led the way [47]. Then, the prison therapeutic community was tried in Delaware with similar promising outcomes. Evaluations of the Key/Crest program found that significantly more of the clients who completed the in-prison program and the transitional aftercare program remained arrest free during the follow-up (55%) than an untreated comparison group (29%) [35]. Those who also had received outpatient aftercare following the transitional residential treatment had the best outcomes, with 69% being arrest free after 3 years. Results for relapse to drug use were similar, reported for 17% of those who completed the in-prison therapeutic community only, 27% who had both the in-prison treatment and transitional residential treatment, and 35% who also had outpatient aftercare remaining drug free during the follow-up, compared to only 5% of the comparison group [35]. Five-year outcomes were similar [24]. Recidivism rates were significantly lower for those who went through both Key and Crest or through Crest. Participation in the in-prison therapeutic community treatment alone did not appear to significantly improve 5-year outcomes, although it was associated with higher rates of aftercare use.

The federal government's Substance Abuse and Mental Health Services Administration subsequently sponsored a treatment project in two of California's prisons, and, by 1992, Texas had adopted prison therapeutic communities as the state's primary means of halting an ever-growing demand for prison construction [31]. California followed Texas and, by 2000, close to 8,500 therapeutic community treatment slots existed in California's prisons. In each state, outcome data supported the financial investment in prison-based therapeutic community as a means of reducing rates of recidivism and extending the length of time former inmates remained out of prison [30].

In the Amity program at the R.J. Donovan prison in California, follow-up studies found 3

years post-parole that only 27% of those who received both in-prison and aftercare treatment were reincarcerated during the follow-up interval, compared to 75% of those in the comparison group, 79% of those who completed only the in-prison treatment, and 82% of those who were in-prison treatment dropouts [46].

Evaluation of the Kyle/New Vision program in Texas demonstrated that completion of 3 months of residential aftercare in a transitional therapeutic community followed by up to another year of supervised outpatient aftercare was the strongest predictor of remaining arrest free for 2 years following release from prison, and aftercare completion was strongly associated with parolee satisfaction with these programs [22]. Three-year follow-up studies showed that in-prison treatment followed by aftercare was most effective for high-risk, high-need offenders [34].

The research showed that positive outcomes would only be sustained if prison therapeutic community treatment was followed by transitional care in the community. Therapeutic communities have been shown to be effective within a prison environment and significantly reduce recidivism. Positive outcomes improve significantly when in-custody treatment is followed by community-based treatment [31, 35, 46].

Also gaining traction in the 1990s were drug courts [8], offering coerced and highly monitored treatment in the community in lieu of prison or jail. As the nation increasingly came to realize that the treatment of addicted offenders—whether in prison or mandated by the courts—was reducing the social cost of crime and promoting health [34], the therapeutic community approach was re-evaluated and its reputation substantially restored [45].

Further studies of prison therapeutic communities, showing substantial variations in outcome, highlighted the need for therapeutic community clinicians to better understand aspects of criminality [33]. Most treatment providers had then presumed that criminal acts were a result of addiction, although, for 30–50% of this population, criminal activity preceded drug misuse. What was becoming clear was the need to recognize and respond to individual client differences [29].

This perception was widespread—and not only in prison therapeutic communities. Programs throughout the country recognized the need for differentiated care and turned to a variety of validated assessment instruments as the basis for differential diagnoses and individual treatment plans. Disorders were becoming more recognized, particularly depression and anxiety, and in women the presence of trauma and post-traumatic stress disorder. Such data demonstrated even further the need for a mix of methods, approaches, intensities, and time in treatment [52]. Increasingly therapeutic communities both in prison and in the community have come to recognize the need for and benefit of adopting other evidence-based approaches, although the resulting changes have been met with varying degrees of enthusiasm, readiness, and workforce willingness.

The therapeutic community has undergone an extraordinary evolution over the years. Yet some troubling issues are being resolved only now, in this first decade of the twenty first century. Many have long been aware that the therapeutic community treatment model was, in large measure, based on male paradigms. But only with today's greater gender sensitivities have those in the field finally come to realize that, because of the staggering amount of trauma visited upon women, some traditional therapeutic community practices (particularly the mixed gender encounter groups) [37] can have profound iatrogenic effects on women [10].

What the therapeutic community has proven during its evolution is that a system once rigid and orthodox is capable of extraordinary flexibility and adaptability. This can be seen in the use of medications, lengths of stay, settings (residential or outpatient), trans-disciplinary staffs, and the adaption of evidence-based practices and validated assessment instruments. But what makes the therapeutic community unique is not simply the power of the community as a treatment force but the uses to which this force is put.

When therapeutic community practitioners speak of treating "the whole person" they have

in mind all the dimensions of the individual—the emotional and psychological, the physical, the social and vocational, as well as the intellectual, ethical, and spiritual. For each of these dimensions, there are discreet goals and means of employing the elements of mutual help to identify strengths, remedy deficits, build competencies, and foster the capacity for continued growth. It is an ultimately enabling mechanism, for therapeutic community treatment is not an end in itself. It is a bridge to recovery and a life path that makes recovery manageable, sustainable, and, yes, enjoyable too.

Introduction

Twelve-step self-help groups, often also called mutual help or support groups, are an important component of the system of informal care for individuals with substance use disorders. Individuals make more visits to self-help groups for help with their own or family members' substance use and psychiatric problems than to all mental health professionals combined. About 9% of adults in the United States have been to an Alcoholics Anonymous meeting at some time in their life, and almost 80% of adults who seek help for alcohol dependence participate in Alcoholics Anonymous [14]. Moreover, many substance use disorder treatment service providers have adopted 12-step principles in treatment, and the majority of them refer clients to self-help groups.

Self-help groups offer a forum wherein members can express their feelings in a safe, structured setting, improve communication and

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_46,

interpersonal skills, better understand the reasons for their substance abuse, learn self-control, and identify new activities and life goals. Accordingly, the American Psychiatric Association [1] and several other professional and health care organizations recommend referrals to self-help groups as an adjunct to the treatment of individuals with substance use disorders.

Major Types of Substance Use-Focused Self-Help Groups

The majority of the literature on self-help groups that address substance abuse focuses on traditional 12-step groups. The most prevalent traditional 12-step groups are Alcoholics Anonymous, Narcotics Anonymous, and Cocaine Anonymous; other important substance-use-focused self-help groups include Secular Organizations for Sobriety, Self-Management and Recovery Training, and Moderation Management. These groups are briefly described next; Women for Sobriety and Double Trouble in Recovery are described in the sections on women and individuals with substance use and psychiatric disorders.

Alcoholics Anonymous

Alcoholics Anonymous is a fellowship whose primary purpose is to help individuals with alcohol-related problems maintain sobriety. It is structured around the Twelve Steps (e.g., admission of powerlessness over alcohol, belief in a higher power) and Twelve Traditions (e.g., an emphasis on common welfare and recognition that personal recovery depends on Alcoholics Anonymous unity). (See www.aa.org/pdf/products/p-42_abriefguidetoaa.pdf for the Twelve Steps and Twelve Traditions.) Other key aspects of Alcoholics Anonymous involve open and closed group meetings and literature that describes Alcoholics Anonymous, shares its tenets, and provides guidance to recovering individuals. Estimated Alcoholics Anonymous membership is about 1,200,000 members and 52,000 groups in the United States and more than 2,000,000 members and 105,000 groups worldwide; about 35% of the members are women (see www.aa.org).

Narcotics Anonymous and Cocaine Anonymous

Narcotics Anonymous is a fellowship of recovering individuals with drug use disorders. Narcotics Anonymous grew out of Alcoholics Anonymous and is similar to Alcoholics Anonymous in that it provides a structured support network in which members share information about overcoming addiction and living productive, drug-free lives through adherence to the Twelve Steps and Twelve Traditions. Narcotics Anonymous encourages complete abstinence from all drugs, including alcohol, but, like Alcoholics Anonymous, accepts the use of prescribed medications for psychiatric and medical disorders. Narcotics Anonymous has about 44,000 weekly meetings in more than 120 countries worldwide; about 70% of the members are Caucasian and 45% are women (see www.na.org).

Cocaine Anonymous is a fellowship open to individuals who want to stop using cocaine, including "crack" cocaine and other mind-altering substances. Cocaine Anonymous' program of recovery was adapted from Alcoholics Anonymous and, like Alcoholics Anonymous, uses the 12-step recovery method. There are an estimated 30,000 members and more than 2,000 groups (see www.ca.org).

Secular Organizations for Sobriety

Secular Organizations for Sobriety provides support for individuals who seek to achieve and maintain sobriety, a forum to express

thoughts and feelings about recovery, and a non-religious or secular approach that does not depend on the Twelve Steps or Twelve Traditions. Members are expected to acknowledge their addiction and take responsibility for achieving and maintaining sobriety. Members tend to be well-educated individuals who have been in professional treatment and have attended and continue to attend Alcoholics Anonymous. The majority of the members are men (see www.secularsobriety.org).

Self-Management and Recovery Training

Self-Management and Recovery Training espouses a rational treatment orientation and focuses on teaching individuals new coping skills and more logical ways of thinking and acting. It emphasizes practical methods of changing maladaptive behavior rather than a 12-step or spiritual approach. Self-Management and Recovery Training's 4-point program includes: (1) building and maintaining motivation to abstain, (2) learning how to cope with urges, (3) managing thoughts, feelings, and behavior, and (4) balancing momentary and enduring satisfactions (see www.smartrecovery.org).

Moderation Management

Moderation Management construes problem drinking as a habit that can be controlled by applying principles of cognitive-behavioral treatment in the context of a network of supportive peers. Moderation Management provides an alternative to the spiritually oriented disease model of traditional 12-step self-help groups and to an abstinence goal; it allows members a choice of abstinence or moderate drinking goals. Moderation Management members tend to emphasize the value of self-control, insight, personal responsibility and choice, and rationality. Most Moderation Management members are Caucasian; they tend to be married, college educated, and employed, and more than half are women (see www.moderation.com).

Participation in Self-Help Groups and Substance Use Outcomes

Individuals with substance use disorders who participate in 12-step self-help groups, especially Alcoholics Anonymous and Narcotics Anonymous tend to experience better alcohol and drug use outcomes than do individuals who do not participate in these groups. The most common index of participation has been attendance at group meetings; however, recent attention has focused on aspects of involvement, such as reading 12-step literature, working the steps, obtaining a sponsor, and doing service work.

Attendance and Substance Use Outcomes

People who attend Alcoholics Anonymous in the first few weeks or months after treatment tend to experience good short-term substance use outcomes. For example, Project MATCH was a large clinical trial that compared 12-step facilitation, cognitive-behavioral, and motivational enhancement treatment for individuals with alcohol use disorders. Participants who attended Alcoholics Anonymous more often in each of the 3-month intervals after treatment were more likely to maintain abstinence from alcohol in that interval. In addition, more frequent Alcoholics Anonymous attendance in the first 3 months after treatment was related to a higher likelihood of abstinence and fewer alcohol-related consequences in the subsequent 3 months; these findings held for participants in each of the three types of treatment [59].

Comparable findings were obtained in two projects conducted among individuals with substance use disorders who were treated in residential programs. Among individuals in hospital-based programs, those who participated in 12-step self-help groups in the 3 months prior to a 1-year follow-up were more likely to be abstinent, in remission, and free of dependence symptoms. Clients who attended more group meetings experienced better outcomes than did clients who attended fewer meetings [48]. Among individuals in community-based programs, those who attended more 12-step self-help group meetings in the 3 months prior to a 1-year follow-up were more likely to be abstinent at follow-up [43].

Individuals who continue to attend self-help groups for a longer interval are more likely to maintain abstinence than are individuals who stop attending. In a 5-year follow-up of individuals with alcohol use disorders who entered treatment, Kaskutas and colleagues [23] identified four types of Alcoholics Anonymous careers: (1) a low Alcoholics Anonymous group mainly attended Alcoholics Anonymous in the year after treatment entry; (2 and 3) medium and high Alcoholics Anonymous groups had stable attendance for 3 years after treatment entry (about 60 meetings per year for the medium group and more than 200 meetings per year for the high group), and (4) a declining Alcoholics Anonymous group attended an average of almost 200 meetings at first but dropped to about six meetings by year 5. Consistent with these attendance patterns, at year 5, the low Alcoholics Anonymous group had a 43% rate of 30-day abstinence, compared with 73% for the medium group, 79% for the high group, and 61% for the declining group.

Another prospective study of individuals with alcohol use disorders showed that a longer duration of attendance in Alcoholics Anonymous in the first year after help-seeking was associated with a higher likelihood of 1-year, 8-year, and 16-year abstinence. These findings were based on better outcomes for individuals who attended Alcoholics Anonymous for 17 weeks or more. Individuals who attended Alcoholics Anonymous for 1–16 weeks had no better outcomes than non-attendees did. Moreover, after controlling for the duration of Alcoholics Anonymous attendance in year 1, the duration of attendance in years 2–3 and 4–8 was related to a higher likelihood of 16-year abstinence [39, 41].

Involvement and Substance Use Outcomes

Attendance is an important indicator of participation, but it may not adequately reflect an individual's level of group involvement, as shown by such indices as acceptance of 12-step ideology, having a spiritual awakening, giving Alcoholics Anonymous talks, socializing with Alcoholics Anonymous members, becoming a sponsor, and self-identification as a group member. These aspects of group involvement may be associated with substance use outcomes independent of the duration and frequency of attendance per se.

In support of this idea, individuals who held stronger beliefs in 12-step ideology were more likely to be abstinent independent of their 12-step group attendance [18]. In the National Institute on Drug Abuse Collaborative Cocaine Treatment Study, individuals who increased their 12-step involvement in the first 3 months of treatment had better cocaine and other drug use outcomes in the next 3 months. Individuals who regularly engaged in 12-step activities but attended meetings inconsistently had better drug use outcomes than did individuals who attended consistently but did not regularly engage in 12-step activities [62].

Caldwell and Cutter [8] identified a group of individuals who showed substantial attendance at meetings but mixed involvement in Alcoholics Anonymous practices. These individuals were likely to have a sponsor, admitted powerlessness, and worked the steps; however, they were less enthusiastic about the concept of a "higher power" and Alcoholics Anonymous literature and were less involved with other Alcoholics Anonymous members. They also had high relapse rates. Individuals who attend

self-help groups but are unable to embrace key aspects of the program appear to be less likely to benefit from it.

Participation and Outcomes Other than Substance Use

Participation in self-help groups is associated primarily with better substance use outcomes; however, it has also been linked with more self-efficacy and spirituality and less distress, better social support and functioning, and enhanced coping skills and community participation.

Participation in self-help groups has been associated with stronger self-efficacy for abstinence, less distress and depression, and fewer psychiatric symptoms [39, 41, 43, 48]. Compared with individuals who had not worked all 12 steps, those who had worked all 12 steps had more self-esteem and social confidence and were more optimistic and trusting [53]. In addition, some studies have shown an association between participation in self-help groups and higher levels of spirituality and perceived meaning of life [30].

There is a relatively robust relationship between self-help group involvement and better social support and functioning. For example, individuals with alcohol use disorders who attended more Alcoholics Anonymous meetings over a 3-year interval had more friend-related support; individuals who attended Alcoholics Anonymous longer over 1-year and 8-year intervals also reported more support from friends [54]. Similarly, individuals who attended Narcotics Anonymous once a week or more had more friends than did individuals who did not attend Narcotics Anonymous or attended infrequently [13].

In a review of this area, Groh and colleagues [19] concluded that more involvement in Alcoholics Anonymous was associated with larger friendship networks, primarily due to acquiring an Alcoholics Anonymous sponsor and the development of new 12-step friends. Involvement in Alcoholics Anonymous was also linked to more specific support for abstinence from friends and to higher quality friendships and more general support. Importantly, the strength of affiliation among Alcoholics Anonymous members may be comparable to or even stronger than feelings for close friends and family members.

Affiliation with 12-step self-help groups tends to promote more reliance on approach coping and behaviorally oriented substance use coping processes. For example, Snow and colleagues [52] found that individuals who were more involved in Alcoholics Anonymous were more likely to rely on coping responses aimed toward reducing substance use, such as spending time with non-drinking friends, talking to someone about their drinking problems, rewarding themselves for trying to stop drinking, and becoming more aware of social efforts to help people stop drinking. In addition, individuals who attend Alcoholics Anonymous for longer intervals tend to rely more on approach coping and less on avoidance coping [54].

There has been speculation that the admonition against public self-identification as a member of Alcoholics Anonymous or Narcotics Anonymous may discourage participation in community activities. However, many long-term Alcoholics Anonymous/Narcotics Anonymous members are active in established neighborhood organizations and civic groups, such as homeless coalitions and parent-teacher associations [29]. Similarly, Alcoholics Anonymous participation has been associated with community helping activities, such as mentoring youngsters or doing volunteer work among alcoholic individuals in recovery [65].

Connections Between Self-Help Groups and Treatment

Many individuals who enter professional treatment also participate in self-help groups; in fact, 50–80% of individuals in substance use disorder treatment also participate in self-help groups, and 60–80% of Alcoholics Anonymous

members have participated in treatment [34]. These two sources of help could contribute independently to better outcomes, or they could either bolster or detract from each other.

Participation in Treatment and Self-Help Groups

In general, individuals who enter treatment are more likely to participate in self-help groups than are individuals who do not enter treatment. Compared with help-seeking individuals who entered only Alcoholics Anonymous, individuals who entered both treatment and Alcoholics Anonymous participated as much or more in Alcoholics Anonymous in the subsequent 15 years. Individuals who stayed in treatment longer in the first year after seeking help subsequently showed more sustained participation in Alcoholics Anonymous. More extended treatment later in individuals' help-seeking careers was not associated with subsequent participation in Alcoholics Anonymous, which suggests that treatment providers' referrals to Alcoholics Anonymous have more influence in the context of an initial treatment episode [40].

Moreover, individuals who participate in self-help groups are more likely to enter and complete treatment. Clients with drug use disorders who attended self-help groups weekly before treatment stayed in treatment longer and were more likely to complete treatment. In turn, clients who stayed in treatment longer subsequently were more likely to attend Alcoholics Anonymous at least weekly [17]. In a study of individuals with alcohol use disorders, those who participated in both treatment and Alcoholics Anonymous attended more treatment sessions and more Alcoholics Anonymous meetings than did those who participated only in treatment or only in Alcoholics Anonymous [57].

Several studies have shown a more specific link, in that individuals who participate in 12-step treatment, which introduces clients to 12-step philosophy and encourages them to join a group, are more likely to affiliate with self-help groups than are individuals who participate in treatment that is not oriented toward 12-step principles. In Project MATCH, participants in 12-step facilitation treatment were more likely to attend and affiliate with Alcoholics Anonymous than were those in cognitive-behavioral treatment or motivational enhancement treatment [59]. Similarly, in another multisite study, participants in 12-step facilitation programs affiliated more with 12-step self-help groups after treatment than did those who were treated in cognitive-behavioral treatment programs [20].

A supportive and spiritually oriented treatment environment can enhance participation in 12-step activities. In this vein, clients in more supportive treatment environments increased more in 12-step involvement during treatment; that is, they were more likely to acquire a sponsor and 12-step friends and to read 12-step literature. Moreover, when clients who had a high risk of dropping out of self-help groups after treatment were treated in a more supportive environment, their risk of dropout declined [27].

These findings suggest that referral and alliance processes contribute to an association between participation in treatment and subsequent participation in self-help groups. A positive treatment alliance may enhance clients' motivation for recovery and underlie the impact of counselors' recommendations to attend self-help groups. Treatment that highlights the value of 12-step self-help groups in recovery encourages more self-help group involvement than treatment that does not highlight this value.

Treatment, Self-Help Groups, and Substance Use Outcomes

Participation in treatment and participation in self-help groups have independent effects on substance use outcomes that tend to augment each other. In this vein, individuals who participated more intensively in self-help groups after

treatment experienced better substance use outcomes even after controlling for the effects of treatment completion and continuing care [16]. This finding has been obtained in follow-ups of individuals discharged from hospital-based and community-based residential care [43, 48].

More importantly, participation in each of these two modalities of help can independently contribute to better outcomes. In a nationwide sample of alcohol-dependent individuals, those who participated in 12-step self-help groups in addition to professional treatment were more than twice as likely to achieve an abstinent recovery as were individuals who obtained professional treatment alone [14]. Similarly, among clients with drug use disorders, longer episodes of treatment and weekly or more frequent self-help group attendance during and after treatment were each independently associated with 6-month abstinence [17].

Participation in self-help groups may compensate for the lack of services provided in treatment. Among dually diagnosed participants in residential programs, the benefits of 12-step self-help group attendance depended on the intensity of treatment services. More 12-step self-help group attendance during treatment was associated with better alcohol and drug outcomes at discharge only among individuals treated in low-service-intensity programs. More 12-step self-help group attendance after discharge from treatment was associated with better psychiatric and family/social functioning at 1 year only among individuals receiving low-service-intensity care [56].

Treatment Orientation and Self-Help Group Outcomes

Twelve-step facilitation treatment may enhance the effectiveness of 12-step self-help groups. Humphreys and colleagues [20] identified a stronger relationship between 12-step self-help group participation and better substance use outcomes among clients from 12-step facilitation treatment programs than among those from cognitive-behavioral treatment or eclectic programs. Post-treatment self-help group involvement partially explained the higher rates of abstinence among individuals from 12-step programs than among those from cognitive-behavioral treatment programs.

In Project MATCH, clients who had networks supportive of drinking at baseline and were assigned to 12-step facilitation treatment had better drinking outcomes at a 3-year follow-up than comparable clients in cognitive-behavioral treatment or motivational enhancement treatment. Treatment assignment did not affect drinking outcomes for clients with networks unsupportive of drinking. In part, this matching effect occurred because 12-step facilitation clients were more involved in Alcoholics Anonymous after treatment than were clients in either cognitive-behavioral treatment or motivational enhancement, and because more Alcoholics Anonymous involvement led to a higher percentage of abstinent days and fewer drinks per drinking day [33].

Essentially comparable findings were obtained in the National Institute on Drug Abuse Collaborative Cocaine Treatment study. Participants in individual drug counseling, which emphasized 12-step principles, were more likely to adopt 12-step beliefs and engage in 12-step behaviors than were those in supportive-expressive therapy, cognitive therapy, or group drug counseling, which placed less emphasis on 12-step ideology. These individuals also experienced better end-of-treatment substance use outcomes; changes in participants' 12-step beliefs and behaviors explained part of this effect [12].

Personal Factors, Participation, and Self-Help Group Outcomes

In an attempt to identify individuals who may be especially well-suited for participation in self-help groups, researchers have considered

a range of personal factors, including severity and impairment related to substance use, and disease model beliefs and religious/spiritual orientation. Studies also have examined the suitability of self-help groups for individuals with substance use and psychiatric disorders, women, older adults, and members of racial and ethnic minority groups.

Severity and Impairment

In general, individuals who are heavier substance users, are more dependent on substances, have more substance-related problems, and lack control over substance use are more likely to affiliate with self-help groups. More impaired clients are more likely to continue self-help group attendance and less likely to drop out after treatment [10]. Compared with Type A alcoholic individuals in 12-step treatment, Type B alcoholics, who have more severe alcohol-related problems, were more likely to attend Alcoholics Anonymous in the 12 months after treatment. Moreover, the less impaired Type A individuals were more than twice as likely to stop attending Alcoholics Anonymous after treatment [58].

Compared with individuals with less severe substance use problems, those with more severe problems may benefit more from self-help group involvement. Morgenstern and colleagues [45] found that individuals with more severe substance use and psychosocial problems who had high levels of self-help group affiliation had better 6-month substance use outcomes; outcomes were poor when group affiliation was low. For those who had less severe problems, levels of self-help group affiliation were not related to outcomes.

Disease Model Beliefs and Religious/Spiritual Orientation

Individuals whose beliefs are more consonant with the 12-step orientation are more likely to affiliate with 12-step self-help groups. More specifically, people who believe in the disease model of substance use, have an abstinence goal, and see themselves as alcoholics or addicts tend to become more involved in self-help groups after discharge from acute treatment and are less likely to drop out [27].

Many individuals see a positive role for an emphasis on spirituality in self-help groups and focus on spirituality as a source of: (a) personal strength and self-protection (e.g., help in maintaining abstinence, reducing craving, and facing mortality) and (b) altruism and protection of others (e.g., not sharing drug paraphernalia or engaging in unsafe sexual practices) [2]. Individuals with stronger religious beliefs are more likely to attend and become involved in 12-step self-help groups during and after treatment. In contrast, less religious individuals, including those who profess atheistic and agnostic beliefs, are less likely to attend and more likely to drop out of 12-step self-help groups. Nevertheless, when they do become involved in self-help groups, less religious individuals appear to obtain as much or more benefit from them as more religious individuals do [24, 27].

More generally, individuals whose religious/spiritual beliefs better match those of their primary self-help group tend to participate more in that group. More religious individuals are more likely to participate in 12-step than in other types of self-help groups; in contrast, religiosity does not seem to be associated with participation in Self-Management and Recovery Training but is associated with less participation in Secular Organizations for Sobriety. Matching an individual's spiritual/religious beliefs to those of a self-help group may increase the individual's participation in the group and perhaps indirectly increase the likelihood of continued sobriety [5].

Individuals who profess a stronger religious/spiritual orientation may be better able to accept their craving and, therefore, become more involved in 12-step self-help groups. Consistent with this view, clients who professed stronger spiritual/religious beliefs at intake to treatment improved more in acceptance-based responding between baseline and a 1-year follow-up.

These individuals became more aware of and able to acknowledge internal experiences, such as cravings and distress, and were able to rely more on adaptive coping responses to confront and manage these experiences. In turn, enhanced acceptance-based responding at a 1-year follow-up predicted increased subsequent self-help group involvement. Thus, together with treatment, spirituality/religiosity may promote self-regulation skills that contribute to 12-step self-help group affiliation [9].

Individuals with Substance Use and Psychiatric Disorders

A high proportion of individuals with substance use disorders have co-occurring psychiatric disorders. With the exception of clients with psychotic disorders, these dually diagnosed individuals are as likely to attend 12-step self-help groups as are those with only substance use disorders. In general, individuals with dual diagnoses appear to benefit from substance-use-focused 12-step self-help groups as much as do those with only substance use disorders [43, 48].

A few studies have focused on participants with specific psychiatric disorders, especially post-traumatic stress disorder and major depression. Individuals with substance use disorders and post-traumatic stress disorder participated as much in 12-step self-help groups after treatment as did those with only substance use disorders. The dually diagnosed individuals who participated more in self-help groups were more likely to be abstinent and experienced less distress; they also were more likely to maintain stable remission over a 2-year follow-up [49].

The situation may be different for clients who have substance use disorders and co-occurring major depression. Compared with individuals with only substance use disorders, those who also had major depression were less likely to become involved in 12-step self-help groups after treatment. At a 2-year follow-up, the association between self-help group involvement and abstinence was stronger for clients who had only substance use disorders than for those who also had major depression. These participants did not benefit as much from contact with a sponsor, 12-step friends, reading 12-step literature, and working the steps. Depressed individuals may have interpersonal problems that make it harder to develop friendships and to acquire and relate to a sponsor; thus, they may need more support and guidance to become involved in and benefit from 12-step self-help groups [26].

Traditional 12-step self-help groups may have some limitations for dually diagnosed individuals, who may be less able to bond with other members who do not share the experiences associated with psychiatric problems. Some group members may have ambivalent or negative attitudes about the use of medications to prevent relapse or alter mood. In addition, some dually diagnosed individuals may be alienated by 12-step philosophy, the emphasis on denial, and an apparent lack of empathy for individuals with psychiatric problems.

Given these issues, some dually diagnosed individuals may do better in dual-focused 12-step self-help groups, such as Double Trouble in Recovery. Double Trouble in Recovery is a 12-step fellowship adapted from the 12-step method of Alcoholics Anonymous; it is designed to meet the needs of individuals who have both substance use and psychiatric disorders. Double Trouble in Recovery specifically addresses the problems and benefits associated with psychiatric medications. It has amended steps 1 and 12 of the 12 steps to include mental disorders so that, for example, step 1 is: "We admitted we were powerless over mental disorders and substance abuse—that our lives had become unmanageable" (see www.doubletroubleinrecovery.org).

Individuals who experience more psychiatric symptoms and more severe consequences of drug use are more likely to maintain attendance in Double Trouble in Recovery. With respect to outcomes, Double Trouble in Recovery members who engaged more in reciprocal learning and assuming a helping role were more likely to be abstinent at a 1-year follow-up. A 2-year follow-up showed that individuals who affiliated

more strongly with Double Trouble in Recovery improved more in self-efficacy for recovery, leisure time activities, feelings of well-being, and social relationships [35, 37].

In a subsequent study, a cohort of dually diagnosed individuals who did not have Double Trouble in Recovery available during treatment was compared with a cohort exposed to it after Double Trouble in Recovery meetings were instituted in the treatment program. Compared with the pre-Double Trouble in Recovery cohort, the post-Double Trouble in Recovery cohort had significantly fewer days of alcohol and drug use, more frequently attended traditional 12-step group meetings outside the program, and adhered more to their psychiatric medications at a 6-month follow-up [36].

Women

Women with alcohol or drug use disorders are at least as likely as men to attend and affiliate with self-help groups. Compared with men, women may be more likely to read Alcoholics Anonymous literature, call an Alcoholics Anonymous member for help, and experience a spiritual awakening. In a study of individuals with alcohol use disorders, women were more likely than men to attend Alcoholics Anonymous and went to more Alcoholics Anonymous meetings in the first year after initiating help-seeking. More extended participation in Alcoholics Anonymous was associated with a higher likelihood of 1-year remission for both women and men; however, the positive association between a longer duration of Alcoholics Anonymous attendance and stable remission was stronger for women [42, 55].

Compared with men, women may be more in tune with 12-step philosophy, which involves acceptance of powerlessness over the abused substance and dependence on a higher power to attain sobriety. Self-help groups are non-hierarchical and non-authoritarian and foster recovery in a relational, mutually enhancing, and safe context, which may especially appeal to women. In addition, compared with men, women may be more comfortable in self-help groups such as Alcoholics Anonymous because they are more interdependent with other people, more likely to gain self-esteem from developing and maintaining close relationships, and more at ease with emotional self-disclosure [51].

Even though many women attend and benefit from Alcoholics Anonymous or Narcotics Anonymous, the emphasis in these groups on powerlessness, humility, and surrender alienates some women, who express discomfort with face-to-face self-disclosure in group meetings populated mostly by men. Alcoholics Anonymous may be especially problematic for women who drink for reasons associated with sexuality and gender roles. Many women report feeling that they do not fit in at Alcoholics Anonymous, and that they find it to be too negative, dislike the primary focus on the past, and feel that interchanges in Alcoholics Anonymous are dominated primarily by men.

These issues led to the development of Women for Sobriety, which provides an alternative for women who prefer an emphasis on improving self-esteem, independence, and personal responsibility rather than powerlessness, humility, and surrender. Women for Sobriety shares Alcoholics Anonymous' focus on meditation and spirituality but espouses the idea that sobriety is dependent on taking personal responsibility for one's behavior rather than on a higher power. Women for Sobriety seems to be especially attractive to well-educated, middle-aged, and middle- and upper-class women, many of whom, nevertheless, continue to attend Alcoholics Anonymous (see www.womenforsobriety.org).

In contrast to Alcoholics Anonymous, Women for Sobriety is based on the idea that women need a positive program that reinforces optimistic thinking about their abilities and independence, reduces their guilt, and enhances their coping skills. Many women report that they attend Women for Sobriety for support and nurturance, a safe environment, sharing about women's issues, and the positive emphasis on self-esteem. In this respect, there is an association between longer membership in Women for Sobriety and higher self-esteem [22].

Older Adults

Late-middle-aged and older adults participate in and benefit from 12-step self-help groups. In two studies, older clients (55+ years of age) with substance use disorders were matched with younger (aged 21–39) and middle-aged (aged 40–59) clients on the basis of race, education, marital status, and dual diagnosis status. These three groups of participants attended a comparable number of self-help group meetings during residential treatment and were equally likely to attend self-help groups in the first 2 years after treatment and to have a sponsor. Overall, individuals who attended more group meetings and those who obtained a sponsor in the first year experienced better 1-year alcohol and psychological distress outcomes. Participants who attended more meetings and had a sponsor in the second year reported less alcohol consumption at a 5-year follow-up. The three age groups did not differ in the associations between 12-step self-help group attendance and these outcomes [32].

In a similar study of clients in community residential care, the three age-matched groups showed comparable self-help group attendance during treatment and in the year after entering treatment. A comparable percentage had a sponsor. Overall, clients who attended more self-help group meetings and those who had a sponsor a year after entering treatment had better alcohol-related and psychological distress outcomes at 1-year and 4-year follow-ups. Again, the three age groups did not differ in the associations between 12-step self-help group involvement and these outcomes [31].

Race and Ethnicity

Compared with Caucasian clients, African-American clients may be more likely to attend self-help groups as part of treatment and to increase their affiliation during treatment; in addition, they appear to be less likely to drop out of self-help groups after treatment [28]. Certain characteristics of 12-step self-help groups may especially appeal to African-American clients, including the fact that meetings are widely available and open to anyone, have a strong social and spiritual component, and are free of charge. African-American clients seem to be more likely to identify as Alcoholics Anonymous members, experience a spiritual awakening in Alcoholics Anonymous, and do service at Alcoholics Anonymous meetings. In contrast, Caucasian clients are more likely to read 12-step literature and have a sponsor [25, 44].

In order to meet their unique recovery needs, African-Americans appear to integrate cultural factors and a unique language and perspective in the process of affiliation with Alcoholics Anonymous. According to Durant [15], African-Americans are more likely to associate their problems with racism and economic disadvantage than with alcohol abuse; they are less likely to accept the disease concept of alcoholism. Nevertheless, they are able to contrast the negative aspects of drinking with the positive aspects of abstinence, to respond to modeling and support from mentors and sponsors, to modify the moral aspects of Alcoholics Anonymous to meet their spiritual needs, and to adapt the Alcoholics Anonymous world view to better fit their racial and cultural background.

Compared with non-Hispanic white individuals, Hispanic individuals may be less likely to attend Alcoholics Anonymous after treatment, perhaps because they tend to turn to their existing support system. However, attendance at Alcoholics Anonymous appears to be similarly associated with decreased alcohol consumption among both Hispanics and non-Hispanic whites [4].

In Project MATCH, Hispanic individuals attended Alcoholics Anonymous less often after 12-step treatment than non-Hispanic white participants did. Nevertheless, as judged by self-identification as an Alcoholics Anonymous member, having an Alcoholics Anonymous sponsor, experiencing a spiritual awakening, and celebrating an Alcoholics Anonymous birthday, they were as committed to Alcoholics Anonymous as were non-Hispanic whites. Thus,

Hispanics' lower Alcoholics Anonymous attendance does not necessarily mean that they are less favorably inclined toward Alcoholics Anonymous. However, Hispanic clients who were more involved in specific Alcoholics Anonymous practices were not more likely to achieve abstinence [3].

Active Ingredients of Self-Help Groups

The effectiveness of self-help groups in curtailing substance use is based largely on four key ingredients: (1) abstinence-specific and general support that emphasizes the value of identification with abstinence-oriented role models and strong bonds with family, friends, work, and religion, (2) the goal direction and structure of a consistent belief system that espouses a substance-free lifestyle, (3) involvement in rewarding activities that do not involve substance use, and (4) an emphasis on bolstering members' self-efficacy and coping skills and helping others overcome substance use problems [38].

These critical factors appear to be common change factors that underlie long-term recovery from substance abuse. A recent survey of self-help groups, including traditional 12-step groups, Self-Management and Recovery Training, Secular Organizations for Sobriety, and Women for Sobriety, supported the idea of common change factors. It showed that active involvement in a support group was associated with a higher likelihood of long-term remission irrespective of the particular group to which the individual belonged [5].

Abstinence-Specific and General Support

Self-help groups are an important source of abstinence-specific and general support, and may be especially effective in counteracting the influence of substance users in a social network. Self-help groups provide modeling of substance use refusal skills, ideas about how to avoid relapse-inducing situations, practical advice for staying sober, and helpful hints about how to address the panoply of everyday life problems. Individuals who continue to attend Alcoholics Anonymous more regularly after treatment are more likely to have social network members who support cutting down or quitting substance use than are individuals who attend Alcoholics Anonymous less regularly. In fact, the increase in friends' abstinence-oriented and general support associated with involvement in self-help groups explains part of their positive influence on remission [21, 61].

According to Bond, Kaskutas, and Weisner [7], individuals who have fewer heavy drinkers in their social network and more people who encourage the reduction of drinking, as well as more Alcoholics Anonymous-based support for reducing drinking, are more likely to initiate and maintain abstinence; the number of Alcoholics Anonymous-based social network members who support reduced drinking explains part of Alcoholics Anonymous' effect on abstinence. Involvement in Alcoholics Anonymous also may protect individuals from the potential negative influence of a "wet" social network [23].

Goal Direction and Structure

Self-help groups provide a context of goal direction and structure in the form of a shared ideology that enhances individuals' immersion into the group. The shared ideology, which is reinforced by explaining group beliefs in understandable terms, specifying changes needed to maintain sobriety, and providing the 12 steps as a guide for change, helps members negotiate the recovery process. Alcoholics Anonymous norms appear to result in more personal and intimate self-disclosures and less conflict in Alcoholics Anonymous groups than in non-Alcoholics Anonymous support groups [60, 63].

There also is a system of taking turns in Alcoholics Anonymous that exemplifies its egalitarian nature, non-differentiated roles of members, and low levels of conflict. In this vein, members acknowledge and identify with previous speakers' contributions and do not openly confront or challenge them, thereby maintaining solidarity, communicating acceptance, and reducing the potential for conflict. Alcoholics Anonymous members tell life stories aligned with Alcoholics Anonymous principles, which supports the development of shared identities characterized by dependence on Alcoholics Anonymous and relevance to the 12 steps [47].

The emphasis on spirituality is a key aspect of the goal direction in 12-step self-help groups. In this sense, Alcoholics Anonymous can be seen as a spiritual recovery movement that rewards compliance with its norms by engaging individuals in a social system that promotes new meaning in their lives. Among individuals in day hospital or residential treatment, increases in 12-step involvement from baseline to a 1-year follow-up predicted a higher likelihood of abstinence at follow-up. This relationship was partially explained by an increase in religious practices and spirituality. Thus, spiritual change may contribute to recovery within the context of self-help group involvement [64].

Involvement in Rewarding Activities

Another active ingredient of self-help groups involves their role in engaging members in rewarding substance-free social pursuits, such as home groups, parties, and community activities. Members who are more involved in group meetings and related activities, such as doing service and becoming a sponsor, are more likely to achieve and maintain abstinence [23]. Involvement in community groups predicted 1-year abstinence among drug-dependent individuals independent of attendance at Alcoholics Anonymous/Narcotics Anonymous and being a sponsor. By helping their members become more socially integrated, self-help groups increase the likelihood of sustained abstinence [11].

Self-help groups also provide members with an opportunity to help other individuals in need, which tends to increase the helper's sense of purpose and personal responsibility, rewards for remaining sober, and commitment to recovery [65]. In a prospective study based on data from Project MATCH, recovering individuals who became sponsors or were otherwise engaged in helping other alcoholics were less likely to relapse [50]. Similarly, compared with Double Trouble in Recovery members who were less involved in sharing at meetings and helping other members, those who were more involved in these activities were more likely to be abstinent at a 1-year follow-up [37].

Sponsors provide other members with support and direction, 12-step instruction, tips to help promote abstinence and improve relationships, and crisis intervention. Engaging in these helping activities can improve the sponsor's self-esteem and social standing, strengthen the sponsor's social network, and provide a model of successful commitment to live a sober lifestyle. Accordingly, self-help group members who become sponsors are more likely to maintain abstinence than those who do not [11].

Self-Efficacy and Coping

Affiliation with Alcoholics Anonymous tends to be associated with increases in members' self-efficacy and motivation for abstinence. For example, an analysis of data from Project MATCH showed that participation in Alcoholics Anonymous was positively related to self-efficacy to avoid drinking. Self-efficacy predicted a higher likelihood of abstinence and explained part of the association between participation in Alcoholics Anonymous and abstinence. In addition, Alcoholics Anonymous attendance at 6 months post-treatment predicted self-efficacy at 9 months, which predicted abstinence at 15 months. Self-efficacy to avoid drinking explained part of the effect of Alcoholics

Anonymous attendance on abstinence for both less severe (Type A) and more severe (Type B) alcoholic individuals [6, 10].

A study that assessed individuals in 12-step treatment during treatment and at 1- and 6-month follow-ups focused on several common change factors, including self-efficacy, commitment to abstinence, appraisal of harm due to substance use, and active cognitive and behavioral coping. More affiliation with Alcoholics Anonymous in the month after treatment was associated with increases in these change factors and with better 1- and 6-month substance use outcomes. In addition, these common change factors appeared to explain all of the effect of Alcoholics Anonymous affiliation on 6-month substance use outcomes [46].

Affiliation with 12-step self-help groups promotes more reliance on coping responses directed toward reducing substance use. Individuals who are more involved in Alcoholics Anonymous are more likely to rely on coping skills directed toward controlling substance use, such as spending time with non-drinking friends, seeking advice about how to resolve their drinking problems, and rewarding themselves for trying to stop drinking [52]. The active ingredients of self-help groups that foster improvement in coping skills likely include modeling of substance use refusal skills, ideas about how to manage relapse-inducing situations, and practical advice for coping with craving.

Participation in self-help groups is also associated with improvements in general coping skills—i.e., increases in approach coping and declines in avoidance coping [46]. Individuals who are more involved in 12-step groups tend to rely more on approach and less on avoidance coping; approach coping responses explained part of the effect of involvement in these groups on the reduction of substance use [21].

Conclusions

The active ingredients of self-help groups reviewed thus far tend to enhance motivation for recovery, self-efficacy to resist substance use, and effective coping skills. In this vein, increases in common change factors such as support, goal direction and structure, and involvement in rewarding activities are likely to result in increased motivation for recovery, self-efficacy to resist drinking, and approach coping.

Most generally, the finding that a longer duration of participation in self-help groups predicts better substance use outcomes indicates that self-help groups are most beneficial when they become a long-term supportive aspect of individuals' lives. Extended 12-step group engagement may initiate and maintain the personal and social changes needed to solidify stable remission, especially abstinence-specific and general support, goal direction and structure, involvement in rewarding substance-free activities, and enhanced self-efficacy and coping skills. Self-help groups represent an important part of the array of effective interventions than can change the enduring aspects of individuals' life contexts and increase the likelihood of a long-term course of recovery.

Introduction

Alcohol dependence is a common disorder. Globally and in the United States, alcohol dependence ranks 5th and 3rd, respectively, on the list of preventable causes of morbidity and mortality [294]. In 2000, the United States had 20,687 alcohol-related deaths, excluding accidents and homicides, with an overall estimated cost to the nation of about $185 billion [294].

In the 1980s, the lifetime prevalence of alcohol-related disorders was estimated to be 13.5% in the United States [255]. Later, the National Comorbidity Survey reported a higher lifetime prevalence of 23.5% [151]. It has been estimated that up to 24.3% of men and 48.5% of women with alcohol dependence have prominent depressive symptoms [152]. Furthermore, alcohol dependence increases the risk of depression up to fourfold [152, 251]. Depression in alcohol-dependent individuals increases the degree of morbidity [233, 239] and risk for suicide [82, 214]. Individuals with bipolar disorder have a high prevalence of 46% to develop an alcohol-related disorder; indeed, the odds of a bipolar disorder if a person has an alcohol-related disorder are 5.1 times greater than in an individual without an alcohol-related disorder [251]. Bipolar

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_47,

alcoholics are at increased risk of violent behavior [264], treatment non-adherence, high rates of hospitalization [278], and mortality. Anxiety-related disorders also occur frequently among alcohol-dependent individuals (with a prevalence rate of 19.4%), especially general anxiety disorder, social phobia, and post-traumatic stress disorder [251]. Up to 90% of alcohol-dependent individuals are smokers, and the heaviest drinkers tend to smoke the most [14]. In a sample size ranging from 80 to 1,142, surveys of alcohol-dependent inpatient and outpatient treatment participants showed an 86–97% smoking rate among males and an 82–90% rate among females [37, 69, 161, 302]. Smoking increases the health risks and associated morbidity and mortality of alcohol dependence greatly, and vice versa. Comorbid psychiatric disorder or smoking complicates the treatment of alcohol dependence and increases the level of public health concern.

Alcohol dependence is a chronic relapsing medical disorder [210]. Notwithstanding its psychological and social ramifications, once established, alcohol dependence is essentially a brain disorder that bears many of the characteristics of other medical relapsing disorders such as diabetes and hypertension. Indeed, without a pharmacological adjunct to psychosocial therapy, the clinical outcome is poor, with up to 70% of clients resuming drinking within 1 year [81, 287]. Comorbid psychiatric or smoking-related behavior with alcohol dependence would be expected to increase these rates of relapse.

Alcohol dependence is a treatable disorder when efficacious medicines are added to enhance the effects of psychosocial treatment. Advances in the neurosciences have facilitated the development of medicines that target neurotransmitter systems, which modulate activity in the cortico-mesolimbic dopamine pathway, the primary circuit by which alcohol's reinforcing effects associated with its abuse liability are expressed. Also, neuronal circuits in the extended amygdala modulate the expression of alcohol reinforcement in the cortico-mesolimbic dopamine pathway and increase the propensity for conditioned behaviors to trigger relapse ([159]; also see Chapter "Opportunities, Challenges, and Successes in the Development of Medicines for the Treatment of Addiction"). Additionally, it is now known that some alcoholics may possess a biological predisposition to the disease. These biologically vulnerable alcoholics can be expected to benefit from specific adjunctive medications targeted toward correcting or ameliorating their underlying abnormalities. Further, we are now better at controlling the "dose" of adjunctive psychosocial treatments, thereby optimizing the therapeutic response of the candidate medicines. Targeting medicinal treatments toward psychiatric or smoking-related disorders that are comorbid with alcohol dependence is complex because the neuronal targets are broadened, and the implications of altering their function are less well understood.

Recently, the treatment of alcohol dependence has been advanced by development of new models as well as broader therapeutic objectives. An important model is that with appropriate pharmacotherapy it is possible to initiate treatment for alcohol dependence while the individual is still drinking heavily and at the point of maximum crisis and help-seeking behavior [140]. To broaden access to treatment, effective but brief and standardized behavioral treatment has been developed to accompany medication delivery; thus, these medicines can now be provided more readily in the general practice setting [136, 245]. Finally, it is now better recognized that although abstinence remains the ultimate goal in treating alcohol-dependent individuals, reducing the frequency of heavy drinking has the major impact of decreasing alcohol-related consequences and improving quality of life [140].

In this review, we focus on the development of those medications for which there is clinical information and that have been designed to reduce the desire to drink, to promote abstinence, or both. Basically, of the numerous neurotransmitter systems that have been identified for the development of new medicines, the most

promising compounds appear to be those that modulate the function of opioids, glutamate with or without gamma-aminobutyric acid, and serotonin. Other putative therapeutic medications including direct modulators of dopamine function and enzyme inhibitors also shall be discussed. Each subsection of this chapter provides an overview of the basic science, clinical studies, and future directions for the development of specific promising medications from these neurobiological systems. Emphasis is made in places where the development of a particular medicine has advanced the development of a new treatment model or broadened therapeutic objectives. As appropriate, subsections are expanded or added where there is the discussion of a medication that has been tested for the treatment of alcohol dependence with a comorbid psychiatric disorder or smoking pertinent to this review. We conclude the chapter with remarks pertaining to current barriers to treatment and how they might be overcome.

Opioids: Mu Receptor Antagonist—Naltrexone

Basic Science and Human Laboratory Studies

The endogenous opioid system, particularly through its interactions with the cortico-mesolimbic dopamine system, is involved in the expression of alcohol's reinforcing effects [97, 108, 117, 130, 147, 177, 203] (Fig. 1). Obviously, opioid receptors also have interactions with other neurotransmitters, including those in the glutamate [172], gamma-aminobutyric acid [83], serotonin [202], cannabinoid [195] and perhaps glycine [252] systems, that contribute to its effects on ethanol intake.

Even though naltrexone has some affinity for the kappa-opioid receptor [250], its principal pharmacological effect on alcohol consumption

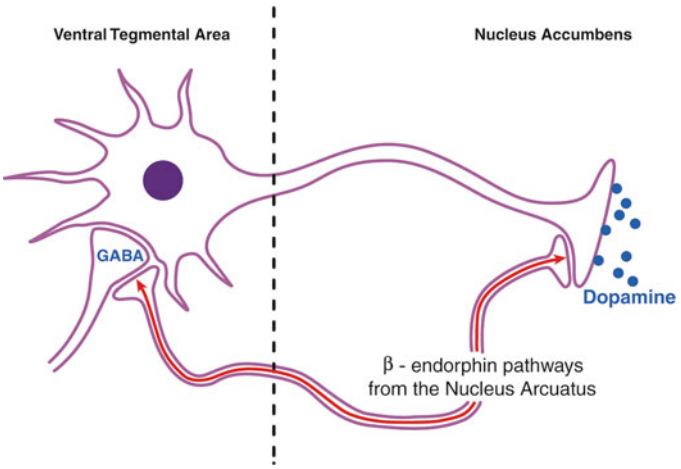

Fig. 1 Schematic representation of opioid interactions with the cortico-mesolimbic dopamine reward pathway. Functional activity of beta-endorphin pathways primarily originating from the nucleus arcuatus can lead to increased dopamine release in the nucleus accumbens via two mechanisms. First, beta-endorphins can disinhibit the tonic inhibition of gamma-aminobutyric acid (GABA) neurons on dopamine cells in the ventral tegmental area [108, 147, 203]. Second, beta-endorphins can stimulate dopamine cells in the nucleus accumbens directly. Both mechanisms may be important for alcohol reward. Alcohol stimulates beta-endorphin release in both the nucleus accumbens and ventral tegmental area [97]. Mu receptor antagonists such as naloxone and naltrexone block these central effects of beta-endorphins [97, 117]. Embellished from Gianoulakis [97]. Reprinted from Johnson and Ait-Daoud [130], with kind permission from Springer Science+Business Media

is through blockade of the mu-opioid receptor as mice that lack the mu-opioid receptor do not self-administer alcohol [254]. Further, alcohol intake increases beta-endorphin release in brain regions such as the nucleus accumbens [196, 197, 234], an effect that is blocked by naltrexone [315]. Mu receptor antagonists such as naltrexone and naloxone also suppress ethanol intake across a wide range of animal paradigms [8, 62, 84–86, 120, 150, 175, 262, 295, 298] cf. [17, 148, 258]. More recently, there also has been interest in elucidating the role of the hypothalamic-pituitary-adrenocortical axis in stress-induced ethanol consumption and sensitivity and how this might be influenced by naltrexone treatment [153, 308].

Ethanol has complex neurobiological interactions that affect the production, secretion, and binding of opioids to their receptors [119], thereby hinting at a fundamental mechanistic process linking the two. This relationship does, however, remain imperfectly understood. For example, animals bred for high ethanol preference exhibit an exaggerated reactive rise in beta-endorphin level following ethanol intake [98]. Yet, naltrexone's ability to suppress ethanol-associated increases in beta-endorphin level appears greater in animals bred for low rather than high preference for alcohol [315]. Indeed, from a group of animals in the beta-endorphin-deficient mutant mouse line—C57BL/6-Pomc1(tm1Low)—the highest ethanol consumption occurred in the heterozygotes (50% beta-endorphin deficient) and not the homozygotes (no beta-endorphin) or control group of sibling wild type mice from the same strain [105]. These findings do, however, suggest that molecular genetic differences that alter beta-endorphin expression, not simply its plasma levels, modulate the level of response to naltrexone. Nevertheless, there is growing evidence in humans that differences in the OPRM1 mu-opioid receptor gene are associated with differential therapeutic response to naltrexone—a theme that is explored in detail later in this review.

Human laboratory studies that have evaluated naltrexone's effects on alcohol-induced positive subjective mood and craving have yielded mixed results. Although it has been shown that naltrexone can reduce alcohol-induced positive subjective mood, albeit with increased sedation [288], and increase the latency to consume alcohol among social drinkers [61], others have reported no effect [67]. It does, however, appear that a positive familial loading for alcoholism might predict the potential anti-drinking and anti-craving effects of naltrexone in human laboratory studies. For example, King et al. [155] showed that social drinkers with a familial loading for alcoholism were more likely than those without it to exhibit a decrease in the stimulant effects of alcohol following naltrexone treatment. Nevertheless, they also reported concomitant negative mood exemplified by increased tension, fatigue, and confusion and decreased vigor, as well as notable adverse events such as nausea and vomiting following naltrexone. More recently, Krishnan-Sarin et al. [169] have shown that individuals with a family history of alcoholism, compared with their family history-negative counterparts, consumed less alcohol in a laboratory paradigm. Obviously, these results would lead to the speculation that a genetic explanation for differential response to naltrexone's effects on craving and alcohol consumption among alcohol-dependent individuals is being studied in the human laboratory. Nevertheless, even here, what has been demonstrated is that naltrexone increases the urge to drink among alcohol-dependent individuals who are aspartate (Asp) carriers of the OPRM1 gene but has no effect on their homozygote, i.e., asparagine-carrying, counterparts in a cue-reactivity laboratory paradigm [207]. Despite the dissimilarities between studies, including the subject's motivation toward seeking treatment, experimental set, setting, expectations, and paradigm, these results do appear to be in contrast with the report that naltrexone preferentially protected against relapse in Asp-carrying alcohol-dependent individuals [240]. The implications of these findings are discussed in the clinical subsection below.

In sum, basic science studies support the finding that naltrexone can reduce ethanol

drinking and related behaviors in animals. Naltrexone appears most effective in suppressing the expected ethanol-induced increase in beta-endorphin level among animals that exhibit an exaggerated beta-endorphin response. The pharmacogenetic construct for understanding preferential response to naltrexone is not well understood and is even contrary to expectations. Generally, human laboratory studies provide some support for naltrexone as a medication that can reduce craving for alcohol as well as its consumption; however, these effects appear to be more readily demonstrable among individuals with high familial loading for alcoholism. An initial pharmacogenetic exploration did not demonstrate that naltrexone's anti-drinking effect is greatest among non-treatment-seeking, alcohol-dependent individuals who carry the Asp variant of the OPRM1 gene.

Clinical Studies with Oral Naltrexone

In 1994, the Food and Drug Administration approved naltrexone for the treatment of alcohol dependence based on data from two relatively small (total $N = 167$) studies [235, 299]. In those studies, recently abstinent, alcohol-dependent individuals who received naltrexone (50 mg/day), compared with their counterparts who got placebo, were less likely to relapse during the treatment period of 12 weeks. Nevertheless, 5 months after treatment, the relapse rates for the naltrexone and placebo groups were similar. The anti-alcohol-craving effects that were ascribed to naltrexone were based on three findings. First, individuals with the highest level of baseline craving appeared to benefit the most from naltrexone [122]. Second, abstinent individuals who had received naltrexone had less of an impulse to initiate drinking [236]. Third, even among those who sampled alcohol, less pleasure was derived from the beverage [300]. These earlier studies were limited by the fact that only male veterans were tested in one of the studies [299], and either there was no biomarker used to corroborate the self-reported data [235] or when the liver enzyme gamma-glutamyl transferase was used as a biomarker the results were not contributory [299]—presumably due to the relative insensitivity of this measure to capture transient drinking patterns.

Notably, in two large meta-analytic studies [30, 283], naltrexone has been demonstrated to be efficacious at reducing the risk of relapse among recently abstinent, alcohol-dependent individuals. What has emerged an examination of these studies was that naltrexone's effect size was small, with a corresponding number needed to treat (i.e., the number of individuals who need to be treated to prevent relapse in a single individual) of 7. An important threat to demonstrating efficacy for naltrexone is not having quite high enough levels of medication compliance. Indeed, in a 3-month follow-up and systematic replication of their study, Volpicelli et al. [301] only found a significant effect of naltrexone treatment compared with placebo recipients if the pill-taking rate exceeded 90%; even here, the difference in the percentage of drinking days between the naltrexone and placebo groups was small—3 and 11%, respectively.

Perhaps because of this small effect size, some studies have failed to demonstrate naltrexone's efficacy in treating alcohol dependence. For instance, in the United Kingdom collaborative trial led by Chick et al., no overall difference was found between the naltrexone 50 mg/day and placebo groups on any of the endpoint measures; however, when individuals with less than 80% pill-taking compliance were excluded from the analysis, naltrexone was associated with a lower percentage of days drinking compared with placebo—12% vs. 20%, respectively [183, 184]. With naltrexone treatment, reduced pill-taking compliance is typically the result of adverse events such as nausea that can be reported as significant in up to 15% of trial participants [56]. Therefore, new technologies that aim to improve compliance by delivering naltrexone in depot form might possess a therapeutic advantage to the oral formulation. These technologies are discussed later in this section.

Importantly, the landmark COMBINE study ($N = 1383$) has served to underscore that naltrexone (100 mg/day) plus medication management to enhance compliance compared with placebo reduced the risk of a heavy drinking day (hazard ratio = 0.72; 97.5% CI = 0.53–0.98; $p = 0.02$) [10]. Uniquely, this study used a higher naltrexone dose (i.e., 100 mg/day vs. 50 mg/day), and the high compliance rate of pill taking—85.4%—improved clinical outcome.

Recently, it has been proposed that individuals with the Asp variant of the OPRM1 gene exhibited preferentially higher relapse prevention rates when receiving naltrexone treatment [240]. As described previously, a similar response to naltrexone treatment on cue-elicited craving was not observed among non-treatment-seeking, alcohol-dependent individuals in a human laboratory study [207]. Further, a recent clinical trial did not find a preferential effect of naltrexone treatment on any of the variants of the OPRM1 gene [92]. Notably, the functional importance of variation in the OPRMI gene is still being elucidated. Although earlier studies in transfected cells suggested that the OPRM1-Asp^{40} variant had a 3-fold higher affinity for beta-endorphin than OPRM1-Asn^{40}, which would suggest enhanced function [29], this has not been corroborated by others [16, 18]. Recent in vitro transfection studies have, however, suggested that the G118 allele might be associated with lower OPRM1 protein expression than the A118 allele [318]. A further complication to estimating the general clinical significance of the effects of the Asp^{40} allele on pharmacotherapeutic response to naltrexone is that its frequency can vary considerably between populations—from as low as 0.047 in African Americans to 0.154 in European Americans, and as high as 0.485 among those of Asian descent [91, 316]. More genetic studies are, therefore, needed to elucidate fully the mechanistic effects of the Asp^{40} allele, and to establish whether or not naltrexone response varies by variation at the OPRM1 gene.

Certain clinical characteristics have, however, been associated with good clinical response to naltrexone, and these include a family history of alcohol dependence [122, 156, 215] or strong cravings or urges for alcohol [215].

Naltrexone's utility compared with placebo as an add-on treatment in alcohol-dependent individuals with comorbid bipolar I or II disorder was investigated recently [269]. All individuals received their concomitant medications prescribed for bipolar disorder prior to study entry, along with standardized cognitive behavioral therapy designed for the treatment of bipolar disorder and substance use at scheduled intervals during treatment [263]. Naltrexone did not differ statistically from placebo on any outcome measure of drinking, and the attrition rate was high—48%.

Naltrexone's utility compared with placebo as a treatment for alcohol dependence and smoking cessation also has been studied recently [157]. In that placebo-controlled study, there was no overall effect of naltrexone on either the consumption of alcohol or smoking. In a subsequent subset analysis confined to heavy drinkers (defined as those with at least one heavy drinking episode during the 2-week pre-enrollment baseline period), there was an effect of naltrexone to reduce heavy drinking; however, again there was no effect on smoking. Interestingly, there was a significant negative association between quitting smoking and decreasing alcohol consumption, whereby greater success in stopping smoking was correlated with increased amounts of heavy drinking. These results do not provide strong support for the use of naltrexone as a medication for the simultaneous reduction or cessation of alcohol consumption and smoking among individuals comorbid for these conditions.

In sum, the majority of the data confirm that naltrexone is an efficacious medication for treating alcohol dependence. The therapeutic treatment effect size is, however, small, and poor pill-taking compliance can be associated with poor clinical outcome. There remains a dearth of published studies on the effects of different doses of naltrexone on drinking outcome. Further research is needed to establish whether naltrexone's therapeutic efficacy in treating alcohol dependence differs among individuals who

have variants of the OPRM1 gene. Alcohol-dependent individuals with a positive family history for the disease and individuals with strong cravings for alcohol appear to benefit the most from naltrexone treatment. Naltrexone does not appear to be a promising medication for the treatment of alcohol dependence with comorbid depression, or for the contemporaneous reduction or cessation of alcohol consumption and smoking.

Clinical Studies with Depot Naltrexone

Three extended-release formulations of naltrexone for deep intramuscular injection have been developed—Vivitrol® (Alkermes, Inc., Cambridge, MA, USA), Naltrel® (Drug Abuse Sciences, Inc., Paris, France), and Depotrex® (Biotek, Inc., Woburn, MA, USA). The premise for developing these depot formulations of naltrexone is three-fold. First, a well formulated depot preparation can maintain relatively constant plasma levels by producing a slow but regular release of naltrexone. Individuals who take oral naltrexone and have notable adverse events such as nausea that can lead to study discontinuation probably experience this phenomenon due to the rapid rise in plasma levels following initial doses of oral naltrexone. Hence, a depot formulation might be expected to decrease these initial adverse events if it provided a more gradual rise in naltrexone plasma levels. Second, by providing a monthly depot preparation, compliance with receiving the medication is optimized and should be greater than reliance on remembering to take tablets. Third, because plasma levels should remain relatively constant throughout the month following the administration of a depot preparation, there should be relatively greater exposure to the therapeutic dose, thereby facilitating good clinical outcome. Information pertaining to the three depot preparations of naltrexone that are being tested is provided below.

Vivitrex® or Vivitrol®

Vivitrex®, or Vivitrol® as it is known now, is naltrexone formulated into poly-(lactide-co-glycolide) [270], small-diameter (<100 μm), injectable microspheres that contain other proprietary active moieties, which lead to its extended-release properties lasting for several weeks [179]. In 2004, Johnson et al. [139] published the initial safety, tolerability, and efficacy trial of Vivitrex® for treating alcohol dependence. The design of the study was a 16-week randomized, placebo-controlled, double-blind clinical trial. Of the 25 alcohol-dependent individuals who participated in the trial, five of them got placebo and the remainder ($N = 20$) got 400 mg of Vivitrex®. Results of that trial showed the safety of Vivitrex®, with the most common adverse events being non-specific abdominal pain, nausea, pain at the injection site, and headaches. None of the placebo recipients dropped out due to adverse events; in contrast, two of those who got Vivitrex® discontinued for that reason. Due to the unbalanced design and small subject numbers, any inferences regarding efficacy had to be viewed quite cautiously. Nevertheless, there was a trend for those on Vivitrex®, compared with placebo, to have a lower percentage of heavy drinking days—11.7% vs. 25.3%. Later, in a large placebo-controlled, double-blind, randomized, multi-site, 24-week clinical trial, Garbutt et al. [90] showed that high-dose Vivitrex® (380 mg) recipients had a significantly lower percentage of heavy drinking days than those who got placebo (hazard ratio = 0.75; 95% CI = 0.60–0.94; $p = 0.02$). Recipients of low-dose Vivitrex® (190 mg) had outcomes similar to those who got placebo. The treatment response signal in the high-dose Vivitrex® recipients came from the male participants as the effect of both Vivitrex® doses was no different from that in women who took placebo (hazard ratio = 1.23; 95% CI = 0.85–1.78; $p = 0.28$). The lack of efficacy for Vivitrol® in women has been ascribed to greater subclinical affective symptoms, less of a family history of alcoholism (which is meant to

be associated with good clinical outcomes to naltrexone), more responsiveness to placebo, and more clinical heterogeneity in the sample. In contrast with the premise for developing depot preparations, the dropout rate of 14.1% in the high-dose Vivitrex® group was similar to that reported in studies with oral naltrexone. The chosen objective biomarker to corroborate the self-reported data—gamma-glutamyl transferase—did not show a difference between any of the Vivitrex® doses and the placebo group. The common reasons for study discontinuation were injection site reactions, headaches, and nausea. Serious adverse events were reported in two participants taking active medication that resulted in an interstitial pneumonia and an allergic-type eosinophilic pneumonia, both of which resolved after medical treatment. Thus, the evidence remains that Vivitrol® appears to be efficacious in preventing heavy drinking in men; however, it was approved by the Food and Drug Administration for treatment of both men and women based on the extant literature on naltrexone as a treatment for alcohol dependence. The expected advantage of Vivitrol® to increase compliance did not materialize quickly although this might become more manifest in generic treatment settings rather than a closely monitored clinical trial. The potential for hypersensitivity reactions to Vivitrol®, while small, does require post-marketing evaluation by the Food and Drug Administration.

Naltrel®

Naltrel® consists of naltrexone incorporated into microspheres of poly-(DL-lactide) polymer. These microspheres, stored in single-dose vials, are suspended in a diluent that contains carboxymethylcellulose, mannitol, polysorbate 80, and water for injection. The polylactide polymer is metabolized to water and carbon dioxide. Then, as the microspheres degrade, naltrexone is released. In 2004, Kranzler et al. [167] studied the safety and efficacy of Naltrel® in treating male and female alcohol-dependent individuals receiving monthly motivation enhancement-based therapy in a double-blind, placebo-controlled, 3-month randomized controlled trial ($N = 157$). The initial dose of Naltrel® (150 mg) was delivered as a deep intramuscular injection into each buttock, and subsequent monthly doses were just 150 mg. Placebo injections were provided at the same frequency and constitution but lacked the active compound. Adverse events reported significantly more frequently in the Naltrel® group than in the placebo group included injection site reactions, chest pain, and upper abdominal pain. Placebo recipients were, however, more likely to report irritability than those who got Naltrel®. While 6 (3.8%) of the placebo recipients dropped out, 13 (8.2%) of those who got Naltrel® discontinued treatment. Naltrel® was superior to placebo at increasing the mean number of cumulative abstinent days (52.8 days, 95% CI 48.5–57.2 days, vs. 45.6 days, 95% CI 41.1–50.0 days, respectively; $p = 0.018$) and having a longer median time to first drink (5 days, 95% CI 3–9 days, vs. 3 days, 95% CI 2–4 days, respectively; $p = 0.003$). The effects of gender on treatment outcome were not examined.

Somewhat in contrast, a single-site, 6-week trial of 16 alcohol-dependent individuals who received one intramuscular dose of Naltrel® (300 mg) [89] suggested low tolerability, with 198 adverse events being reported. Of these, 17 were considered to be severe and included fatigue, gastrointestinal pain, irritability, nausea, somnolence (two reports), headache (four reports from three subjects), injection site pain, injection site mass, lethargy, depression, increased level of gamma-glutamyl transferase (an index of heavy drinking [53]), back pain, and flatulence. No serious adverse events were reported. Drinking outcomes showed an improving trend over the duration of the trial.

Nevertheless, further studies on the safety and efficacy of the Naltrel® formulation are warranted. Additional data are needed to determine whether, as with Vivitrol®, there is a differential response on drinking outcomes between men and women who get Naltrel®.

Depotrex®

Rather little public information is available on the Depotrex® depot formulation. Like the other depot formulations, Depotrex® appears to provide steady increases in plasma naltrexone levels [165] and is an effective mu-opioid receptor antagonist [7, 113]. Pharmacokinetic data from 12 heroin-dependent individuals who received low and high doses of Depotrex®—192 mg and 384 mg, respectively—showed that both doses maintained plasma naltrexone levels above 1 ng/ml for up to 4 weeks [52]. Average peak levels for the low and high doses of Depotrex® were 3.8 ng/ml and 8.9 ng/ml, respectively. Plasma beta-naltrexol, the major metabolite of naltrexone, was greater proportionately but could not be detected 5 weeks following Depotrex® administration. Both doses of Depotrex® antagonized the positive subjective effects of heroin. Reported adverse events were minimal and included mild discomfort at the injection site, with no irritation or erythema. The promising earlier study by Kranzler et al. [165] of Depotrex® (206 mg) in the treatment of alcohol dependence needs to be followed up.

In sum, depot formulations of naltrexone may offer some advantages such as increased compliance over the oral formulations. This advantage has, however, been difficult to demonstrate in randomized controlled trials but might become more apparent when these depot formulations are used in generic practices. Depot formulations do not appear to be more efficacious than the oral formulations, and with one of these—Vivitrol®—no therapeutic effect in women has been demonstrated. The adverse events profiles of depot formulations of naltrexone that have been reported in randomized controlled trials appear similar in frequency and intensity to those observed for the oral formulation. The different depot formulations do appear to be similar in characteristics and profile, and more clinical information about which one to select to treat a particular alcohol-dependent individual, if all are approved by the Food and Drug Administration, shall be needed.

Glutamate

Metabotropic Glutamate Receptor-5 Modulator and N-*Methyl*-D-*Aspartate Antagonist—Acamprosate*

Acamprosate's principal neurochemical effects have been attributed to antagonism of *N*-methyl-*D*-aspartate glutamate receptors [63, 320], which restores the balance between excitatory and inhibitory neurotransmission that is dysregulated following chronic alcohol consumption [64]. Recently, however, it also has been proposed that acamprosate modulates glutamate neurotransmission at metabotropic-5 glutamate receptors [111]. Evidence that acamprosate modulates a novel site of action at metabotropic-5 glutamate receptors comes from the finding that it inhibits the binding and neurotoxic effects of ±-1-aminocyclopentane-*trans*-1,3-dicarboxylic acid [111]. Acamprosate has been shown to decrease: (a) ethanol consumption in rodents [27, 57, 178], but this effect may not be specific in food-deprived C57BL/6 J mice as both ethanol and water were reduced in a schedule-induced polydipsia task [75]; (b) dopamine hyperexcitability in the nucleus accumbens during alcohol withdrawal [59, 259]; (c) general neuronal hyperexcitability [96, 282]; (d) glutamatergic neurotransmission in alcohol-dependent rats [28, 59]; (e) voltage-gated calcium channel activity, and (f) the expression of brain *c-fos*, an immediate early gene associated with alcohol withdrawal [185, 247]. Nevertheless, it is acamprosate's ability to suppress alcohol-induced glutamate receptor sensitivity [171], as well as conditioned cue responses to ethanol in previously dependent animals even after prolonged abstinence [273, 280, 281, 311], that has been linked with its therapeutic effect in humans—dampening negative affect and craving post-abstinence [130, 279] (Fig. 2).

Interestingly, there has been a paucity of human laboratory studies that have examined the potential effects of acamprosate on alcohol-related behaviors associated with its

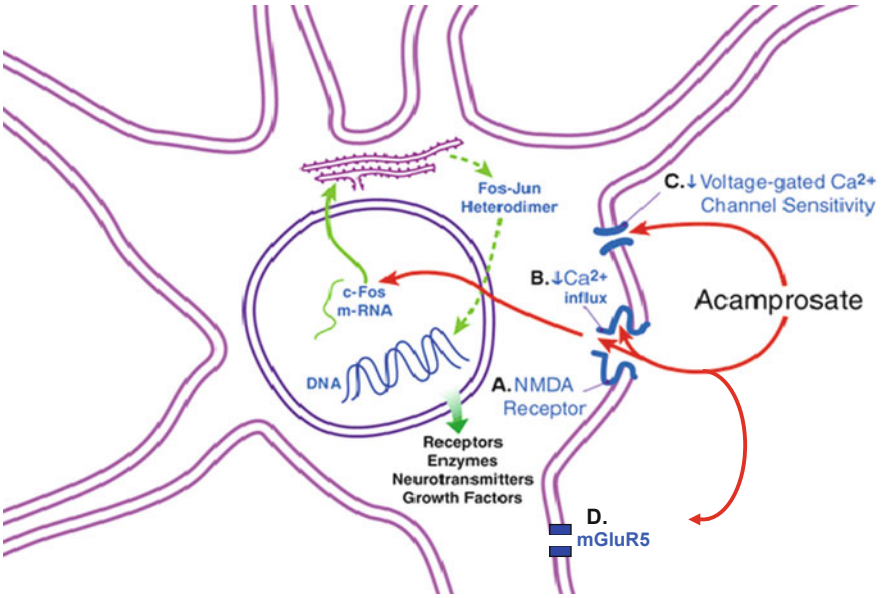

Fig. 2 Schematic representation of acamprosate's effects. Acamprosate has four principal effects: (**A**) reducing post-synaptic excitatory amino acid neurotransmission at *N*-methyl-*D*-aspartate (NMDA); (**B**) diminishing Ca^{2+} influx into the cell, which interferes with expression of the immediate early gene *c-fos*; (**C**) decreasing the sensitivity of voltage-gated calcium channels, and (**D**) modulating metabotropic-5 glutamate receptors (mGluR5). mGluR5 are post-synaptic and are coupled to their associated ion channels by a second messenger cascade system (not shown). Also shown in this representation is synthesis of *c-fos* and *c-jun* in the endoplasmic reticulum, which can bind with DNA to alter the transcription of late effector genes. Late effector genes regulate long-term changes in cellular activity such as the function of receptors, enzymes, growth factors, and the production of neurotransmitters. Embellished from Spanagel and Zieglgansberger [279]. Adapted from Johnson and Ait-Daoud [130], with kind permission from Springer Science+Business Media. Adapted version reprinted from Johnson [127], with permission from Elsevier

abuse liability. Evidence from a human magnetic resonance imaging study does, however, support acamprosate's ability to modulate glutamate neurotransmission as it decreases activity in brain regions rich in *N*-acetylaspartate and glutamate [28]. Human laboratory studies in both volunteers [199] and alcohol-dependent individuals [138] also have shown that acamprosate—i.e., calcium acetyl homotaurinate—is relatively safe, with the most important adverse events being diarrhea, nervousness, and fatigue, especially at a relatively high dose (3 g/day). Since acamprosate is excreted unchanged in the kidneys, there is no risk of hepatotoxicity, but it should be used with caution in those with renal impairment [138, 199]. Acamprosate has no significant clinical interaction with alcohol. Recently, it was shown that acamprosate can reduce heart rate response but not the increase in cortisol or subjective craving following the presentation of alcohol cues—a finding that suggests utility for acamprosate in managing autonomic dysregulation in abstinent alcoholics exposed to a high risk for relapse situations [237].

Most of the clinical evidence for the efficacy of acamprosate in the treatment of alcohol dependence comes from a series of European studies. In 2004, Mann et al. [194] wrote a meta-analysis of 17 published studies that included 4087 alcohol-dependent individuals. In that report, continuous abstinence rates at 6 months were greater than for those who got placebo (acamprosate, 36.1%; placebo, 23.4%; relative benefit, 1.47; 95% CI = 1.29–1.69; $p < 0.001$). The overall pooled difference in

success rates between acamprosate and placebo was 13.3% (95% CI = 7.8–18.7%), and the number needed to treat was 7.5. Similar results were obtained from another meta-analysis conducted at about the same time [30]. Generally, the effect size of acamprosate is small—0.14 for increasing the percentage of non-heavy drinking days [162] and 0.23 for reducing the relapse to heavy drinking [42]. Early studies also had some methodological problems, including non-standardization of diagnostic criteria and the psychosocial adjunct to the medication, which were resolved in later trials.

Despite approval by the Food and Drug Administration on July 29, 2004, for the use of acamprosate in the treatment of alcohol dependence, largely based on the data from European studies, the results of studies in the United States have been disappointing. In the United States multi-site trial by Lipha Pharmaceuticals, Inc., there was no overall clinical evidence that acamprosate was superior to placebo among a heterogeneous cohort of alcohol-dependent individuals; however, post-hoc analysis suggested that a subgroup of alcoholics with a treatment goal of abstinence might derive benefit [200]. Further, in 2006, the multi-site COMBINE study also failed to find any therapeutic benefit of acamprosate compared with placebo on any drinking outcome measures [10]. Obviously, the findings of these United States studies have reduced the enthusiasm for using it by addiction specialists in the United States. From a scientific perspective, these findings do beg the questions as to what type of alcohol-dependent individual benefits the most from acamprosate and why there is an important discrepancy between the results of United States and European studies.

From the European studies, acamprosate appears to benefit alcohol-dependent individuals with increased levels of anxiety, physiological dependence, negative family history, late age of onset, and female gender [297].

There are at least four possible explanations for the discrepancy between United States and European studies. First, the populations sampled differ, with European, compared with United States, studies having alcohol-dependent individuals with more prolonged drinking histories and alcohol-related neurological and psychosocial impairments. Thus, it is tempting to speculate that European studies might have included individuals with greater neuroplasticity and, therefore, higher response to the ameliorating effects of anti-glutamatergic agents such as acamprosate. Second, United States, compared with European, studies have tended to have higher levels of standardized psychosocial intervention as an adjunct to acamprosate, thereby masking the effect of the medication. Third, the therapeutic effect of acamprosate is small; hence, by chance, some trials can be expected to fail, especially those conducted in a multi-site rather than a single-site environment due to the greater heterogeneity and variability of the cohort and research settings. Fourth, it is possible that future research might uncover other important differences between United States and European cohorts to explain the discrepant findings such as potential differences in participants' subtype, stage of the alcoholism disease, or biomolecular constitution.

In sum, European studies have clearly demonstrated efficacy for acamprosate as a treatment for alcohol dependence. Acamprosate was Food and Drug Administration approved in the United States largely based on the results of the European studies. Acamprosate's therapeutic effect is small, but it is well tolerated, with the most prominent adverse events being diarrhea, nervousness, and fatigue, especially at a relatively high dose (3 g/day). In contrast, studies in the United States have, to date, been unable to find efficacy for acamprosate among a heterogeneous group of alcohol-dependent individuals. The reason for this discrepancy between the results of United States and European studies has not been established. Perhaps, however, this discrepant finding might be due to differences in participants' selection, subtype, stage of the alcoholism disease, or bio-molecular constitution that are yet to be determined. Intriguingly, preliminary results presented for the recently completed multi-site collaborative European Study—Project Predict—also did not

find an effect for acamprosate in the treatment of alcohol dependence [193]. Future studies are needed to delineate more clearly what type of alcohol-dependent individual can benefit from acamprosate treatment.

Other N-*Methyl*-D-*Aspartate Receptor Antagonists*

Other *N*-methyl-*D*-aspartate receptor antagonists such as memantine and neramexane are being studied for the treatment of alcohol dependence. Both compounds have been shown in animal models to suppress ethanol-induced *N*-methyl-*D*-aspartate receptor up-regulation, thereby reducing ethanol sensitization and the propensity for subsequent drug use (for a review, see Nagy [224] and Kotlinska et al. [160]). In a human laboratory study, memantine reduced alcohol craving prior to but not after the experimental administration of alcohol. This would suggest that memantine might have the effect of reducing post-cessation craving for alcohol [20]. This finding is supported by a later report that memantine might have comparable effects to diazepam at ameliorating alcohol withdrawal symptoms [170]. Nevertheless, despite the early preliminary findings, a recent pilot clinical trial comparing memantine with placebo for the treatment of alcohol dependence reported that the greater therapeutic effect at reducing the percentage of heavy drinking days and increasing the percentage of days abstinent [76] occurred among the placebo group. Although this pilot study did not provide support for memantine as an efficacious treatment for alcohol dependence, further studies are needed to make a final determination of memantine's therapeutic potential for this indication. Recently, it was reported that memantine was as effective as escitalopram (the S-enantiomer of citalopram, a selective serotonin reuptake inhibitor) for the treatment of alcohol dependence in individuals with comorbid major depressive disorder [217]. That study, however, lacked a placebo treatment arm; therefore, it has not been established that memantine is an efficacious treatment for alcohol dependence with comorbid major depression. No human study on the therapeutic effects of neramexane in treating alcohol dependence has been published.

Alpha-Amino-3-Hydroxy-5-Methylisoxazole-4-Propionic Acid and Kainate Glutamate Receptor Antagonist—Topiramate

Topiramate, a sulfamate-substituted fructopyranose derivative, has six important mechanisms of action. Additional to its ability to antagonize alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptors and kainate glutamate receptors [99, 106, 274], topiramate also facilitates inhibitory gamma-aminobutyric acid-A-mediated currents at non-benzodiazepine sites on the gamma-aminobutyric acid-A receptor [305, 306], inhibits L-type calcium channels and limits calcium-dependent second messenger systems [317], reduces activity-dependent depolarization and excitability of voltage-dependent sodium channels [290], activates potassium conductance [118], and is a weak inhibitor of carbonic anhydrase isoenzymes, CA-II and CA-IV [65], which are found in both neuronal and peripheral tissues. In renal tubules, carbonic anhydrase isoenzyme inhibition reduces hydrogen ion secretion and increases secretion of Na^+, K^+, HCO_3^-, and water, thereby enhancing the likelihood of acidosis and renal stone formation [65, 268].

Johnson [124, 125] has proposed a neuropharmacological model by which topiramate can decrease alcohol reinforcement and the propensity to drink (Fig. 3). Nevertheless, few studies on the effects of topiramate on ethanol consumption in animals have been published. An initial animal study had shown complex effects of topiramate on ethanol drinking in C57BL/6 mice. In that study, high-dose (50 mg/kg) but not low-dose (1, 5, and 10 mg/kg) topiramate suppressed ethanol intake 2 h after it was injected into

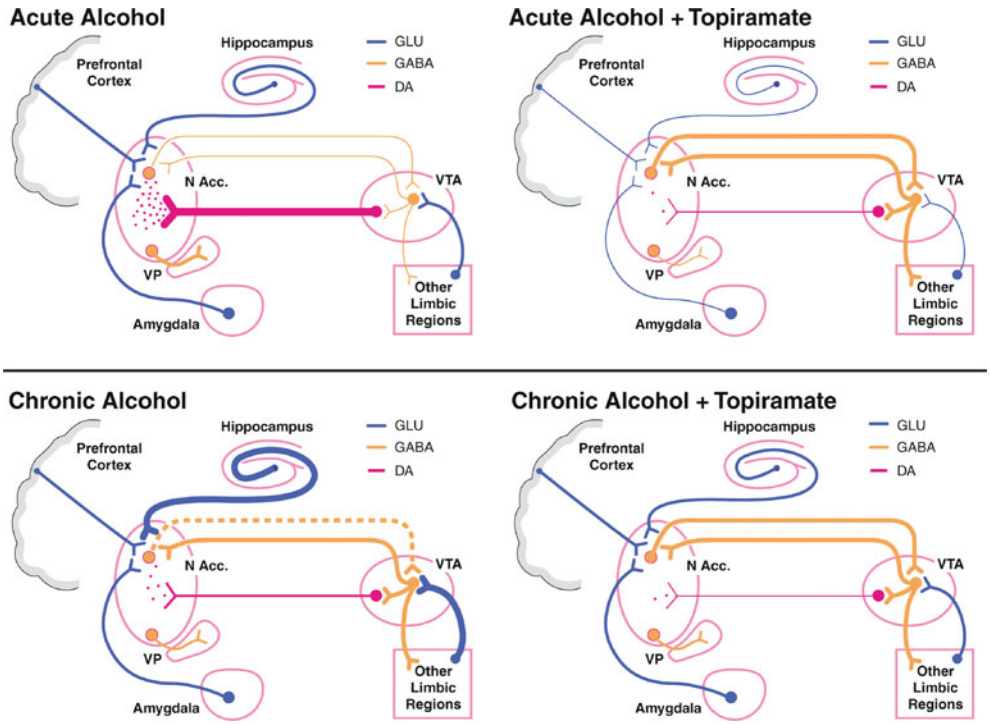

Fig. 3 Schematic illustration of the hypothesized effects of acute and chronic alcohol, both with and without topiramate, on the cortico-mesolimbic dopamine (DA) reward circuit [124]. (*Upper left*) Acute alcohol suppresses the firing rate of ventral tegmental area (VTA) gamma-aminobutyric acid (GABA) neurons, which leads to less suppression of VTA DA neuronal activity. This disinhibition leads to VTA DA neuronal firing and DA release in the nucleus accumbens (N Acc.) [124]. (*Lower left*) With chronic drinking, VTA GABA neurons are hyperexcitable, mainly because of increased glutamatergic input, less GABA tone from the N Acc., and rebound firing of GABA neurons because of their long-term suppression from repeated alcohol ingestion. This leads to VTA DA hypofunction and decreased release (compared with the acute condition) of DA in the N Acc. [124]. (*Upper right*) During acute drinking, the GABAergic influence of topiramate probably predominates, particularly in the N Acc. This leads to greater inhibition of N Acc. DA neurons, and greater GABA tone from the N Acc. to the VTA suppresses VTA DA cell firing. Topiramate concomitantly inhibits the excitatory effects of glutamatergic neurons on DA neurons in the VTA and N Acc. These combined actions of topiramate should lead to profound suppression of DA neuronal activity and DA release in the N Acc. Hence, topiramate reduces the DA-mediated reinforcing effects of acute alcohol [124]. (*Lower right*) During chronic drinking, the predominant neuronal activity resides with the hyperexcitable state of VTA GABA neurons. Because of GABA-mediated inhibition and glutamatergic blockade of these neurons, topiramate "normalizes" VTA GABA neuronal activity. Although this would, at first, suggest that DA release in the N Acc. would be enhanced, this does not occur, and DA release in the N Acc. is most likely reduced because these N Acc. terminals are contemporaneously inhibited by GABA inhibition and blockade of glutamate (GLU). In the chronic drinker, the anti-glutamatergic and L-type calcium channel effects of topiramate to block sensitization might predominate. Hence, topiramate would make it easier for a chronic alcoholic to withdraw from alcohol because rebound DA release would not occur (if drinking were ceased abruptly), and topiramate would aid in relapse prevention because alcohol's reinforcing effects would be decreased [124]. *Line weights* represent relative strengths of neuronal activity (heavy, medium, and light). The *broken line* represents decreased tone. VP, ventral pallidum. Reprinted from Johnson [124], courtesy of Blackwell Publishing, Inc.

the animal. Topiramate also decreased saccharin preference, but its ability to suppress ethanol preference was associated with some increase in water intake [88]. Notably, in an elegant, recent animal study, Nguyen et al. [232] demonstrated that topiramate can suppress ethanol drinking in C57BL/6 mice; additionally, in contrast with the effects of naltrexone and tiagabine in the

same animals, the mice treated with topiramate did not develop any tolerance to its anti-drinking effects. Furthermore, topiramate has been shown to suppress ethanol drinking persistently in alcohol-preferring (P) but not Wistar rats [35]. Additional to its ethanol-suppressing effects, there is evidence that topiramate can reduce alcohol withdrawal symptoms in a model of handling-induced convulsions [79]. Hence, the preponderance of the animal literature does support topiramate as a promising medication for the treatment of alcohol dependence. Nevertheless, the effect of topiramate on ethanol drinking in animals appears to be less striking than that on drinking outcomes in humans, which are presented below. This challenges the notion that animal models can predict directly treatment response in humans, especially when a variety of models have not been used or been available to characterize or "fingerprint" response [141]. The results of additional animal experiments examining topiramate's mechanistic effects on ethanol consumption or related behaviors in animals are, therefore, awaited eagerly.

Recently, Johnson et al. [137, 140] and Ma et al. [191] showed in a double-blind, randomized clinical trial that topiramate (up to 300 mg/day), compared with placebo, improved all drinking outcomes, decreased craving, and improved the quality of life of alcohol-dependent individuals who received 12 weeks of weekly brief behavioral compliance enhancement treatment [136]. The improvements in self-reported drinking outcomes were confirmed by plasma gamma-glutamyl transferase, an objective biochemical measure of alcohol consumption [53]. The therapeutic effect size for the primary efficacy variable—percentage of heavy drinking days—was 0.63.

In a 6-week experimental study of 76 heavy drinkers who were not seeking treatment, Miranda et al. [213] showed that low- and high-dose topiramate—200 mg/day and 300 mg/day, respectively—were significantly better than placebo at decreasing the percentage of heavy drinking days.

Further, in a subsequent 17-site ($N = 371$) United States trial, topiramate (up to 300 mg/day) was again superior to placebo at improving all self-reported drinking outcomes, gamma-glutamyl transferase level, and some measures of quality of life among alcohol-dependent individuals who received 14 weeks of weekly brief behavioral compliance enhancement treatment [144, 146]. Topiramate's therapeutic effect size for the reduction in percentage of heavy drinking days was 0.52, and the number needed to treat was 3.4 [143].

Taken together, these clinical studies provide strong evidence that topiramate is a promising medication for the treatment of alcohol dependence. Encouragingly, topiramate's therapeutic effect size is in the moderate range, and the clinical effects appear to increase with greater length of time on the medication.

Generally, topiramate has a favorable adverse event profile, with most reported symptoms being classified as mild to moderate [125]. The most common adverse events are paresthesia, anorexia, difficulty with memory or concentration, and taste perversion. Slow titration to the ceiling dose (up to 300 mg/day) for 8 weeks is critical to minimizing adverse events and improving tolerability (see Table 1); however, about 10% of individuals taking topiramate may experience some cognitive difficulty irrespective of the dose titration schedule [21]. Topiramate use has been linked with acute but rare visual adverse events. As of January 2005, there had been 371 spontaneous reports of myopia, angle-closure glaucoma, or increased intraocular pressure, for a rate of 12.7 reports per 100,000 patient-years exposure [127]. Usually, the syndrome of acute bilateral myopia associated with secondary angle-closure glaucoma presents as the acute onset of visual blurring, ocular pain, or both. Associated bilateral ophthalmologic findings can include myopia, shallowing of the anterior chamber, conjunctival hyperemia, and raised intraocular pressure. This syndrome resolves within a few days of discontinuing topiramate administration [125].

Table 1 Topiramate dose-escalation schedule

Week	AM dose	PM dose	Total daily dose (mg)
1	0 mg	1 25-mg tablet	25
2	0 mg	2 25-mg tablets	50
3	1 25-mg tablet	2 25-mg tablets	75
4	2 25-mg tablets	2 25-mg tablets	100
5	2 25-mg tablets	1 100-mg tablet	150
6	1 100-mg tablet	1 100-mg tablet	200
7	1 100-mg tablet	1 100-mg tablet and 2 25-mg tablets	250
8	1 100-mg tablet and 2 25-mg tablets	1 100-mg tablet and 2 25-mg tablets	300

Although topiramate has not shown efficacy in the treatment of bipolar disorder [296], there is an ongoing National Institutes of Health–funded study of its efficacy in the treatment of individuals with comorbid alcohol dependence and bipolar disorder. It is presumed that among individuals whose bipolar disorder is stabilized by concurrent medication prior to the trial, topiramate would have an added effect to improve drinking outcomes. Results of this study are awaited eagerly. Promisingly, another anticonvulsant, valproic acid, has been shown to decrease heavy drinking in alcohol-dependent individuals with bipolar disorder [261].

As a subgroup analysis of a 12-week double-blind, randomized, controlled trial, the effect of topiramate vs. placebo among alcohol-dependent smokers was evaluated [142]. Topiramate recipients were significantly more likely than placebo recipients to become abstinent from smoking (odds ratio = 4.46; 95% CI 1.08–18.39; $p = 0.04$). Using a serum cotinine level of $\leq$28 ng/ml to segregate non-smokers from smokers, the topiramate group had 4.97 times the odds of being non-smokers (95% CI 1.1–23.4; $p = 0.04$). The strength of these results showing topiramate's treatment efficacy is bolstered by the fact that smoking cessation was not a goal of the study, and no specific measures, advice or counseling, or therapeutic targets were provided to help the participants quit smoking; thus, the improvements in smoking rate represent a naturalistic change in behavior. Interestingly, cigarette consumption and serum cotinine levels lessened as individuals became more abstinent in the topiramate group. In contrast, increasing abstinence from alcohol was associated with greater consumption of cigarettes and higher serum cotinine levels for the placebo group. These findings provide initial support for the proposal that topiramate may be an efficacious medicine for the simultaneous treatment of alcohol dependence and smoking.

In sum, predicated upon a neuropharmacological conceptual model, there now is strong clinical support for topiramate as a promising medication for the treatment of alcohol dependence. Topiramate's therapeutic effects appear to be robust, with a medium effect size, thereby potentially ushering in a new era of a reliably efficacious medicine for the treatment of alcohol dependence with or without smoking. Intriguingly, although the animal data do provide support for topiramate's anti-drinking effects, more research is needed to characterize fully or "fingerprint" the pattern of response. Such preclinical studies should enable us to elucidate more clearly the basic mechanistic processes that underlie topiramate's efficacy as a treatment for alcohol dependence. Whilst it is not yet known whether topiramate will be useful in treating alcohol-dependent individuals with bipolar disorder, another anticonvulsant (i.e., valproic acid) has shown some promise.

Serotonin

For almost three decades, there has been intense interest in the effects of serotonergic agents in the treatment of alcohol dependence.

Encouraged by increased knowledge about the various serotonin receptor subtypes, researchers have examined the effects of various medications that bind to specific receptor sites. Here, we provide a synopsis of the preclinical and clinical studies that have been done on these serotonin function-altering medications in the treatment of alcohol dependence.

Serotonin Reuptake Inhibitors

For decades, it has been known that pharmacological manipulations that deplete the brain of serotonin decrease the preference for ethanol [221, 223]. Using preference paradigms, pharmacological agents that inhibit serotonin reuptake from the synapse reduce the voluntary consumption of ethanol solutions using the preference paradigm [60, 93, 101, 102, 206, 314]. Knockout mice at the serotonin transporter do, however, exhibit a general decrease in ethanol preference and consumption [31]. Thus, there is ample preclinical support for the notion that selective serotonin reuptake inhibitors suppress ethanol consumption in animals.

Although these preclinical studies have shown that selective serotonin reuptake inhibitors can reduce ethanol consumption, the selectivity of this effect on reinforcement as opposed to general consummatory behaviors has been questioned [25, 26, 204].

The inhibition of serotonin reuptake function has complicated the effects on food intake and fluid consumption [100]. Selective serotonin reuptake inhibitors do suppress food intake [104, 272] and fluid consumption [100] and decrease palatability [176]. Yet, motivational factors exert some control on the expression of these behaviors [285]. For instance, selective serotonin reuptake inhibitors enhance satiety [25] but selectively reduce preference for certain macronutrients (i.e., sweet items and carbohydrates) [180, 312, 313] cf. [114, 115] that increase the palatability and rewarding effects of food [78, 276, 310]. Hence, selective serotonin reuptake inhibitors might decrease ethanol consumption via the suppression of non-specific general consummatory behaviors and specific anti-reinforcing effects.

Studies conducted using operant techniques have also supported a role for selective serotonin reuptake inhibitors in the suppression of ethanol consumption. Haraguchi et al. [110] showed that same-day pretreatments with fluoxetine dose-dependently reduced ethanol responding. Nevertheless, whereas the chronic administration of selective serotonin reuptake inhibitors to C57BL/6 J male mice produced an initial suppression of lever pressing for ethanol, there was a later rebound to baseline levels of responding for ethanol and ethanol consumption [107]. These results are somewhat similar to those of Murphy et al. [218], who observed that fluoxetine administered to rats in a single daily infusion produced a significant reduction in ethanol-reinforced responding that started on the first day of treatment and increased on subsequent days of the 7-day treatment regimen. Responding for ethanol returned to pretreatment levels following cessation of fluoxetine treatment. Food intake, while somewhat suppressed initially, appeared to return to baseline levels on subsequent treatment days. Again, these results demonstrate that the suppression of ethanol intake by selective serotonin reuptake inhibitors follows a pattern of initial suppression of consummatory behavior followed by a reduction in reinforcement; thus, when the selective serotonin reuptake inhibitors are discontinued, there is an extinction-like pattern of a return to the baseline behavior.

Despite the promise of these preclinical results, there is, at present, little support for the proposal that selective serotonin reuptake inhibitors are an efficacious treatment for a heterogeneous group of alcohol-dependent individuals. Initial studies of small sample size reported that selective serotonin reuptake inhibitors can produce short-term (1–4 weeks) decreases in alcohol consumption among problem drinkers [225–229]. Nevertheless, these studies were limited by at least three factors. First, most of the studies were conducted in men, thereby limiting the generalizability of the results to the general population [225–227]. Second, the

adjunctive psychosocial treatment, which can decrease the apparent efficacy of the putative therapeutic medication because this too can have an important effect on drinking outcomes, was not standardized. Third, the treatment periods were short; thus, it was not possible to determine whether these initial effects, which could be due to non-specific factors, would be sustained. Indeed, the problem with studies of short duration that focus on a chronic relapsing disorder such as alcohol dependence was highlighted in a later study by Gorelick and Paredes [103], who found that there also was an effect for fluoxetine, compared with placebo, to decrease alcohol consumption by about 15% in the first 4 weeks of the trial but not over the entire length of the trial. Also, Naranjo et al. [231] did not demonstrate that citalopram (40 mg/day) was superior to placebo in a 12-week treatment trial. Further, neither Kabel and Petty [149] nor Kranzler et al. [163] in two separate 12-week studies found fluoxetine (60 mg/day) to be superior to placebo for the treatment of alcohol dependence.

There has been renewed understanding about how the administration of functionally different serotonergic agents can lead to different drinking outcomes among various subtypes of alcoholic (for a review, see Johnson [123]). Adapted from Cloninger's classification scheme [45], two methods for subtyping alcoholics have been used in these pharmacotherapy studies. Basically, a particular type of alcoholic (i.e., Type A-like or late onset) characterized by a later age of onset of problem drinking (typically over the age of 25 years), a preponderance of psychosocial morbidity, and low familial loading can experience improved drinking outcomes after selective serotonin reuptake inhibitor treatment.

Although early human laboratory studies showed that Type B-like or early-onset alcoholics, characterized by an early age of problem drinking onset (i.e., before the age of 25 years), high familial loading for alcohol dependence, and a range of impulsive or anti-social traits, might be centrally deficient in the major metabolite of serotonin, 5-hydroxyindoleacetic acid [38, 181, 182], the implications of this finding were, perhaps, oversimplified. At a cursory glance, it would appear that a selective serotonin reuptake inhibitor, by increasing serotonin turnover, would compensate for this dysfunction; thus, these Type B-like or early-onset alcoholics would then be expected to experience improved drinking outcomes following selective serotonin reuptake inhibitor treatment. Remarkably, the literature has demonstrated quite the opposite. For instance, Kranzler et al. [164] observed that fluoxetine treatment appeared to worsen the clinical benefit of the adjunctive cognitive behavioral treatment and there was no difference from placebo. Actually, Type A-like or late-onset alcoholics, with presumably more normative serotonin function, have been observed to experience improved drinking outcomes from sertraline both during active treatment [244] and at 6-month follow-up [70]. Also, Chick et al. [43] have shown that early-onset or Type B-like alcoholics were more likely to relapse than their late-onset or Type A-like counterparts following fluvoxamine treatment.

Obviously, the relationship between serotonergic dysfunction and Type B-like or early-onset alcoholism is not the simple result of a deficiency state. Indeed, Johnson [123] has hypothesized that an explanation for this effect might be allelic variation at the serotonin transporter, which leads to the differential expression of serotonin function. Of course, other bio-molecular explanations are possible, and further research is needed to elucidate this important area of research.

Fluoxetine has been reported to be beneficial for the treatment of alcohol-dependent individuals with suicidal tendencies and severe comorbid depression [54]. A recent study did not find that sertraline treatment was more beneficial than placebo in treating depressed men and women with alcohol dependence irrespective of the severity of the depression [168]. In another trial, sertraline was again found not to be beneficial in both men and women for the treatment of comorbid alcohol dependence and depression, although women did have a very slight but not clinically meaningful improvement in depressive symptoms [214]. Notably, it has not been shown that the reduction in dysphoria in depressed

alcoholics is associated with concomitant decreases in alcohol consumption [198, 208]. Hence, the only conclusion that can be drawn at present is that except for a subtype of depressed alcoholic with suicidal tendencies or, perhaps, in women, there is not much evidence to recommend selective serotonin reuptake inhibitors over placebo for the treatment of depressed alcoholics.

Sertraline might have some utility in the treatment of alcohol-dependent individuals whose comorbid post-traumatic stress disorder is associated with early trauma [34], thereby suggesting that different subtypes might vary in treatment response. Also, there is promise that paroxetine might prove useful in treating alcohol-dependent individuals with social phobia [249]. There is no specific treatment, apart from symptomatic management, for the treatment of alcohol-dependent individuals with comorbid generalized anxiety disorder [33].

In sum, despite strong animal data that would support the use of selective serotonin reuptake inhibitors as a promising treatment for alcohol dependence, there is no evidence that they are of therapeutic benefit to a heterogeneous group of alcohol-dependent individuals. Notably, however, there is growing confirmation that selective serotonin reuptake inhibitors can improve the drinking outcomes of Type A-like or late-onset alcoholics. Rather than being a cause for discouragement, this finding might (a) open up the possibility of identifying important bio-genetic or pharmacological mechanisms that underlie the alcoholism disease and (b) improve understanding about which type of alcohol-dependent individual can benefit the most from specific serotonergic treatment. Further, there is no current evidence that providing a selective serotonin reuptake inhibitor to a depressed alcoholic without severe depressive symptoms and suicidal tendencies is of therapeutic benefit. Hence, what is clear is that clinicians should be cautious in prescribing selective serotonin reuptake inhibitors to alcohol-dependent individuals for the treatment of minor depressive or affective symptoms. Not only is this strategy unlikely to be a therapeutic benefit over placebo, and perhaps appropriate psychosocial management, but drinking outcomes can actually be worsened, especially if the alcohol-dependent individual is Type A-like or of late onset. There is some evidence that selective serotonin reuptake inhibitors might be useful in treating a cohort of alcohol-dependent individuals whose post-traumatic stress disorder is associated with early trauma, and in treating alcoholics with social phobia.

Serotonin-1 Partial Receptor Agonist

Preclinical studies have suggested that the serotonin-1A partial agonist, buspirone, may be effective at reducing ethanol consumption. Buspirone decreased volitional alcohol consumption from 60 to 30% in macaque monkeys, but there was considerable inter-individual variation [47]. In Sprague-Dawley rats, buspirone significantly reduced ethanol intake in animals induced to drink by repeated brainstem injection of tetrahydropapaveroline. In a group of medium alcohol-preferring rats, buspirone (0.0025–0.63 mg/kg) reduced, while buspirone (>2.5 mg/kg) increased, alcohol consumption without affecting water consumption [211]. While buspirone is a partial serotonin-1A agonist, the net effect of its repeated administration is to enhance serotonin function via facilitation of the post-synaptic receptor, which is more sensitive than the autoreceptor, and down-regulation of autoreceptor function [22]. Nevertheless, this preclinical evidence would have been strengthened by operant studies examining the dose-response characteristics of buspirone as a function of ethanol concentration.

Buspirone has not been demonstrated to be an efficacious medication for the treatment of alcohol-dependent individuals without comorbidity. In a review of five published trials, buspirone was without a convincing effect in non-comorbid alcoholics; however, alcoholics with comorbid anxiety experienced some benefit [36, 192]. Hence, buspirone's anxiolytic effects

might translate to those who also are dependent on alcohol.

In sum, there is no current evidence that would suggest a role for buspirone in the treatment of alcohol dependence without comorbid anxiety disorder.

Serotonin-2 Receptor Antagonist

Preclinical studies have suggested that the serotonin-2 receptor antagonist, ritanserin, can reduce ethanol consumption in animals [212, 222] cf. [286]. Also, the serotonin-2 antagonists, amperozide [19, 219, 220, 241] and FG5974 [174, 253], significantly suppress ethanol intake without affecting water consumption. The exact mechanism by which serotonin-2 receptor antagonists might reduce ethanol consumption is unknown. It has, however, been suggested that they might exert their effects by acutely substituting for alcohol's pharmacobehavioral effects by facilitating burst firing in cortico-mesolimbic dopamine neurons [293], or by the suppression of dopamine neurotransmission following their chronic administration.

In the clinical setting, ritanserin is not an efficacious treatment for alcohol dependence. In a rigorously conducted, 12-week, multicenter clinical trial ($N = 423$) of ritanserin (2.5 or 5 mg/day) vs. placebo as an adjunct to weekly cognitive behavioral therapy, none of the ritanserin doses were superior to placebo [133]. In a later study using similar methodology, ritanserin (2.5, 5.0, or 10.0 mg/day) was not superior to placebo at improving drinking outcomes [307]. Although higher doses of ritanserin might be of therapeutic benefit, testing these doses is precluded by ritanserin's potential to cause dose-dependent prolongation of the QTc interval on the electrocardiogram, thereby increasing the potential for life-threatening cardiac arrhythmias.

In sum, there is no clinical evidence that would support the use of ritanserin as a treatment for alcohol dependence.

Serotonin-3 Receptor Antagonists

Preclinical studies provide strong support for the role of the serotonin-3 receptor in mediating alcohol's important neurochemical effects, and for serotonin-3 receptor antagonists to be promising treatment for alcohol dependence.

In neurophysiological experiments, ethanol potentiates serotonin-3 receptor-mediated ion currents in NCB-20 neuroblastoma cells [189, 319] and in human embryonic kidney 293 cells transfected with serotonin-3 receptor antagonist complementary DNA [190]. Serotonin-3 receptor antagonists block these effects [186]. Thus, the serotonin-3 receptor is a site of action for ethanol in the brain [187, 188].

Pharmacobehavioral studies show that many of alcohol's reinforcing effects are mediated by serotonin-3 and dopamine interactions in the cortico-mesolimbic system [12, 117, 131, 158, 309].

Serotonin-3 receptor antagonists have three principal effects that demonstrate their ability to modulate ethanol consumption and related behaviors. First, serotonin-3 receptor antagonists suppress hyperlocomotion in the rat induced by dopamine or ethanol injection into the nucleus accumbens [32]. Second, serotonin-3 receptor antagonists inhibit DiMe-C7 (a neurokinin)-induced hyperlocomotion, which also is reduced by the dopamine antagonist, fluphenazine [73, 109]. Third, serotonin-3 receptor antagonists reduce ethanol consumption in several animal models and across different species [12, 55, 71, 77, 121, 132, 205, 211, 256, 265, 291] cf. [15].

Human laboratory studies have generally supported a role for the serotonin-3 antagonist ondansetron in reducing preference and craving for alcohol. In two distinct experiments, Johnson and Cowen [131] and Johnson et al. [132] showed that ondansetron pretreatment attenuated low-dose alcohol-induced positive subjective effects (including the desire to drink). Swift et al. [289], using much higher alcohol and ondansetron doses, also discovered that ondansetron compared with placebo pretreatment reduced alcohol preference; however, a

mixture of both stimulant and sedative interactions between ondansetron and alcohol also was observed. Whereas Doty et al. [68] did not find an effect of ondansetron on alcohol-induced mood, their experimental model of using a group rather than individual experimental setting could have decreased the sensitivity of their assessments.

Three clinical studies have provided evidence that ondansetron is a promising treatment for alcohol-dependent individuals, particularly those with an early-onset or Type B-like subtype.

First, in a 6-week, double-blind, placebo-controlled study of 71 non-severely alcohol-dependent males, Sellers et al. [266] observed that the 0.5-mg dose but not the 4-mg dose of ondansetron was associated with a non-significant trend ($p = 0.06$) toward a reduction in alcohol consumption. Post-hoc analysis that eliminated 11 subjects who consumed less than 10 drinks/drinking day rendered the difference in drinking outcomes between the ondansetron 0.5 mg and placebo groups to be significant statistically ($p = 0.001$). Despite the limitations of this initial trial, which included a relatively short treatment period, the inclusion of just males, and the small number of subjects, the results of this study provided general support for ondansetron's promise in treating alcohol dependence. Also, these results showed that ondansetron may exhibit a non-linear dose-response effect in the treatment of alcohol dependence.

Second, in a large-scale ($N = 321$), 12-week, randomized, double-blind clinical trial in which alcohol-dependent individuals received weekly cognitive behavioral therapy, Johnson et al. [134] showed that ondansetron (1, 4, and 16 μg/kg b.i.d.) was superior to placebo at improving drinking outcomes of those of the early onset or Type B-like subtype but not the late onset or Type A-like subtype. The self-reported decreases in alcohol consumption were corroborated by the concomitant reduction in carbohydrate-deficient transferrin level—a biomarker of transient alcohol consumption.

Third, Kranzler et al. [166] provided replication of the results by Johnson et al. [134] by showing that early-onset (Type B-like) alcoholics had a significantly greater improvement in drinking outcomes compared with their late-onset (Type A-like) counterparts following 8 weeks of ondansetron (4 μg/kg b.i.d.) treatment.

Intriguingly, these results demonstrate a differential effect of ondansetron treatment by subtype of alcohol-dependent individual. Indeed, the contrast is striking when compared with the effects of selective serotonin reuptake inhibitors on different subtypes of alcohol-dependent individuals as described above. Basically, early-onset or Type B-like alcoholics with apparent serotonergic deficiency respond best to a medication that blocks the serotonin-3 receptor, whereas late-onset or Type A-like alcoholics with apparently normal serotonergic function derive the most benefit from a medication that can increase serotonin turnover and function. One potential disadvantage of subtyping by psychosocial variables is that they might not be stable across all populations (i.e., differences by ethnicity and regions could occur due to different exposure levels to alcohol), and the more complex algorithms for subtyping (e.g., into Type A or B) cannot be carried out prospectively or applied directly to a single individual. Arguably, more stable and generalizable dichotomization of different populations of alcoholics responsive to ondansetron might be achievable using pertinent and specific bio-molecular variables.

As mentioned earlier, Johnson [123] has proposed a bio-molecular explanation for these effects; however, other plausible possibilities might exist. A detailed elaboration of this concept is beyond the scope of this review. Nevertheless, the key feature is that polymorphic variation(s) at the serotonin transporter gene might result in a relative intrasynaptic hyposerotonergic state with consequent up-regulation of post-synaptic serotonin receptors. Alcohol-dependent individuals with these polymorphic types may be prone to a heavier and more chronic pattern of drinking [145, 267], perhaps through a counter-regulatory mechanism to increase serotonin turnover. Because this attempted counter-regulation through increased alcohol consumption can only be partially effective, as further drinking reduces the expression of the serotonin transporter gene further [145], a vicious cycle is set up. Johnson [128]

has proposed that ondansetron treatment may ameliorate heavy or severe drinking in such alcohol-dependent individuals, presumably by blockade of up-regulated post-synaptic serotonin receptors. Indeed, preliminary statistical analysis of a recent clinical trial does suggest that ondansetron may have an effect to decrease severe drinking among individuals with specific polymorphisms of the serotonin transporter gene. Publication of the details of these findings is expected soon. Obviously, a molecular genetic explanation for this effect, if proven, may enable a pharmacogenetic approach to treatment whereby the appropriate medication can be provided to the particular subtype of alcohol-dependent individual who would benefit the most from such treatment.

Intriguingly, ondansetron has shown efficacy in treating alcohol-dependent individuals with social phobia, presumably because of its anxiolytic effects [275]. The results of this study do, however, need to be validated by a larger clinical trial.

In sum, preclinical data support an important role for serotonin-3 receptors in mediating alcohol's important reinforcing effects associated with its abuse liability. Ondansetron is a promising medication for the treatment of early-onset or Type B-like alcohol dependence. Studies to determine whether alcohol-dependent individuals with allelic differences at the serotonin transporter gene respond differently to ondansetron shall be published soon. Ondansetron's potential to treat alcohol-dependent individuals with comorbid social phobia will need validation in larger clinical trials.

Acetylcholine: Cholinergic Receptor Antagonist—Varenicline

Varenicline is an agent that binds with high affinity to alpha-4/beta-2 nicotinic acetylcholine receptors to release dopamine in the cortico-mesolimbic dopamine system [46]. Hence, it might mimic the effect of alcohol to excite central nicotinic acetylcholine receptors and cause cortico-mesolimbic dopamine activation [23, 24, 74, 277]. Hence, varenicline might "substitute" for the stimulating effects of alcohol.

The Food and Drug Administration has approved varenicline as an aid to smoking cessation [126]. Interestingly, it was reported recently in a human laboratory study that varenicline attenuated alcohol-induced craving and positive subjective mood and decreased alcohol self-administration [209]. A randomized controlled clinical trial is needed to test varenicline's efficacy as a treatment for alcohol dependence in comorbid smokers.

Dopamine

Dopamine Receptor Antagonists

Cortico-mesolimbic dopamine neurons have been implicated as the principal pathway by which alcohol and most other abused drugs express their reinforcing effects associated with abuse liability [117, 158, 309]. Yet it has been difficult to show evidence that direct dopamine receptor antagonists have a role in the treatment of alcohol dependence. Presumably, direct opposition of dopamine pathways is associated with neuroadaptive changes that tend to reverse the initial effects of the blockade [125]. No traditional dopamine receptor blocker has been demonstrated to be an efficacious treatment for alcohol dependence. With the advent of atypical neuroleptics, there has been renewed interest in testing these medications as potential treatment for alcohol dependence. Indeed, medications such as aripiprazole and quetiapine are currently in clinical testing, and the results are awaited eagerly. Other medications that are selective for dopamine-3 receptor antagonism also are under development.

Dopamine Receptor Agonists

At low doses, dopamine-2/dopamine-3 agonists such as bromocriptine and 7-OH-DPAT can

reduce ethanol consumption in animals [201, 260, 304]. Although this might appear paradoxical to the dopamine theory of reinforcement for most abused drugs, it is possible that low-dose dopamine agonists preferentially augment autoreceptor function, thereby decreasing dopamine turnover.

Although an earlier report proposed that bromocriptine can decrease alcohol craving, subsequent studies have found no effect on alcohol drinking or related behaviors [66, 230, 246]. Nevertheless, perhaps due to the high addictive potential of dopamine agonists, this research approach has largely been abandoned in the clinical setting. Currently, dopamine receptor agonists do not hold promise as a treatment for alcohol dependence.

Gamma-Aminobutyric Acid-B Receptor Agonist—Baclofen

Animal studies have demonstrated that the gamma-aminobutyric acid-B receptor agonist, baclofen [beta-(4-chlorophenyl)-gamma-aminobutyric acid], causes decreases in voluntary ethanol intake [48], the ethanol-deprivation effect [49, 248], and morphine-induced stimulation of ethanol consumption [50].

Clinical trials have bolstered the findings of animal studies that suggest a role for baclofen in treating alcohol dependence. In an open-label, 4-week study, 9 alcohol-dependent men were given baclofen (up to 30 mg/day). Seven of the 9 subjects achieved abstinence, while the other 2 participants improved their self-reported drinking outcomes during the study period, according to self-reports corroborated by family members. Several objective biological markers of alcohol intake also showed significant reductions between the beginning and end of the study. Furthermore, craving, as measured by median Alcohol Craving Scale scores, decreased in the first study week and remained stable thereafter [1].

In a 4-week, randomized, placebo-controlled, double-blind clinical trial with 39 alcohol-dependent individuals, 14 of 20 (70%) participants treated with baclofen (up to 30 mg/day) achieved abstinence, compared with 4 of 19 (21.1%) in the placebo group ($p < 0.005$). Baclofen treatment improved significantly drinking outcomes, state anxiety scores, and craving measures. Baclofen generally was well tolerated and had no apparent abuse liability. Adverse events, none of which were serious, consisted of nausea, vertigo, transient sleepiness, and abdominal pain [2].

Recently, Addolorato and colleagues [3] reported in a randomized double-blind clinical trial that baclofen was more efficacious than placebo at promoting abstinence in alcohol-dependent individuals with liver cirrhosis. Because baclofen is primarily excreted unchanged in the urine and feces, it might be uniquely suitable for treating alcoholics with compromised hepatic function. Baclofen was well tolerated in this study, with few adverse events.

These findings indicate that baclofen is a promising medication for the treatment of alcohol dependence, particularly among those with compromised hepatic function. Additional studies of larger sample size and longer duration are awaited to establish the efficacy of baclofen for this indication.

Disulfiram

Disulfiram is a Food and Drug Administration–approved medication that has been used for treating alcoholism since the 1940s and is perhaps still the most widely used such medication in the United States today. Its principal mode of action is as an aversive agent. Disulfiram inhibits aldehyde dehydrogenase and prevents the metabolism of alcohol's primary metabolite, acetaldehyde. In turn, the accumulation of acetaldehyde in the blood causes unpleasant effects to occur if alcohol is ingested; these include sweating, headache, dyspnea, lowered

blood pressure, flushing, sympathetic overactivity, palpitations, nausea, and vomiting. The association of these symptoms with drinking discourages further consumption of alcohol [5]. Serious side effects also have been reported, including hepatitis, hepatotoxicity, depression, and psychotic reactions [238, 271]. Disulfiram also has been shown to reduce norepinephrine synthesis by inhibiting dopamine beta-hydroxylase [242], a mode of action that has been proposed to support early reports of its potential efficacy as a treatment for cocaine dependence. For further details on the pharmacological effects of disulfiram, see also Johnson [129]. While a review of disulfiram's potential effects on cocaine taking are outside the scope of this review, the reader is referred to recent studies by Petrakis et al. [242], Carroll et al. [41], and Baker et al. [11].

A 52-week, multi-site, randomized, controlled trial with 605 alcohol-dependent men found that disulfiram might help prevent relapse in compliant individuals yet be ineffective at promoting continuous abstinence or a delay in the resumption of drinking [87].

Disulfiram has no significant effect on craving for alcohol. Hence, individuals must be highly motivated to maintain disulfiram treatment, whereas those who wish to drink can simply stop taking the medication. The efficacy of disulfiram generally is limited to those who are highly compliant or who receive their medication under supervision—i.e., the type of alcohol-dependent individuals who might be likely to abstain on their own, without adjunctive pharmacotherapy. Including a supportive spouse or partner in a disulfiram treatment plan helps to improve outcome [5, 9].

Disulfiram has been combined with naltrexone as a potential treatment for alcohol dependence with comorbid depression [243]. Although the combination appeared to be well tolerated, there was no significant advantage of the combination over either of the medications alone or placebo. These results do not support the use of the combination of disulfiram and naltrexone as a treatment for comorbid alcohol dependence and depression.

Potential Treatments on the Horizon

Cannabinoid-1 Receptor Antagonists

Endocannabinoid receptors are found ubiquitously in the central nervous system, particularly in the cortex, hippocampus, basal ganglia, and cerebellum. Endogenous cannabinoids include anandamide and 2-arachidonylglycerol, which are metabolized by fatty acid amide hydrolase [112].

In C57BL/6 J mice, cannabinoid-1 receptor blockade reduced ethanol consumption to the amounts ingested by cannabinoid-1 receptor null mutant mice [303]. Endocannabinoids may be involved in the neurochemical expression of susceptibility to the effects of ethanol. For instance, ethanol exposure can increase levels of brain 2-arachidonylglycerol and anandamide and down-regulate cannabinoid-1 receptors [13, 39]. In pharmacobehavioral studies, cannabinoid-1 receptor antagonists suppress ethanol intake in rats with a chronic history of alcohol administration [173, 257], reduce ethanol drinking in alcohol-preferring sP rats [51, 95], and decrease operant responding and cue-induced reinstatement of ethanol consumption [44, 72]. It is plausible, however, that an important method by which cannabinoid-1 receptors influence ethanol taking is via their extensive connections to modulate other neuronal systems including monoamine pathways and their metabolism [216, 284, 292]. Figure 4 shows the interactions between cannabinoid-1 and other neuronal systems [126].

In Europe, initial human studies of the effects of cannabinoid receptor blockade on the drinking outcomes of alcohol-dependent individuals have been completed, and the results are awaited eagerly. Nevertheless, the recent finding that the cannabinoid-1 receptor antagonist (rimonabant) can increase mood disturbance and suicidality in smokers, which precluded the Food and Drug Administration from granting approval for that indication, might also impact the development of similar compounds for the treatment of alcohol dependence.

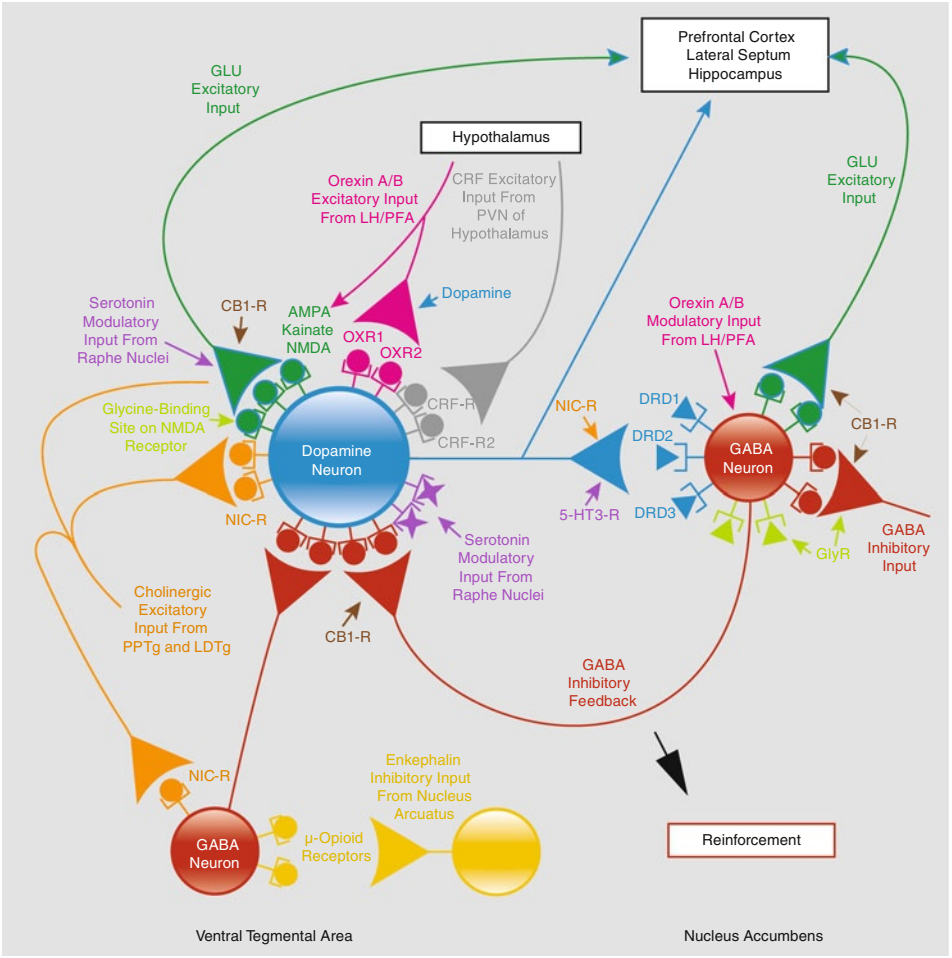

Fig. 4 Neuronal pathways involved with the reinforcing effects of alcohol, nicotine, and other abused drugs. Cholinergic inputs that arise from the caudal part of the pedunculopontine tegmental nucleus (PPTg) and laterodorsal tegmental nucleus (LDTg) can stimulate ventral tegmental area (VTA) dopamine (DA) neurons. The VTA DA neuron projection to the nucleus accumbens (nACC) and cortex, the critical substrate for the reinforcing effects of abused drugs (including alcohol), is modulated by a variety of inhibitory [gamma-aminobutyric acid (GABA) and opioid] and excitatory [nicotinic (NIC-R), glutamate (GLU), and cannabinoid-1 receptor (CB1-R)] inputs. The GLU pathways include those that express alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), kainate, and *N*-methyl-*D*-aspartate (NMDA) receptors. Serotonin-3 receptors (5-HT3-R) also modulate DA release in the nACC. The glycine system, orexins, and corticotrophin-releasing factor also are shown. LH/PFA: perifornical region of the lateral hypothalamus; PVN: paraventricular nucleus; GlyR: glycine receptor; CRF-R1 and CRF-R2: corticotrophin-releasing factor receptors 1 and 2, respectively; OXR1 and OXR2: orexin receptor types 1 and 2, respectively; DRD1, DRD2, and DRD3: DA receptors D1, D2, and D3, respectively. Other Neurochemicals and Small Molecules

Presently, there are a host of other neurochemicals with potential benefit in treating alcohol dependence. At this stage, testing remains within the animal literature and other preclinical models, and it would, therefore, be beyond the scope of this review to discuss them in detail. These compounds include antagonists at metabotropic-5 glutamate receptors, metabotropic-2/3

glutamate receptor agonists, stress-related neuropeptides such as corticotrophin-releasing factor antagonists and modulators of neuropeptide Y, and nociceptin (for a review, see Heilig and Egli [112]). Recently, data from a combination of preclinical and human laboratory experiments were unveiled, showing that the neurokinin-1 antagonist LY686017 might be a promising medication for the treatment of alcohol dependence [94]. These early results are being followed up by phase II clinical efficacy trials. Interestingly, there has been renewed interest in gamma-hydroxybutyrate as a treatment for alcohol dependence; however, its successful use would require the development of a formulation that has very low addictive potential. For recent reviews, see Caputo and colleagues [40] and Addolorato and co-workers [4].

Combination Treatments

Combination treatments offer the promise of augmenting the effects of single medications by engaging multiple neuronal networks associated with the expression of alcohol's reinforcing effects associated with its abuse liability. While this idea is alluring, medication combinations do create the potential for reduced compliance (due to the need to take additional tablets), heightened or new treatment emergent adverse events, or even inefficacy if the medications counteract one another.

Perhaps the best studied medication combination so far has been that of naltrexone and acamprosate. This combination has been proposed to be of potential added therapeutic benefit for three reasons. First, naltrexone, by its action on endogenous opioids, modulates cortico-mesolimbic dopamine activity, thereby reducing the reinforcing effects of alcohol [116, 158]. Acamprosate modulates alcohol withdrawal-induced increases in extracellular glutamate in the cortico-mesolimbic system [58, 59]. Thus, the combined effect of both naltrexone and acamprosate may be to modulate both the neurochemical effects responsible for triggering drinking and those associated with conditioned responses to drink even after a prolonged period of abstinence. Second, while naltrexone decreases positive craving for alcohol [300], acamprosate attenuates negative or conditioned craving post-drinking cessation [279]. It is, therefore, tempting to speculate that the combination of naltrexone and acamprosate would make it easier both to abstain and to prevent a "slip" from turning into a relapse. Third, acamprosate can increase blood levels of naltrexone, thereby augmenting its neurochemical effects [138, 199].

In a European study, Kiefer et al. [154] showed that the combination of naltrexone and acamprosate was clinically additive at improving the drinking outcomes of alcohol-dependent individuals, but only the effect of the combination vs. acamprosate achieved statistical significance. Nevertheless, the recently completed COMBINE study in the United States did not find any therapeutic advantage to combining the two medications [10]. Hence, at present, it is not possible to advise practitioners to combine naltrexone and acamprosate. Further research may, however, provide a definitive answer as to the utility of the combination.

Mechanistically, there are many other medication combinations that are possible, some of which are being pursued. For instance, the combination of naltrexone and sertraline was tested recently in a pharmacotherapy trial for the treatment of alcohol dependence. Unfortunately, there was no evidence that the combination was any better than naltrexone alone, and, therefore, it cannot be recommended as a treatment strategy [80]. Notably, however, preliminary clinical evidence suggests that the combination of ondansetron and naltrexone may result in added or synergistic therapeutic effects on alcohol drinking [6, 135]. The results of definitive confirmatory trials are awaited.

In sum, medication combinations may afford the opportunity to augment the treatment effects of single medications for the treatment of alcohol dependence. Such studies should, however, be conducted where there is a compelling pharmacological rationale for combining the medicines.

This is because there also is the potential for reduced compliance, heightened or new treatment emergent adverse events, and inefficacy. Further, there are important issues that must be determined for all medication combinations, such as optimal dosing, sequencing of the medications, duration of treatment, and the increased complexity of managing such protocols.

Conclusions

Recently, there has been renewed interest in developing efficacious medicines for the treatment of alcohol dependence. Naltrexone and its depot formulations have demonstrated utility, but their therapeutic effect size is small. Despite Food and Drug Administration approval of acamprosate based upon the positive results of European studies, there has, as yet, not been a clear demonstration of its efficacy in United States studies. Even in the European studies, the therapeutic effect size of acamprosate is small. These discrepant findings might be the result of different populations of alcohol-dependent individuals, selection criteria, chronicity of the alcoholism disease, bio-molecular differences, different methodologies between United States and European studies, or sampling error due to the small effect size. For both naltrexone and acamprosate, research is ongoing to determine what type of alcohol-dependent individual benefits from using either medication. There also is the possibility that a pharmacogenetic approach may make it possible to improve the therapeutic outcome for those who receive naltrexone. At present, the combination of naltrexone and acamprosate cannot be recommended to be of therapeutic benefit, but this conclusion might change with future research. Topiramate is a promising medication for the treatment of alcohol dependence with or without comorbid smoking. Based on two studies, its therapeutic effect size appears to be in the medium range. Future research is needed to extend these results to other subpopulations of alcohol-dependent individuals. Serotonergic medications need to be administered with care to ensure that they are provided to the subtype of alcohol-dependent individual who will benefit the most from such treatment. While selective serotonin reuptake inhibitors benefit late-onset or Type A-like alcohol-dependent individuals, the serotonin-3 receptor antagonist ondansetron has efficacy in treating early-onset or Type B-like alcohol-dependent individuals. Molecular genetic studies are ongoing to understand the underpinnings of this differential response among various subtypes of alcoholic to different serotonergic agents. Selective serotonin reuptake inhibitors might have utility in treating alcohol-dependent individuals with comorbid post-traumatic stress disorder associated with early trauma and, probably, alcohol-dependent individuals with major depression associated with suicidality. Both selective serotonin reuptake inhibitors and ondansetron appear effective in treating alcohol-dependent individuals with comorbid social phobia. Baclofen is a promising medication for the treatment of alcohol-dependent individuals with compromised hepatic function, but further studies are needed for this to be established. Although disulfiram is also Food and Drug Administration approved for the treatment of alcohol dependence, it is perhaps best utilized under supervised conditions. New medications in development for the treatment of alcohol dependence with or without comorbid psychiatric disorder or smoking include varenicline, cannabinoid-1 receptor antagonists, and the neurokinin-1 receptor antagonist LY686017. Neuroscientific effort to uncover medication combinations with additive or synergistic therapeutic effects is ongoing.

Alcohol Withdrawal: Treatment and Application

Nassima Ait-Daoud and Robert Malcolm

Contents

Introduction

Alcohol was used in Egypt since the time of the pharaohs, when wine played an important part in ceremonial life [11]. Egyptian texts over 8,000 years old made reference to alcohol abuse and its consequences. The ancient Greeks were also experienced with alcohol abuse and alcoholism. They first drank as part of a religious ritual to please their gods and forget their worries [21, 36] but soon realized that it caused seizures. Around 400 B.C., Hippocrates described seizures related to alcohol abuse and withdrawal, and the Romans used the term "morbius convivialis" to describe alcohol-related seizures [13]. European physicians in the late eighteenth and early nineteenth centuries gave detailed clinical descriptions of delirium tremens and noted a 50% mortality rate. Although delirium tremens was described as early as 1787, its relationship to acute alcohol withdrawal was not firmly established until the twenty first century [15, 37].

Victor and Adams [44] described a series of alcohol-dependent patients admitted to a specialist unit in the United States. They identified the now well-recognized spectrum of symptoms, including tremor, nausea, anxiety, tinnitus, muscle cramps, diaphoresis, seizures, hallucinations, and delirium tremens, that constitute the alcohol withdrawal syndrome. Severe alcohol withdrawal has a mortality rate of up to 35% if untreated; if treated early, death rates range from 5 to 15% [8].

Alcohol withdrawal is defined as a maladaptive behavioral change, with accompanying physiological and cognitive symptoms, that occurs in an individual whose blood- or tissue-alcohol concentrations decline following prolonged heavy use of alcohol [1]. Withdrawal symptoms can occur when an individual who has consumed excessive alcohol daily stops drinking suddenly or reduces the quantity of alcohol. The likelihood of withdrawal symptoms increases with both the chronicity and quantity of drinking, the number of previous withdrawals, and the presence of complicating comorbid conditions [3]. Symptoms associated with the withdrawal

syndrome include anxiety, psychomotor agitation, sweating, nausea, vomiting, insomnia, tremor, and rapid heart rate. In severe cases, delirium tremens, hallucinations, grand mal seizures, and disturbances in consciousness can occur [1].

The goals of treatment for alcohol withdrawal include treating the immediate symptoms, preventing complications, and initiating long-term preventative therapy. The current agents of choice for the treatment of mild-to-moderate alcohol withdrawal in the outpatient setting are benzodiazepines [29]. While the use of benzodiazepines is supported by an extensive literature, their use is limited by their potential for abuse, psychomotor sedation, cognitive impairment, and the possibility of a pharmacological interaction with alcohol. Additionally, benzodiazepines might increase the risk of relapse to abuse of other substances in individuals with genetic predisposition to alcoholism or comorbid anxiety or personality disorder [22, 26].

In light of the limitations associated with benzodiazepine use, there has been a growing interest in alternative treatment options for the alcohol withdrawal syndrome. A number of recent studies suggest that anticonvulsants might provide safe and effective alternatives to benzodiazepines, especially among those with moderate to severe alcohol withdrawal symptoms. These agents have demonstrated mood-stabilizing or anxiolytic effects, or both, in addition to their anticonvulsant activity, and are widely used in psychiatric practice.

Although their mechanism of action is not understood completely, the efficacy of anticonvulsants in the alcohol withdrawal syndrome is thought to be related to their ability to reduce "kindling" and facilitate gamma-aminobutyric acid inhibitory neurotransmission [22]. The kindling hypothesis proposes that long-term alcohol dependence combined with repeated withdrawal episodes induces long-lasting neuronal and neurochemical changes in the brain. As a result of these neurobiological changes, the individual's response to alcohol is affected, resulting in increasingly severe episodes of withdrawal. An agent that ameliorates the kindling response might, therefore, prevent the summative effects of repeated drinking and withdrawal [30].

Recently, Polycarpou et al. [34] published a *Cochrane Database* review of 48 studies with 3610 participants on the utility of anticonvulsants for treating alcohol withdrawal. Compared with placebo, there was a trend for anticonvulsants to improve the participants' global assessment of efficacy, and there was added protection against the development of seizures. Protection from seizures occurred whether anticonvulsants were given alone or in combination with other medications. Also, anticonvulsants appeared to be superior to non-anticonvulsants at reducing the frequency of hallucinations, sweating, gastrointestinal symptoms, and sleep disorders. Furthermore, data from a subset of 12 of these studies ($N = 960$) that used anticonvulsants as anti-withdrawal agents—and in which mortality was reported as an outcome—showed that no participants died. Individuals who received anticonvulsants during detoxification from alcoholism, compared with those who received either placebo or benzodiazepines, were less likely to discontinue treatment due to adverse effects. The data from which the researchers could draw any conclusions to compare the efficacy of various anticonvulsants, especially the newer agents, against one another were too limited. Nevertheless, the authors of the *Cochrane Database* review exercised caution with the interpretation of their results because most studies were of small sample size, outcome measures were generally heterogeneous (a recommendation was made for the revised Clinical Institute Withdrawal Assessment for Alcohol scale [43] to be used as the standard), and there was little consistency between studies on the methods and parameters for randomizing participants to treatment groups.

Anticonvulsants were found to be relatively safe and efficacious medications for treating alcohol withdrawal. Carbamazepine, the most studied medication compared with benzodiazepines, appears to confer added advantages such as fewer adverse events, no demonstrated abuse potential, and the lack of potentiation of

alcohol's psychomotor and cognitive effects. Other anticonvulsants appear to share these properties, as well as being useful for reducing the frequency of a range of other withdrawal symptoms including hallucinations, sweating, gastrointestinal disturbance, and sleep disorders. While the *Cochrane Database* review did not provide any specific recommendations based upon the statistical analysis, clinical experience suggests that anticonvulsants should be considered the medication of choice among those with the potential to experience moderate to severe alcohol withdrawal symptoms and who can tolerate an oral route of administration. Adding benzodiazepines to an anticonvulsant regimen might confer some benefit among those with delirium tremens or severe agitation.

Anticonvulsants in the Treatment of Alcohol Withdrawal

New insights into the pathophysiology of alcoholism have paved the way for studies of novel pharmacological tools for treating the behavioral, cognitive, and physiological symptoms associated with dependence. Among anticonvulsant agents evaluated for efficacy in alcohol dependence, some studies have found that carbamazepine treatment might reduce drinks per drinking day and time to first drink after withdrawal [26, 30]. Small studies of valproate in alcohol-dependent individuals suggest that it might reduce relapse to heavy drinking and promote abstinence [7, 22]. Interestingly, in a recent placebo-controlled trial among alcoholics with comorbid bipolar disorder, valproate treatment was associated with improved drinking outcomes [40].

Sodium Valproate

Sodium valproate is an antiepileptic compound with an unknown mechanism of action although it is suggested that its antiepileptic action may be attributed to increased gamma-aminobutyric acid levels in the brain.

Sodium valproate has been used for over 30 years for the treatment and prevention of alcohol withdrawal. A number of anecdotal and open-label studies indicate that the efficacy and safety of the anticonvulsant valproate (divalproex sodium) are similar to the effects of the anticonvulsant phenobarbital and the benzodiazepine lorazepam in reducing symptoms of alcohol withdrawal [24]. For example, Reoux et al. [35], in a study of individuals with moderate alcohol withdrawal characterized as a score of $\geq$10 on the revised Clinical Institute Withdrawal Assessment for Alcohol scale [43], showed that sodium valproate treatment was well tolerated, reduced the need for benzodiazepine treatment, and led to a decreased likelihood of progression in severity of withdrawal symptoms compared with placebo.

A recent unblinded pilot study by Longo et al. [22] used stringent inclusion and exclusion criteria to compare the safety and efficacy of valproate with those of standard benzodiazepines for detoxification in a small ($N = 16$) inpatient population of individuals with mildly to moderately severe alcohol dependence and moderate alcohol withdrawal. Subjects received standard benzodiazepine detoxification (with lorazepam or chlordiazepoxide), 5-day detoxification with valproate, or detoxification with valproate plus 6-week maintenance. Valproate was administered using a loading-dose strategy (20 mg/kg/day in two doses 6–8 h apart on day 1, then twice daily for 4 days or 6 weeks). Although the differences were not significant, perhaps due to small sample size, alcohol withdrawal symptom reduction tended to be more rapid in the valproate treatment group than in the benzodiazepine control group at 12- and 24-h intervals. Four out of five subjects (80%) in the valproate maintenance group were completely abstinent at the 6-week follow-up, compared with 5 out of 11 (45%) in the combined detoxification-only groups. Furthermore, the participants receiving valproate showed lower liver transaminase levels than at baseline and no other hematological

abnormalities at the 6-week follow-up [22]. This study demonstrated the importance of using a loading dose to achieve rapid therapeutic anticonvulsant blood levels. Despite the small sample size of this pilot study, the finding of higher abstinence rates at the 6-week follow-up in the valproate group supports further investigation of anticonvulsants as post-detoxification relapse prevention agents.

Notably, most trials have been open-label; seizure rates were reported by only a few authors, and standardized multidimensional alcohol rating scales were seldom included. A notable limitation to the use of valproate for the prevention and treatment of alcohol withdrawal symptoms was its disadvantageous adverse events profile. Fatalities due to hepatic failure, life-threatening pancreatitis, and thrombocytopenia have all been reported among individuals who had received valproic acid or its derivatives. Because non-specific gastrointestinal symptoms also have been reported following the ingestion of valproic acid, its clinical utility as an anti-withdrawal agent has been limited.

Carbamazepine

Recent studies support the use of the potent anticonvulsant, carbamazepine, as a pharmacological agent for the treatment of acute alcohol withdrawal. Several double-blind studies have demonstrated that carbamazepine has efficacy at reducing alcohol withdrawal symptoms equal or superior to that of lorazepam, oxazepam, clomethiazole, tiapride, and placebo [24, 26]. It also has been reported that carbamazepine can reduce effectively some measures of alcohol consumption (drinks per drinking day, number of heavy drinking days, and time to the first drinking day) during the post-withdrawal phase [26, 30].

Malcolm et al. [26] examined the efficacy of carbamazepine vs. lorazepam for the treatment of alcohol withdrawal symptoms as well as drinking behavior in the 7 days immediately following the treatment period. They hypothesized that while both carbamazepine and lorazepam would suppress alcohol withdrawal, carbamazepine would show the greater efficacy at ameliorating symptoms and reducing post-treatment drinking among those with a history of multiple episodes of previously treated alcohol withdrawal. In that double-blind trial ($N = 136$), carbamazepine 600–800 mg on day 1—tapered to 200 mg on day 5—was compared with lorazepam 6–8 mg on day 1—reduced to 2 mg on day 5—in a group of individuals experiencing moderate alcohol withdrawal. Participants were randomized to receive the carbamazepine or lorazepam fixed-dose taper across two levels of detoxification histories (0–1 or $\geq$2 prior medicated detoxifications). Also, participants were administered the 10-item revised Clinical Institute Withdrawal Assessment for Alcohol scale [43], an aggregate measure of the severity of alcohol withdrawal that assessed individual symptoms such as nausea, tremor, sweating, anxiety, and agitation [26], prior to medication treatment, daily for 5 days during the treatment phase, and on days 7 and 12 of the post-treatment period. The authors reported that carbamazepine and lorazepam were equally effective at decreasing the acute symptoms of alcohol withdrawal. There were no significant differences by treatment group in revised Clinical Institute Withdrawal Assessment for Alcohol scale scores when all 12 study days were considered. There was, however, a significant treatment-group effect on post-treatment drinking. Participants who had zero or one previous detoxification episode showed no differences in post-treatment drinks per day based on treatment group. Among participants with multiple detoxifications, those who received carbamazepine drank an average of <1 drink/day compared with about 5 drinks/day among the lorazepam group ($p = 0.004$). Furthermore, the relative risk of having a first drink during the post-treatment period was 3 times higher for the lorazepam-treated group than for the carbamazepine group [26]. Potential limitations of the study were the reliance on subjects' reports of previous medically treated withdrawal episodes, the fairly homogeneous demographic profile, and the low level of concomitant substance abuse

by the participants. Nonetheless, the results of the study showed that carbamazepine was as efficacious as lorazepam at treating acute alcohol withdrawal, and had greater efficacy than lorazepam in preventing post-treatment relapse to drinking.

Psychosocial domains such as anxiety, depression, sleep quality, and the ability to return to work might be equally important in mediating outcomes of outpatient treatment, but are often given only limited attention in the outpatient setting. Malcolm et al. [25], therefore, extended their findings by comparing the effects of previous withdrawal history and treatment with carbamazepine or lorazepam on psychosocial outcome measures. In that study, designed as a 2 × 2 factorial (carbamazepine vs. lorazepam, 0–1 vs. ≥2 prior detoxifications), subjects completed a variety of self-rated measures of psychosocial function during the study period. The authors reported a statistically significant effect for scores to be lower for carbamazepine compared with lorazepam on the Zung anxiety scale (34.8 vs. 38.9, respectively; $p = 0.01$) but to be higher on the visual analog scale of sleep quality (i.e., 62.1 vs. 51.2, respectively; $p = 0.02$). Neither the treatment group nor the number of previous withdrawals significantly affected the depression scores. Both the carbamazepine and lorazepam treatment groups did not produce a statistically significant effect on the ability to return to work [25].

The finding that carbamazepine was more efficacious than lorazepam at reducing anxiety and improving sleep is clinically important because the treatment of these psychiatric symptoms during acute detoxification could result in less distress and improved sleep during withdrawal—both of which could reduce the likelihood of relapse. Furthermore, these results have important implications for the subtle withdrawal symptoms, known as "protracted withdrawal syndrome", which can persist for weeks to months following the 5- to 7-day acute detoxification [25]. The symptoms that occur during the protracted withdrawal syndrome include anxiety, sleep disturbances, and mood instability. During the protracted withdrawal period, there is an increased risk of relapse to drinking. Thus, the effective treatment of the symptoms of protracted withdrawal with carbamazepine during the acute detoxification period might improve long-term drinking outcomes.

In sum, carbamazepine and valproate appear to be as effective as benzodiazepines in reducing the symptoms of mild-to-moderate alcohol withdrawal in relatively healthy individuals. The doses given in these studies were generally lower than those that are used when the goal is to achieve anticonvulsant effects. Also, carbamazepine appears to have efficacy that is superior or at least equal to that of other agents such as clomethiazole and tiapride in reducing withdrawal symptoms [24]. Despite the potential advantages of carbamazepine over benzodiazepines, its use can be associated with hepatotoxicity. Therefore, the use of carbamazepine is contraindicated for the treatment of alcohol withdrawal among those with clinically significant hepatic disease. Because carbamazepine can cause blood dyscrasias, it should not be prescribed to individuals with either a propensity toward or a pre-existing hematological disorder.

Gabapentin

Gabapentin has a structural relationship similar to gamma-aminobutyric acid [28], and its mechanisms of action, though understood imperfectly, include the blockade of L-type calcium channels as well as facilitation of gamma-aminobutyric acid synthesis [28, 33]. Preclinical studies show that gabapentin decreases ethanol withdrawal-induced hyperexcitability in isolated slices of hippocampus [2] as well as convulsions and anxiety in alcohol-withdrawn mice [46]. Additional to these pharmacological properties, gabapentin's suitability as a promising candidate medication for treating alcohol withdrawal symptoms is aided by the fact that it does not induce hepatic enzymes and it is excreted unmetabolized in the urine. Hence, gabapentin will not exacerbate alcohol's hepatotoxic effects.

Preliminary evidence supporting the potential of gabapentin to reduce alcohol withdrawal symptoms came from a case report [9] and a few case series that investigated the open-label use of the medication [4, 6, 18, 31, 45]. In a double-blind trial (N = 101), gabapentin was more efficacious than lorazepam at reducing insomnia during alcohol withdrawal [27]. Additionally, it has been proposed, from a case series, that gabapentin could be useful for a particular facet of a severe alcohol withdrawal syndrome—the reduction of tonic-clonic seizures [39].

Nevertheless, in a controlled study by Bonnet et al. [5] of gabapentin (400 mg four times daily) vs. placebo for treating alcohol withdrawal symptoms, there was no significant difference between the two groups in the frequency and severity of their withdrawal symptoms or in the frequency with which the "rescue medication", clomethiazole, was used in the first 24 h. Thus, despite earlier evidence for a potential role of gabapentin in treating the alcohol withdrawal syndrome, such an effect remains to be substantiated by controlled trials. Additionally, large-scale controlled studies are needed to determine whether gabapentin can be useful in treating tonic-clonic seizures that occur during severe alcohol withdrawal.

Although other modulators of gamma-aminobutyric acid function such as tiagabin and vigabatrin—anticonvulsants that inhibit gamma-aminobutyric acid transport and metabolism [41], respectively—have been proposed as potential treatment agents for alcohol withdrawal symptoms [23], there is at present no empirical support for their utility.

Topiramate

Topiramate, a sulfamate-substituted derivative of fructopyranose, was identified originally as a potential anti-diabetic agent [42]. Due to its structural similarity to known anticonvulsants, it was tested and found to have activity in several animal-seizure models. The compound was subsequently developed as an anticonvulsant based on its potency, duration of action, and neuroprotective effect [42]. The anticonvulsant effects of topiramate have been validated in the traditional rodent maximal-electroshock seizure test, as well as in several animal models of epilepsy. In the rat and mouse maximal-electroshock seizure test, topiramate showed potency similar to that of phenytoin and carbamazepine and greater than that of valproate [42].

Recent studies of topiramate suggest that its pharmacokinetic properties provide several advantages over other antiepileptic agents. These advantages include its rapid and complete absorption, minimal metabolism, and minimal interaction with other medications, such as oral contraceptives. Similar to most marketed anticonvulsant agents, topiramate exerts its anticonvulsant effects through blockade of voltage-dependent Na^+ and L-type high voltage-gated Ca^{++} channels and facilitation of gamma-aminobutyric acid-ergic neurotransmission via gamma-aminobutyric acid-A. Additionally, topiramate inhibits the activity of the alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid and kainate subtypes of glutamate receptors, rather than the more traditional action at the N-methyl-D-aspartate subtype, and selectively inhibits carbonic anhydrase-II and carbonic anhydrase-IV [42]. Topiramate also has been reported to activate potassium conductance due to its ability to inhibit carbonic anhydrase [14].

Titrating topiramate (over a range of 200–800 mg/day) produces a dose-proportional increase in its plasma concentration; both the maximal plasma concentration (C_{max}) and the area under the plasma concentration-time curve are linear and increase in proportion to the dose of topiramate at doses from 200 to 800 mg/day [12, 32]. Due to its low binding to plasma proteins (9–17%), topiramate is unlikely to be displaced by highly protein-bound medications, thus limiting the likelihood for its interaction with other agents [12]. Furthermore, because topiramate is eliminated predominantly in the urine, with an elimination half-life of approximately 21 h [12, 32, 42], and is not metabolized extensively in humans (~20%) [12], topiramate

will not exacerbate the hepatic-enzyme-inducing effects of alcohol.

The pharmacokinetic properties of topiramate might be altered in some special populations. While no specific age-related changes in topiramate clearance or elimination half-life have been reported, a decline in renal function might occur with normal aging. Thus, renal function should be evaluated in all elderly individuals receiving topiramate, since decreased renal function can alter the pharmacokinetics of medications eliminated by the kidneys, and adjustments of topiramate dose might be necessary in individuals with impaired renal function as well as in those undergoing hemodialysis [12, 32].

Topiramate's activity profile would appear to make it an ideal treatment for alcohol withdrawal. Topiramate might reduce the overactivity of the sympathetic nervous system and neuronal hyperexcitability commonly seen in the early phase of alcohol withdrawal, through suppression of glutaminergic input, facilitation of gamma-aminobutyric acid-A-mediated inhibitory impulse, blockade of sodium and calcium channels, and facilitation of potassium conductance.

Indeed, a recent inpatient study by Choi et al. [10] found that topiramate 50 mg/day ($N = 25$) was as efficacious as lorazepam up to 4 mg/day ($N = 27$) at treating alcohol withdrawal, while allowing the individual to transition into outpatient care on the same regimen without the potential for abuse or the increased risk of relapse commonly seen in alcoholics treated with benzodiazepines. Previously, Rustembegovic et al. [38], in a pilot open-label study ($N = 12$), found topiramate (50 mg twice daily) to be efficacious in the treatment of tonic-clonic seizures associated with alcohol withdrawal, with no side effects. Furthermore, Krupitsky and colleagues [20], in a placebo-controlled, randomized single-blind study comparing the safety and efficacy of three antiglutamatergic agents including topiramate (25 mg four times daily), memantine (10 mg thrice daily), and lamotrigine (25 mg four times daily) versus diazepam (10 mg thrice daily) for the treatment of alcohol withdrawal and detoxification in moderately severe alcoholic male patients ($N = 127$), found that all active medications significantly reduced observer-rated and self-rated withdrawal severity, dysphoric mood, and supplementary use of diazepam compared with placebo. All medications were well tolerated. This study also provided suggestive evidence of subtle advantages of lamotrigine over memantine and topiramate in reducing observer-rated (revised Clinical Institute Withdrawal Assessment for Alcohol scale [43]) and self-reported withdrawal severity. However, this study compared only single doses of each drug; the dose used for topiramate is not the one shown to be efficacious in outpatient trials, thereby rendering it difficult to extrapolate such conclusions from this study.

Because topiramate can be initiated while an alcohol-dependent individual is still drinking, and has been shown to improve drinking outcomes in such individuals [16, 17], it is reasonable to hypothesize that topiramate treatment might be a strategy that can be used to decrease alcohol withdrawal as well as initiate and maintain abstinence from alcohol. Individuals who receive topiramate treatment do, however, need to be monitored closely during dose escalation to avoid adverse events such as sedation, paresthesia, anorexia, and cognitive impairment, and at all times for the rarer adverse events of glaucoma, transient blindness, depression, and suicidal ideation.

Neurosteroids—Another Promising Non-Benzodiazepine Approach to Decreasing the Anxiety Response in Alcohol Withdrawal

Another approach has been to determine the potential utility of neurosteroids. Of these, one compound that appears to be promising is alphaxalone (5alpha-pregnan-3alpha-ol-11,20-dione). Alphaxalone might modulate the sympathetic and other neuronal systems by inhibiting nicotinic acetylcholine receptors, and has been used clinically as an anesthetic.

Alphaxalone has been shown to modulate ethanol-induced, withdrawal anxiety-like behavior in rats ($F = 10.58$; $p < 0.001$) without affecting locomotor activity [19]. While studies in other animal models, as well as future human studies, would be required to evaluate this compound further, this effort will be limited by the withdrawal of alphaxalone from the market by its manufacturer because of its ability to cause anaphylactic reactions.

Summary and Conclusions

The use of anticonvulsant medications in treating alcohol-dependent individuals proffers the novel approach of an anti-withdrawal agent, an anti-drinking medication, or both. Anticonvulsants appear to be more effective against a larger range of withdrawal symptoms than benzodiazepines, especially among alcohol-dependent individuals with moderate to severe withdrawal symptoms. Additionally, anticonvulsants such as sodium valproate and topiramate might have a further advantage to benzodiazepines in that they appear useful both for treating the acute withdrawal symptoms and, once abstinence has been achieved, for preventing relapse by modulating post-cessation craving and affective disturbance. Obviously, this is an attractive pharmacological prospect as the use of a single medication that is efficacious at the various stages of treatment reduces the need for polypharmacy, facilitates the buildup of dosing levels early in treatment, and minimizes the potential for unexpected adverse events and alcohol/medication interactions. Research specifically designed to determine the utility and feasibility of such an approach is needed.

Because of the potential utility of certain anticonvulsants (e.g., valproate) in treating other psychiatric disorders such as bipolar disorder, it is possible that their utility might also be extended to treating alcohol-use disorders with a comorbid psychiatric condition.

Notably, the adverse events profile of anticonvulsants has limited their use for treating the alcohol withdrawal syndrome. These limitations have highlighted the need for newer pharmacological agents that suppress withdrawal rapidly and have fewer adverse events, limited interaction with alcohol and other medications, and low potential for abuse. These agents should also be well tolerated in alcohol-dependent individuals with comorbid psychiatric conditions. With the ongoing explosion of neurobiological knowledge associated with the treatment of alcohol-related disorders, other classes of medications such as neurosteroids might find a therapeutic role.

Tobacco Use: A Global Health Epidemic

One in five Americans are current smokers [36]. Between 1997 and 2004, national prevalence rates of tobacco use showed a significant decline (24.7–20.9%); however, recent trends indicate that this decline has stalled [36]. Other developed regions in the world, such as countries of Western Europe (Great Britain, France), have also witnessed a plateauing of smoking prevalence rates [268]. Compounding these disappointing recent trends is the dramatic increase in tobacco use in low-income countries such as China and India [243]. Estimates from 2002 suggest that one-third of adults in China and India are current smokers [148], and, with intensive marketing strategies being employed by the tobacco companies in these regions, these rates are expected to increase.

Each year, cigarette smoking causes more than 400,000 premature deaths in the United States and 4.2 million premature deaths around the world from cancer, cardiovascular and respiratory diseases, and perinatal conditions [37]. Tobacco use accounts for at least 30% of all cancer deaths in the United States and smoking has been causally linked to lung, head and neck, esophageal, pancreatic, bladder, kidney, cervical, endometrial, and gastric cancer, and acute myeloid leukemia [255]. By the year 2030, more than 80% of world's deaths attributable to tobacco use are expected to be among smokers in developing countries [148, 243].

Given this global health epidemic, there is a need to gain a greater understanding of the determinants of tobacco use and dependence as well as effective treatment approaches. We begin this chapter with a brief overview of the neurobiology of nicotine's effects. Next, we summarize research on the environmental and genetic etiology of nicotine dependence, followed by a discussion of conditioned factors that contribute to smoking persistence, in parallel with nicotine's pharmacologic effects. This background information is followed by a brief review of methods for assessing nicotine dependence, available treatments for nicotine dependence and individual differences in treatment response, and the cost-effectiveness of these treatments in the context of public policy.

Neurobiology of Nicotine Dependence

Nicotine is the addictive component of tobacco that has been consistently shown to perpetuate cigarette smoking behavior, even if the user intends to quit [10, 206]. Inhaled nicotine is rapidly absorbed into the lungs and then passes to the brain within 10 S of absorption [12]. Once in the brain, nicotine binds to nicotinic acetylcholine receptors located on dopaminergic neurons in the ventral tegmental area, as well as other neuronal cell bodies [51, 158]. To date, at least 17 nicotinic acetylcholine receptor subunits have been identified (α1–α10, β1–β4, γ, δ, and ε) [159]. The α4β2 subunit-containing nicotinic acetylcholine receptors predominate in the ventral tegmental area and have higher affinity for nicotine, as compared with homomeric α7 nicotinic acetylcholine receptors that are less abundant in this region [40, 265].

A single cigarette provides sufficient nicotine to occupy approximately 90% of α4β2–containing nicotinic acetylcholine receptors for several hours [30]. Stimulation of these nicotinic acetylcholine receptors by nicotine increases burst firing of dopamine neurons, increasing dopamine levels in the nucleus accumbens and rewarding effects [200]. Over time, however, the proportion of unbound nicotinic acetylcholine receptors increases, producing a corresponding increase in smoking urges [235]. Further, during nicotine withdrawal, neurotransmitter release (including dopamine) is reduced and smokers report symptoms that include negative mood, fatigue, and mild cognitive deficits [139, 163]. This anhedonic state can be reversed by smoking a cigarette [2, 121].

Many additional neurotransmitters play a role in nicotine's effects, including norepinephrine, acetylcholine, glutamate, serotonin, beta-endorphin and γ-aminobutyric acid (GABA) [14]. α4β2 nicotinic acetylcholine receptors are also located on GABAergic interneurons, although these nicotinic acetylcholine receptors desensitize quickly, while α7 nicotinic acetylcholine receptors on glutamate neurons desensitize more slowly [53]. The endogenous opioid system also contributes to these influences, via release of beta-endorphin, which binds to mu-opioid receptors on GABAergic interneurons in the ventral tegmental area [141, 238].

Etiology of Nicotine Dependence

Abundant evidence from twin studies indicates that nicotine dependence arises from both genetic and environmental influence [141, 237]. Indeed, approximately 60–70% of the variability in nicotine dependence and smoking persistence is due to genetic factors [31, 115, 122, 141, 156]. Adoption studies, likewise, indicate that nicotine dependence has heritable components [179]. However, as a complex trait, nicotine dependence is most likely the result of genes, environment, and their interactions.

Smoking initiation is partly determined by peer influences, parental exposure, and tobacco advertising [56, 65, 253]. In fact, it is estimated that the odds of a teenager initiating a smoking habit are increased 1.5- to 2-fold if he or she has a parent or close childhood friends who smoke [29]. Experimentation with cigarettes

among adolescents is also strongly influenced by tobacco marketing [188, 189]. Another important environmental determinant in the process of initiation and development of a regular smoking habit is access to cigarettes. Data from the Youth Risk Behavior Surveillance System report that approximately one-quarter of teenagers buy their own cigarettes (23.5%) while 30% had someone else purchase them [109]. State-level tobacco control policies to limit teen access to cigarettes significantly deter smoking behavior among teens [120, 226].

Evidence from twin studies for genetic influences on smoking has prompted intense investigation of the role of specific genes and polymorphisms associated with nicotine dependence and related phenotypes. A likely candidate for association is the gene that codes for the enzyme CYP2A6, which metabolizes nicotine [149]. Associations of CYP2A6 have been replicated in independent studies [125, 150, 164]. Specifically, persons carrying low-activity alleles (slow metabolizers) smoke fewer cigarettes per day and report lower levels of nicotine dependence [125, 150].

Given the important role of neuronal nicotinic acetylcholine receptors in nicotine reinforcement [152, 187, 212] (see Fig. 4 in Chapter "Pharmacotherapy for Alcoholism and Some Related Psychiatric and Addictive Disorders: Scientific Basis and Clinical Findings"), genetic variation in these receptors has also been recently examined. Variants in the gene coding for the α4 nicotinic acetylcholine receptor subunit, *CHRNA4*, have been related to nicotine dependence [61, 102, 142], as have variants in *CHRNA3* and *CHRNA5* [15, 209, 244]. In contrast, associations of nicotine dependence with polymorphisms in *CHRNB2* have not been identified, but most studies did not have sufficient coverage of single nucleotide polymorphisms in this gene [146, 231]. A haplotype in *CHRNB1* has also been associated with nicotine dependence among African Americans and Caucasians [145].

Congruent with the central role of dopamine signaling in the rewarding effects of nicotine [83, 121, 173], genes in this pathway have been a particular research focus. Association studies have reported a higher prevalence of the Taq1A A1 allele in the ANKK1 gene (about 10 kb upstream of the *DRD2* gene) among smokers compared with nonsmokers [46, 234], while other findings have been negative [18]. A variable number tandem repeat polymorphism in the 3′ end of the dopamine transporter (*SLC6A3*) gene has also been associated with smoking behavior [130, 208]; however, this has not been replicated in other studies [259]. Finally, two independent studies have provided evidence for interacting effects of the *ANKK1* Taq1A and *SLC6A3* variants on the likelihood of cessation [132, 242]. A separate study found associations of *SLC6A3* genotypes with cessation following treatment with either nicotine replacement therapy or bupropion [178]. The high-activity (Val) allele of the $Val^{158}Met$ polymorphism in the catechol-*O*-methyltransferase gene has also been associated with nicotine dependence and relapse in smoking cessation treatment [17, 45, 108, 169, 245]. Lastly, the reduced activity 7-repeat allele of the *DRD4* gene variable number tandem repeat has been related to cue-elicited smoking behavior [101] and smoking persistence [221], and a synonymous single nucleotide polymorphism of unknown function in the dopamine beta-hydroxylase gene has been related to smoking behavior [107, 157].

Consistent with neurobiological evidence described above, the mu-opioid receptor (OPRM1) Asn40Asp functional variant (Asp40 allele) has been associated with smoking persistence [135], as well as reduced nicotine reward among women [198]. A recent study comparing smokers with high versus low levels of nicotine dependence did not find associations with this *OPRM1* variant; however, haplotype analysis suggests that other variants, which may be in linkage disequilibrium with the Asn40Asp polymorphism, are related to this smoking phenotype [270]. Finally, despite effects of nicotine on serotonin neurotransmission, there is no strong evidence linking smoking cessation with genes in the serotonin pathway [55, 129, 166] although associations with nicotine dependence have been reported [165].

In general, it has proven difficult to identify candidate genes with robust, replicable associations with nicotine dependence and smoking persistence. Consequently, the candidate gene approach is being supplemented by genome-wide association studies that have identified novel genes associated with smoking behaviors [19]. For example, a recent genome-wide association study of smoking cessation identified several novel genes involved in signaling as well as cell adhesion molecules [257].

Conditioned Rewarding Factors and Smoking Persistence

In addition to the highly addictive nature of nicotine, a growing body of literature has also documented how the sensory aspects of smoke inhalation become reinforcing through a behavioral conditioning process. Indeed, denicotinized cigarettes produce significant increases in levels of smoking satisfaction and reward and reductions in craving [205, 263]. Consistent with these data are results showing that when the sensory aspect of inhalation is blocked, smokers' subjective ratings of smoking a denicotinized cigarette are attenuated [204].

Environmental cues associated with nicotine delivery also can reinstate self-administration, supporting the extension of the conditioning process to learned environmental associations [143]. Human laboratory studies have shown that smoking cues, such as a lit cigarette and the smell of smoking a cigarette, reliably induce subjective and physiological responses in smokers [35, 57, 160]. This physiological reactivity is associated with a decreased likelihood of sustained abstinence among treatment-seeking smokers [174]. Overnight abstinent smokers "work" harder to earn cigarette puffs in a computer game of the reinforcing value of nicotine when exposed to cigarette cues than in the absence of such cues [183]. Neuroimaging studies also provide evidence for increased activation in the brain's visuospatial and reward pathway during passive viewing of smoking-related versus neutral cues [155, 233]. Moreover, this brain response is accentuated among smokers with higher levels of nicotine dependence [233]. Importantly, these effects may occur only when smokers have an expectation to smoke immediately after the scan [153].

The data described in this section suggest that smoking persistence is maintained, not only by pharmacologic factors, but also by conditioned rewarding factors, suggesting the importance of addressing both the biological and behavioral influences in smoking behavior within treatment programs. In the following sections, we turn to clinical issues in nicotine dependence, such as methods of assessment and treatment efficacy.

Assessment of Nicotine Dependence

Two formal diagnostic systems for nicotine dependence have been developed by the American Psychiatric Association and the World Health Organization. The American Psychiatric Association diagnostic system is the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition [5], and the World Health Organization system is the International Statistical Classification of Diseases and Related Health Problems, 10th Revision [267]. The latest *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, criteria require that a smoker meet at least 3 of the following criteria in the same 12-month period: (1) tolerance (i.e., a need for increased amounts of nicotine to achieve the desired effect or a decreased effect from using the same amount of nicotine); (2) withdrawal (see below); (3) nicotine is often taken in larger amounts or over a longer time period than was intended; (4) repeated unsuccessful attempts to quit smoking; (5) a great deal of time is spent in activities necessary to obtain or use the substance (i.e., chain smoking) or to recover from its effects; (6) giving up recreational or occupational activities for smoking, and (7) continued use despite health risks.

The International Statistical Classification of Diseases and Related Health Problems, 10th Revision system includes the criteria of tolerance, withdrawal, unsuccessful attempts to stop, use in larger or longer amounts and giving up activities to use as well as compulsion to use tobacco. Unlike the International Statistical Classification of Diseases and Related Health Problems, 10th Revision, the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition conceptualizes nicotine withdrawal as a separate disorder [7]. Occurring within 24 h of abstinence, nicotine withdrawal is present if four or more of the following criteria are experienced: (1) dysphoria or depressed mood; (2) insomnia; (3) irritability; (4) frustration or anger; (5) anxiety; (6) difficulty concentrating; (7) restlessness; (8) decreased heart rate; and (9) increased appetite. In addition to experiencing 4 or more of these criteria within 24 h of abstinence, the symptoms should also produce clinically significant levels of distress that interfere with the individual's capacity to function [8].

In the clinical research setting, assessment of nicotine dependence is more typically carried out using the Fagerstrom Test for Nicotine Dependence [60]. This 6-item self-report measure of nicotine dependence has received criticism for having low internal consistency (Cronbach's alpha=0.64) [194] and for defining nicotine dependence as a unidimensional, physiological construct [82], despite evidence to the contrary [28, 89, 192]. Further, data show poor concordance between the *Diagnostic and Statistical Manual of Mental Disorders*/International Statistical Classification of Diseases and Related Health Problems criteria with the Fagerstrom Test for Nicotine Dependence [94, 161]. In terms of criterion validity, some studies have shown that higher levels of dependence (as measured by the Fagerstrom Test for Nicotine Dependence and/or single Fagerstrom Test for Nicotine Dependence items) are inversely related to quitting success [26, 104, 171] whereas other studies have shown the Fagerstrom Test for Nicotine Dependence to have limited ability to reliably predict abstinence [20, 92, 116], especially for more dependent smokers [124]. Despite these concerns, the Fagerstrom Test for Nicotine Dependence remains a widely used and reported test of nicotine dependence [236].

Food and Drug Administration-Approved Treatments for Nicotine Dependence

Nicotine Replacement Therapies

Currently, five nicotine replacement therapies are approved by the United States Food and Drug Administration for the treatment of nicotine dependence: the gum, the transdermal patch, the nasal spray, the inhaler, and the lozenge (see Table 1). Nicotine replacement treats nicotine dependence by: (1) relieving withdrawal symptoms (e.g., irritability, restlessness, depressed mood, increased appetite) that characterize initial physical and psychological reactions to cessation; (2) reducing the experience of nicotine craving, and (3) providing a safer way to experience the neurobiological and psychophysiological effects of nicotine. Meta-analyses have demonstrated that nicotine replacement therapies double cessation rates, versus placebo (pooled odds ratio = 1.58, 95% CI: 1.50–1.66) [236]. Yet, only one-quarter to one-third of smokers who use nicotine replacement therapies to aid their smoking cessation attempt can expect to have quit by 6 months after treatment [201, 214, 215, 223, 248].

Nicotine Gum

In 1996, the nicotine gum became the first over-the-counter treatment for smoking cessation [203, 227]. Despite some adverse side-effects such as oral and gastric symptoms, jaw ache and under-dosing, nicotine gum has been found to produce significantly higher quit rates,

Table 1 Food and drug administration-approved medications for tobacco dependence

Medication	Recommended duration and dose[a]	Estimated quit rate[b] (95% CI) number of studies [reference]	Advantages	Disadvantages	Cost
Nicotine Gum	Up to 12 weeks; 2 mg (for those who smoke < 25 cigarettes/day); 4 mg (for those who smoke ≥ 25 cigarettes/day)	17.4% (17–18%) 52 Trials [230]	Treat oral behavioral ritual and cue-elicited craving; prevent weight gain	Adverse side effects and poor compliance	$4.00-$5.00/day
Nicotine Patch	Up to 10 weeks; Dose duration varies by cigarettes/day	13.7% (13–15%) 37 Trials [230]	Better compliance and nicotine replacement; few side effects	Does not treat cue-elicited craving	$2.50/day
Nicotine Spray	Up to 6 months; 8–40 sprays/day	24% (20–28%) 4 Trials [230]	Nicotine is rapidly absorbed; treat cue-elicited craving	Unpleasant side effects and poor compliance	$5.00-$15.00/day
Nicotine Inhaler	Up to 6 months; 6–16 cartridges/day	17% (14–21%) 4 Trials [230]	Treat oral behavioral ritual and cue-elicited craving	Unpleasant side effects and poor compliance	$7.00-$18.50/day
Nicotine Lozenge	Up to 12 weeks; 2 mg (for those who smoke their first cigarette more than 30 min after waking) and 4 mg (for those who smoke their first cigarette within 30 min of waking)	17% (15–20%) 4 Trials [230]	Good nicotine replacement; treats oral behavioral ritual and treats cue-elicited craving; few side effects	Compliance is unknown	$3.00-$4.00/day
Bupropion	Up to 12 weeks; 300 mg/day; 150 mg per day for 3 days then 300 mg/day from day 4 to end of treatment	30.5% (23–38%) 2 Trials [64] 31 Trials [95]	Good side effect profile; low abuse liability; prevent weight gain	Relatively more costly	$4.00-$5.00 (300 mg)
Varenicline	Up to 12 weeks; 2 mg/day; 0.5 mg for days 1–3, 0.5 mg twice daily for 4 days, and 1 mg twice daily from day 8 to end of treatment	35% (33.5–36.7%) 3 Trials [75, 112, 266]	Well-tolerated by the majority of users; reduces withdrawal and reinforcing effects of nicotine	A Food and Drug Administration warning regarding some side effects (depressive symptoms) may deter users	Unknown

[a]Recommendations are taken from the manufacturer of the agent and/or from Fiore [64]
[b]6-month or greater point-prevalence quit rates, biochemically verified

compared with placebo [39, 229]. In one of the first randomized, double-blind, controlled trials, participants who received nicotine gum (2 mg) were significantly more likely to be abstinent at the 1- and 6-month follow-up assessments than placebo controls [90]. In a review of 108 randomized clinical trials that incorporated at least a 6-month follow-up assessment, participants using the gum were over one-and-a-half times more likely (odds ratio=1.66) to remain abstinent at 1-year post-quit date, compared with placebo [229]. The 4-mg gum capsule produces higher quit rates than the 2-mg dose, particularly among highly-dependent smokers [68, 210, 246], while the addition of smoking cessation counseling bolsters the effectiveness of nicotine gum further [39].

A novel formulation of the standard nicotine gum in the form of a rapid release gum has recently become available. This may provide greater relief of craving compared with the standard nicotine gum. A study with 319 smokers exposed subjects to a smoking cue (i.e., lighting a cigarette, but not smoking it) and then randomly assigned them to standard or the rapid-release nicotine gum, and repeatedly assessed nicotine craving. Compared with standard nicotine gum, the rapid-release gum significantly reduced cravings [176]. The nicotine gum is easily available, has low abuse potential, and is effective for many smokers [224, 236].

Transdermal Nicotine Patch

The nicotine patch is one of the most widely used forms of nicotine replacement therapy, presumably because of the relatively few side effects and the ease with which it can be administered [62, 262]. In a meta-analysis of 17 studies and over 5,000 participants, quit rates among patch users were found to be more than double those for placebo at the end of treatment (27% vs. 13%, respectively) and at 6-month follow-up (22% vs. 9%) [62]. Other randomized controlled trials have yielded similar results (e.g., [52, 98, 140, 247]).

An important question is whether higher patch doses (e.g., 42 mg) or using the nicotine patch for a longer duration increases quit rates. Studies comparing the efficacy of a 42-mg patch with the standard 21-mg dose have had mixed results. One study found the 42-mg dose to produce non-significantly higher quit rates than the 21-mg dose at a 4-month follow-up (39% vs. 24%); another study reported that, while the two doses produced similar quit rates, the 42-mg dose significantly increased rates of side effects (nausea, vomiting, erythema) vs. the 21-mg dose [110]. In contrast, another study reported a significant effect of patch dosage on abstinence rates at 8 weeks post-quit date; however, at 1-year follow-up, differences in abstinence rates by patch dosage were no longer significant (67% vs. 35%) [50]. Thus, although the higher patch dose (i.e., 42 mg) may produce higher quit rates than the standard 21-mg dose, in the short term, evidence for enhanced efficacy in the long-term is lacking.

Currently, there are few data available to evaluate the efficacy of extended treatment with transdermal nicotine [62, 228]. A meta-analysis compared the odds ratios for transdermal nicotine trials with $\leq$8 weeks of treatment with the odds ratios from trials with >8 weeks of treatment found no effect for treatment duration [230]. In this comparison, only 3 trials were used to represent studies that provided >8 weeks of patch treatment. The review concluded that there was no difference in the odds ratios for cessation. However, this comparison included studies that varied in terms of sample size, treatment duration, patch dose, presence of adjunctive behavioral counseling, and outcome measures utilized. A close look at these studies underscores the lack of complete data to assess the relative benefits of maintenance therapy with transdermal nicotine. Two studies used fewer than 100 participants [22, 72], and the third study only assessed continuous abstinence, a far more conservative measure of cessation no longer recommended [249]. The recent Agency for Healthcare and Research Quality clinical guidelines state that extended treatment with nicotine patch or gum is an effective treatment strategy and

advocate extended treatment for nicotine dependence as being preferable to returning to smoking [258]. Thus, an important area of future research is the systematic evaluation of maintenance therapy with transdermal nicotine for nicotine dependence.

Nicotine Spray

Nicotine nasal spray more closely mimics the rate of nicotine delivery that is achieved by cigarettes [213]. While transdermal nicotine patch has been shown to reach a flat peak of plasma concentration within 5–10 h and the gum within 30 min, nicotine nasal spray reaches this peak within 10 min [85]. However, this more rapid nicotine delivery produces side effects such as burning sensation and watery eyes that have been reported to deter adherence, particularly in the first week of a quit attempt [97]. These effects typically dissipate after one week of treatment, as smokers develop tolerance to the spray's effects. Nevertheless, nicotine nasal spray has been reported in numerous randomized, controlled clinical trials to produce significantly higher abstinence rates than placebo spray [20, 86, 215, 240]. At 6- and 12-month follow-up, abstinence rates of 29–32% and 18–27% have been reported, while placebo quit rates at the same time points have ranged from 10–18% to 8–17% [20, 86, 215, 240].

Nicotine Inhaler

The nicotine inhaler is "puffed" by the user to obtain vaporized nicotine and, as such, is thought to mimic the behavior of smoking more closely than other forms of nicotine replacement therapy [93]. Three randomized clinical trials have shown the active inhaler to be more effective than placebo [87, 216, 248]. For example, 6-month quit rates of 17–35% vs. 8–9% have been reported for the inhaler versus placebo [87, 216, 248]. More recent studies comparing preference for different forms of nicotine replacement therapy and patterns of use have shown the nicotine inhaler (in addition to nasal spray) to be the preferred mode of nicotine replacement therapy among heavier smokers [262]. Additionally, highly dependent smokers using the nicotine inhaler were reported to have lower relapse rates than those using other nicotine replacement therapy products (e.g., patch, spray, gum). However, compliance rates for the nicotine inhaler may be lower than for other forms of nicotine replacement therapy [77].

Nicotine Lozenge

Fewer studies have evaluated the efficacy of the nicotine lozenge. The pharmacokinetic properties of the lozenge are comparable to those of nicotine gum, where the nicotine is rapidly absorbed via the buccal mucosa, providing a "peak" level of nicotine that declines with time [41]. Levels of nicotine absorption from the nicotine lozenge are reported to be 25–27% higher than nicotine gum at both the 2 and 4-mg doses [41]. This difference has been attributed to the fact that nicotine gum retains some nicotine in the gum base whereas the lozenge does not [41]. With regard to efficacy, both the 4-mg and 2-mg lozenges have been shown to produce significantly higher quit rates than placebo (e.g., 4 mg vs. placebo: 49% vs. 21%; 2 mg vs. placebo: 46% vs. 30% at 6 weeks follow-up) [223]. The lozenge may also reduce self-reported withdrawal symptoms such as anxiety, craving, difficulty concentrating, impatience, and restlessness [170]. Additionally, one study has shown the lozenge to be particularly effective for smokers who were unable to quit using other forms of pharmacotherapy [225]. Taken together, these studies suggest that the lozenge is a potentially effective form of treatment that warrants further study.

Comparing and Combining Nicotine Replacement Therapies

Studies that have compared the efficacy of the different forms of nicotine replacement both

directly [77, 134] and indirectly [230] suggest that no one form of nicotine replacement therapy outperforms the other. For example, in a randomized clinical trial that compared the short-term efficacy of nicotine gum vs. patch vs. nasal spray vs. inhaler, there were no significant differences in sustained abstinence rates at a 3-month follow-up (gum 19.7%; patch 21.0%; spray 23.8%; inhaler 24.4%) [77].

Meta-analytic assessments of combined nicotine replacement therapy vs. a single therapy indicate that combination therapy is more effective [63, 230]. Specific studies have shown that patch plus gum is more efficacious than gum alone [123, 196], while another study showed that patch plus spray outperformed patch alone [21]. In contrast, Tonnesen and Mikkelson [250] reported that quit rates were equivalent among smokers treated with patch plus inhaler versus either nicotine replacement therapy alone, and Croghan et al. [49] showed no differences in quit rates among smokers treated with the patch plus the nasal spray, compared with either nicotine replacement therapy alone. Despite the over-the-counter availability of some forms of nicotine replacement therapy (gum, patch, lozenge), less than one quarter of treatment-seeking smokers reported using over-the-counter nicotine replacement therapy in their most recent quit attempt [190]. Identification and implementation of efficacious strategies to improve the uptake of these pharmacotherapies is an important area of work that warrants greater attention.

Non-Nicotinic Treatments for Nicotine Dependence

Bupropion Sustained Release

Many studies have demonstrated the efficacy of sustained release bupropion as a treatment for tobacco addiction and relapse prevention [63, 154]. The 300-mg dose of bupropion outperformed placebo and transdermal nicotine patch both at end of treatment and at one-year follow-up [99, 111]. Specifically, one-year quit rates of 30% were achieved by bupropion recipients, compared with 16% of those who received patch and 16% for those who received placebo [111]. Bupropion has also demonstrated efficacy for African-American smokers, producing a quit rate of 36% at the end of treatment for participants taking bupropion compared with 19% for placebo [4]. Finally, bupropion has been shown to reduce relapse rate, especially among older smokers and those who gained little or no weight when quitting [100].

Bupropion's precise mode of action has yet to be determined, although evidence suggests that it inhibits post-synaptic uptake of dopamine and norepinephrine [9, 47, 211]. Consistent with this, bupropion reduces negative affective states associated with abstinence [219]. There is also evidence that bupropion is a nicotinic receptor antagonist, leading to the hypotheses that treatment may reduce the reinforcing effects of smoking [232]. This putative mechanism has received some support in a recent study that compared the effects of an acute dose of bupropion versus placebo in a sample of non-treatment-seeking smokers [48]. Smokers treated with a single dose of bupropion had significantly lower ratings of cigarette intensity than those treated with placebo, and there was a trend for a reduction in ratings of smoking satisfaction; however, they also smoked significantly more cigarettes during an ad-lib smoking phase, leading to speculation that they were compensating for reduced rewarding effects of nicotine [48]. While bupropion's mode of action remains to be identified, its role as an efficacious smoking cessation treatment has been well established.

Varenicline

In May 2006, varenicline was approval by the United States Food and Drug Administration as a treatment for nicotine dependence. Varenicline is a selective $\alpha 4\beta 2$ neuronal nicotinic acetylcholine receptor partial agonist (up to 60%)

[106]. By activating α4β2 nicotinic acetylcholine receptors, which are expressed widely on dopamine and γ-aminobutyric acid neurons in the ventral tegmental area, varenicline attenuates nicotine's effect on dopamine release, while maintaining dopaminergic tone [44, 106]. Varenicline's agonist function is thought to minimize craving and withdrawal, while its antagonist properties are expected to attenuate the reinforcing effects of nicotine, thereby reducing satisfaction from a "slip" cigarette and the likelihood of relapse [66].

Data from three large scale randomized clinical trials have demonstrated varenicline's efficacy as a treatment for nicotine dependence. The first two trials randomized 2,052 smokers to placebo, 300-mg bupropion, or 2-mg varenicline for 12 weeks and assessed quit rates up to 1 year following the start of treatment [75, 112]. Assessment of continuous quit rates for the last 4 weeks of treatment (weeks 9–12) across the two trials at the end of treatment showed an advantage for varenicline (44%), versus bupropion (30%) and placebo (18%). The continuous quit rate for varenicline at the 1-year follow-up diminished (22%), but it remained significantly better than for bupropion (16%) or placebo (10%). In a third study [251], smokers received open-label varenicline (1 mg twice daily) for 12 weeks; subjects who remained abstinent at the end of 12 weeks were randomized to 12 additional weeks of 1 mg twice daily of varenicline or placebo. Quit rates were assessed 28 weeks from the end of the second 12-week treatment phase. The quit rate at the end of the first 12-week treatment phase was 63%. The continuous abstinence rate at the end of the 28-week follow-up period was significantly greater for the varenicline-treated participants, versus placebo (71% vs. 50%). Across all three trials, adverse events and rates of discontinuation were similar across the placebo and varenicline arms, indicating that the agent was well tolerated as well as efficacious. Subsequent studies found varenicline to be significantly more effective than placebo among male Asian and Japanese smokers [172, 252]. Finally, one study that reported on the safety and efficacy of 52 weeks of varenicline versus placebo found that although adverse events were reported by 96% of the subjects receiving varenicline and 83% of those receiving placebo, at the end of treatment (52 weeks), varenicline produced significantly higher quit rates (37% vs. 8%) [266]. In 2008, the Food and Drug Administration issued a warning regarding side effects such as suicidal ideation and severe changes in mood and behavior that were noted by smokers taking varenicline [256]. To date, this "black box" warning remains in effect.

Other Potential Medications for Nicotine Dependence

Despite the availability of Food and Drug Administration-approved treatments for smoking cessation (nicotine replacement therapy, bupropion, and varenicline), only 1 in 4 smokers can expect to remain abstinent using these therapies [217]. The identification and testing of potential new medications for the treatment of nicotine dependence remain a research priority [138, 217]. To date, several early-stage trials (Phase II or III) have evaluated: monoamine oxidase inhibitors such as lazabemide, selegiline, and moclobemide; selective serotonin reuptake inhibitors such as paroxetine, fluoxetine, and sertraline; mu-opioid receptor antagonists such as naltrexone; GABAergic agents that include baclofen and gabapentin; nicotinic agents such as mecamylamine and the nicotine vaccine; and the cannabinoid receptor-1 antagonist, rimonabant. A comprehensive review of these potential treatments can be found in a review article by Schnoll and Lerman [217]. Additionally, the α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid and kainate glutamate receptor antagonist, topiramate, has shown potential as a safe and promising medication for the treatment of cigarette smoking in alcohol-dependent individuals [105] and as an aid to smoking cessation among men [6].

Individual Differences in Treatment Response

Investigation into individual differences in response to various treatments for nicotine dependence has been an extensive area of study. A primary goal of this line of work is to identify subgroups of smokers for whom different treatments might be more effective. In this way, specific criteria for prescribing treatments can be identified, and targeted treatments for smoking cessation can become more of a reality. Studies to date have evaluated individual differences in response to treatment based on gender, race, depression, and genetic variation.

Gender

Recent population data indicate that, although fewer women than men are current smokers (18% vs. 24%, respectively), the quit ratio (former smokers to current smokers) is lower for women than for men (42% vs. 48%, respectively) [36, 38]. Consistent with these data are results from clinical trials of nicotine replacement therapy (gum, transdermal nicotine) showing that women tend to respond less favorably than men [117, 264]. In contrast, data from two meta-analyses showed that nicotine replacement therapies have comparable efficacy for men and women [118, 163]. These meta-analyses included trials that provided only partial outcome data, omitted some relevant trials, and may have possessed limited statistical power to examine gender differences in light of low absolute abstinence rates [218].

Several hypotheses have emerged to account for the gender differential response to cessation treatments. These include: concern about post-cessation weight gain [184, 193], reduced response by women to physical smoking cues (i.e., onset of withdrawal, craving) compared with "behavioral" smoking cues (i.e., smell of tobacco, coffee, situational prompts) [182, 185]; reduced effect of nicotine replacement therapy treatments (i.e., patch, spray, gum, etc.) [184]; and elevated rates of depression (both clinical and sub-syndromal) [1, 23, 24, 71]. Menstruation has also been shown to influence quitting success. Preliminary data suggest that women whose quit dates occur in the follicular phase of their menstrual cycle as compared with their luteal phase had better treatment outcomes [67]. Lastly, women have significantly higher rates of nicotine metabolism than men, particularly when using oral contraceptives [96], indicating that women may require higher nicotine replacement therapy doses.

Gender differences in treatment response to non-nicotine based treatments such as bupropion and varenicline have been more equivocal. One the one hand, Killen et al. reported that women showed lower quit rates following bupropion compared with men [119]. On the other hand, another study that tested the efficacy of bupropion reported 52-week quit rates for men and women at 37.8% and 36.4%, respectively [74]. More recent studies that have examined gender differences in response to varenicline showed that biochemically confirmed continuous abstinence rates at weeks 9 through 12 were roughly equivalent for men and women (43% vs. 46%, respectively) [44]. Moreover, a pooled analysis of data from three trials showed no gender differences in 12-month quit rates in varenicline-treated participants [199]. Thus, bupropion may reduce the reported gender disparity in smoking cessation outcomes.

Race

Data suggest that there are important differences in smoking behavior across United States ethnic/racial groups. African Americans smoke approximately 35% fewer cigarettes than Caucasian smokers and tend to prefer mentholated, high-nicotine cigarettes [3, 43]. African-American smokers also tend to have slower nicotine metabolism [13, 34, 181, 261], and show a different smoking topography, compared with Caucasians [3, 13]. Despite smoking fewer

cigarettes, African Americans bear a disproportionately higher prevalence of the negative health-related illnesses associated with smoking as well as having higher rates of smoking-related morbidity and mortality compared with any other ethnic group [81].

Data suggest that African-American smokers are motivated to quit smoking and are more likely than Caucasians to have quit for at least one day in the last year; yet, African Americans are less likely to achieve sustained tobacco abstinence than their Caucasian counterparts [254]. Some suggest that this is attributable to African Americans' reduced utilization of available treatments for nicotine dependence [191]; these treatments may lack cultural relevance [207, 260]. However, a recent study showed that while smoking cessation materials that were targeted to African-American treatment seekers were used significantly more than the generic materials, there was no difference in 6-month smoking cessation rates (targeted materials: 18%; generic materials: 14.4%) [177].

Biological factors may contribute to differences in sustained abstinence rates in African-American compared with Caucasian smokers. For example, African Americans report higher levels of nicotine dependence, even when number of cigarettes smoked per day is controlled [181, 261]. African Americans are more likely to smoke higher nicotine/tar cigarettes, inhale more deeply, and puff more frequently [3, 13]. This more efficient smoking topography is believed to result in increased exposure to tobacco smoke toxins and greater susceptibility to disease and illness [13].

Racial differences in the genetic basis of nicotine dependence have also been reported. A recent study evaluated the role of the genes β-arrestin 1 and 2 (*ARRB1* and *ARRB2*) in nicotine dependence in a sample of African-American and European-American smokers [239]. Results from this study showed that the *ARRB1* and *ARRB2* variants contributed significantly to determining the time to first cigarette of the day among European-American but not African-American smokers. More recent data have shown racial differences in taste receptor genes (*TAS2Rs*) such that decreased oral sensitivity was positively associated with nicotine dependence among African-American but not European-American smokers [151].

Depression

Smokers are more likely to report a history of, or current, major depressive disorder or sub-syndromal forms of depression than non-smokers [27, 114]. The process of smoking initiation and progression to a regular habit typically occurs in adolescent and young adult populations. While tobacco use and depression commonly co-occur in these groups [197], the temporal relationship between these variables is less clear. Specifically, while there is evidence that adolescents with higher levels of depression symptoms are more likely to initiate smoking behavior than those who report lower levels of depression symptoms [58], still other studies have shown the opposite, namely that regular smoking behavior is a precursor to the development of depression symptoms [42, 76]. In a recent study that used data from the National Longitudinal Study of Adolescent Health to examine the relationship between smoking initiation, progression and depression symptoms, the authors reported that among adolescents who reported never smoking at the baseline assessment, level of depressed mood at baseline predicted smoking uptake, but not the progression of a regular smoking habit [168]. Further, among those adolescents who reported never smoking at the baseline assessment, starting to smoke was associated with higher levels of depression symptoms at the 1-year follow-up assessment, independent of the baseline depression symptoms, and this effect was even more pronounced for females [168]. Together, these data suggest that there is a degree of reciprocity between smoking initiation, progression, and depression symptoms that future research can elucidate.

With regard to smoking cessation, depression has been identified as a barrier to sustained

abstinence [70]. From the outset, smokers are more likely to report having depression symptoms than their non-smoking peers [69, 70, 202], and smokers reporting major depression have a greater likelihood of relapse. There are several hypotheses as to why major depressive disorder is more prevalent among smokers and why smokers with this history are less likely to be able to quit. First, depressed smokers may use nicotine to moderate negative affect and depression symptoms [33, 128, 175]. Depressed smokers, compared with non-depressed smokers, are more likely to report smoking as a means to reduce negative affect and increase stimulation [128]. Treatment-seeking smokers with a history of major depressive disorder have also been reported to experience increased levels of depression and anger while quitting than those without a history of depression (e.g., [69]). Heightened feelings of depression and negative affect following cessation have been found to prompt relapse [222]. Finally, smokers with higher levels of depression have been found to be more likely to have higher levels of nicotine dependence [128]. In turn, a higher level of nicotine dependence at baseline is predictive of continued smoking (e.g., [25]).

Smoking cessation interventions targeted to smokers with a history of depression have typically included strategies for management of depressive symptoms and negative affect (e.g., [32, 78, 79, 139]). Hall and colleagues (1998) found that 10 sessions of cognitive-behavioral therapy that included mood management techniques produced higher quit rates among participants with a history of major depressive disorder than those without such a history [79]. Similarly, another study that compared the efficacy of a cognitive-behavioral treatment with a depression component with a standard smoking cessation intervention found that the cognitive-behavioral treatment was more efficacious for participants with recurrent major depressive disorder [32]. These studies indicate the need for more intensive, tailored interventions for individuals who have a history or recurrent major depression.

Genetic Influences on Treatment Response

The emerging field of pharmacogenetics has the potential to advance the science and practice of smoking cessation treatment by facilitating our understanding of how inherited differences in drug metabolism and drug targets have important effects on treatment toxicity and efficacy [59, 195].

One such area of research has been the role of variation in the nicotine-metabolizing enzyme *CYP2A6* in response to nicotine replacement therapy. Data from an open-label trial of nicotine patch versus nicotine nasal spray showed that *CYP2A6* slow metabolizers had significantly higher levels of plasma nicotine after 1 week of nicotine patch treatment, compared with those homozygous for the wild-type alleles [150]. Data from this trial also showed that the 3-hydroxycotinine/cotinine ratio, a phenotypic marker of *CYP2A6* activity, predicted both plasma nicotine levels after 1 week of patch therapy, as well as abstinence, in this treatment group [137]. A recent study, which evaluated whether nicotine metabolism measured by this phenotype affected response to bupropion treatment, showed that, among fast metabolizers, bupropion significantly improved end-of-treatment quit rates, compared with placebo (34% vs. 10%), whereas the difference in quit rates among slow metabolizers who had received bupropion versus placebo was equivocal (32% for both groups) [180].

Response to bupropion treatment is also influenced by the *CYP2B6* gene that has been implicated in bupropion kinetics and brain metabolism of nicotine [126, 131]. Data show that smokers with the slower metabolism *CYP2B6* variant report greater increases in cravings for cigarettes following the target quit date and have significantly higher relapse rates than those with the faster metabolism variant [131]. Further, among females, greater bupropion efficacy was observed for those with the decreased activity variant. There is also evidence that genetic polymorphisms in CYP2B6, such as CYP2B6*6 (versus CYP2B6*1), can also affect

response to bupropion treatment. Specifically, among smokers with the CYP2B6*6 variant, bupropion produced significantly higher abstinence rates than placebo, whereas, in the CYP2B6*1 group, bupropion was no more effective than placebo [127].

Additional investigations have examined the role of genetic variation in the dopamine pathway and response to nicotine replacement therapy. For example, one trial reported that carriers of the *DRD2* A1 allele had significantly higher quit rates from using the nicotine patch, compared with placebo, whereas there was no difference in treatment response for carriers of the more common A2 allele [107]. A longer-term follow-up of this analysis supported the association of the *DRD2* variant with abstinence at 6- and 12-month follow-up; however, the effect was observed only among women [269]. Other data have shown that smokers carrying the low-activity DRD2 allele (Del C) reported significantly higher quit rates on nicotine replacement therapy compared with high-activity allele carriers (Ins C) [136]. Another dopamine variant that has been shown to modify response to nicotine replacement therapy is the catechol-O-methyltransferase enzyme that has been shown to inactivate dopamine [73, 113, 220]. Smokers carrying the high-activity catechol-O-methyltransferase allele (Val) have been shown to experience stronger dependence on nicotine's dopamine stimulating effects [144], and demonstrate a significantly lower likelihood of smoking cessation as shown in both case control and prospective clinical trials [45, 108, 169].

With regard to genetic variation in the dopamine pathway in the context of response to bupropion therapy, there is preliminary support for enhanced efficacy of bupropion among smokers who carry increased-activity alleles for *DRD2* [54, 136, 241]. This effect appears to be modified by the *CYP2B6* genotype [54]. Similarly, smokers with the increased-activity alleles for *DRD2* 141 Insertion (141 Ins C allele) were shown to have a more favorable response to bupropion as compared with the low-activity allele carriers (Del C allele) [136]. Finally, there is recent evidence for an association between bupropion treatment outcome and genetic variation in the catechol-O-methyltransferase enzyme that inactivates dopamine [16].

The mu-opioid receptor (OPRM1) gene has been a focus of pharmacogenetic investigations of treatment response. In an open-label trial that randomized participants to transdermal nicotine versus nicotine nasal spray, a differential treatment response was reported whereby smokers receiving transdermal nicotine, carriers of the Asp40 variant (G, reduced activity) were significantly more likely to be abstinent than carriers of the Asn40 variant, whereas there was a non-significant difference among smokers receiving nicotine nasal spray [135]. A more recent study reported that carriers of the Asn40 variant had a more favorable response to nicotine replacement therapy than those with the Asp40 variant [167]. Data from this study also showed an interaction between the *OPRM1* genotype and sex whereby female carriers of the Asp40 variant were significantly more likely to have quit by the end of treatment as compared with females with the Asn40 variant, while the reverse was true for males [167]. A potential mechanism for this interaction between sex and *OPRM1* genotype in response to nicotine replacement therapy was implicated by data published by Ray and colleagues showing an association of the *OPRM1* A118G variant with the relative reinforcing value of nicotine among females [198]. Specifically, among females, the Asp40, low-activity G allele was associated with a reduced reinforcing value of nicotine; among male smokers, there was no association with genotype. Further work is needed to reconcile these findings.

Public Policy: Cost-Effectiveness of Smoking Cessation Treatments

Given the constraints in the health care system, it is critical to consider the cost-effectiveness of treatment for nicotine dependence. Overall,

smoking cessation treatments and programs are cost-effective when considering the medical care costs associated with treating health-related consequences from smoking. Indeed, smoking cessation has been identified as one of the three most important preventative medicine approaches [147].

Evaluation of the cost-effectiveness for a smoking cessation program typically requires consideration of the cost of treatment in relation to the benefits of cessation such as life years saved and health care costs savings [11, 80]. With the outcome variable of 12-month employer cost-savings per non-smoking employee, treatment with varenicline was a more cost-saving treatment method than bupropion ($540.60 vs. $269.80 for bupropion generic and $150.80 for bupropion brand) in a general population of smokers [103]. Consistent with these data, a recent study conducted in Europe reported that varenicline was a more cost-effective treatment than either bupropion or nicotine replacement therapy [88].

An important clinical question addressed by the cost-effectiveness literature is whether targeting smoking cessation treatments is a more cost-effective approach than applying a "one-size-fits-all" treatment model that traditionally recommends pharmacotherapy on the basis of patients' prior experiences and preferences [91]. This question is particularly salient in the area of pharmacogenetics, where treatments for nicotine dependence can potentially be recommended on the basis of genetic make-up [131, 133, 136]. In a recent report, Heitjen and colleagues [84] evaluated simulation models of the costs and effectiveness of five alternative strategies for managing cigarette smokers who were attempting to quit: (1) no treatment plan, (2) treatment of all individuals with transdermal nicotine, (3) treatment of all individuals with bupropion, (4) a genetically tailored plan that chooses between transdermal nicotine and bupropion based on the result of a genetic test that predicts therapy outcome [136], and (5) treatment of all individuals with varenicline. When the primary outcome of cost-effectiveness based on discounted life-years and lifetime tobacco cessation treatment costs was compared across the five treatment strategies, the results showed that either the non-tailored varenicline or bupropion treatment approaches were the most cost-effective approaches. Although tailoring treatment using pharmacogenetic data produced negligible survival benefits over the non-tailored approaches, when the simulations imposed several favorable assumptions including a large treatment-by-genotype interaction, the results showed that the pharmacogenetic approach simultaneously improved abstinence rates and reduced the number of quit attempts needed to achieve long-term abstinence [84]. These data suggest that, under some circumstances, pharmacogenetically tailored treatment can be advantageous. The continual evaluation of smoking cessation treatment cost-effectiveness is a priority, especially with the advent of novel approaches designed to enhance treatment efficacy.

Conclusions

The growing prevalence of worldwide smoking in combination with the high percentage of treatment-seeking smokers who fail to quit using currently Food and Drug Administration-approved medications warrants the identification and appropriate dissemination of new treatments for nicotine dependence as well as finding alternative methods for using existing treatments to boost treatment response. With regard to the identification of novel treatments for nicotine dependence, work is ongoing to develop clinically valid animal and human laboratory models that support the translation of knowledge from laboratory studies to clinical research [138, 186]. For example, recent work suggests that utilizing treatment-seeking smokers, as opposed to unmotivated quitters, in short-term, screening laboratory studies that are used to test novel medications, may provide a more valid indication of how these therapies will perform in later-stage clinical trials [186]. Improving the medication development continuum can only shorten the process of finding new and effective nicotine dependence treatments [138].

As reviewed in this chapter, there are several other lines of research in the field of nicotine and tobacco research that provide some optimism. First is the Food and Drug Administration approval of varenicline, the most recent addition to the list of treatments approved for nicotine addiction treatment. Second, research concerning smoker characteristics related to responsiveness to nicotine replacement therapies and the potential development of fast-acting nicotine replacement therapies may help clinicians to tailor the use of nicotine replacement therapy type, dose, and duration to the smoker's characteristics, thereby enhancing nicotine replacement therapy effectiveness. Third, methods to offset the costs of nicotine replacement therapy and innovative marketing approaches to increase the appeal of, and access to, nicotine replacement therapies may significantly increase utilization of nicotine replacement therapy products, in turn, broadening the impact of over-the-counter therapies on the population smoking rate. Finally, results from pharmacogenetic studies of treatments for nicotine addiction, although preliminary at this stage, offer future potential for individualizing patient care. There is much reason to speculate that combined these efforts can help improve outcomes for treatment-seeking smokers.

Strategies for Selecting Candidate Medications for Testing

Bottom–Up Approach: Modulation of Appetitive Drives

Preclinical animal models of cocaine addiction, self-administration, reinstatement, and cue reactivity are commonly used to screen compounds for their potential as medications for treating cocaine dependence. These models, though helpful in selecting compounds, have very limited predictive validity. This issue is a critical one and will not be resolved fully until an effective medication is found that can be tested in animals for model validation. Until then, these limitations need to be factored in any go-no-go decision for advancing compounds for further development.

Preclinical Data

The role of corticotropin-releasing factor in drug addiction is very important, especially for relapse (which has been reviewed extensively [41, 56, 65]). Corticotropin-releasing factor appears to be a mediator of stress-induced reinstatement in rodent models. This effect was found not to be unique only to cocaine in the rat models of stress-induced relapse [23, 59] but also has been shown in heroin [59, 60] and alcohol [43]. These data support the well-known notion that stress is a major

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_50,

precipitator of relapse in abstaining individuals. Modulating the stress circuitry will be beneficial not only for cocaine but also for other substances. Multiple corticotropin-releasing factor-1 antagonists are currently in development for the treatment of depression and anxiety. One that is being developed in collaboration between the National Institute on Drug Abuse and the National Institute of Mental Health will be tested for addiction as well.

Dopamine D3 receptors, cloned in 1990 [1], are located mainly in the accumbens. This dopamine receptor subtype was found to be up-regulated in post-mortem brains of individuals with cocaine addiction who died of cocaine overdose [63]. D3 agonists exhibit cocaine-like effects in rodents and primates [1, 63]. D3 partial agonists have been shown to block cue-induced cocaine reinstatement [20, 52], cocaine-primed cocaine seeking [20, 27], and footshock-induced reinstatement of cocaine self-administration in rats [69], suggesting overall a potential role for D3 antagonists in preventing the three triggers of relapse.

The cannabinoid-1 receptor antagonists have been shown in different animal models to have potential to treat multiple addictions [4, 44]. Cannabinoid-1 antagonists act either by blocking the subjective/rewarding effects of drugs such as tetrahydrocannabinol or by blocking the ability of conditioned cues to promote reinstatement of drug-seeking behavior in animals, presumably through the endocannabinoid system. Taken together, results suggest a role for the cannabinoid system for polysubstance addiction.

Vigabatrin is a gamma-aminobutyric acid transaminase inhibitor, which leads to marked elevation of gamma-aminobutyric acid levels in the brain. It has been shown to be very effective in animal models to block cocaine self-administration, and to block dopamine release in a primate positron emission tomography imaging study [19]. Early open-label pilot data in cocaine- and methamphetamine-addicted individuals showed promising results in facilitating abstinence [8]. Vigabatrin has been reported to cause visual field defects following prolonged use, which may be an issue in its development for addiction treatment. Safety and proof-of-concept trials are planned to clarify this issue further.

Other compounds with interesting preclinical data include metabotropic glutamate receptor 5 [12], alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor antagonists [2, 16], orexin-A receptor antagonists [6, 30], opioid receptor-like 1 agonists [13, 14], muscarinic M5 receptor ligands [3, 25], and N-acetylated-alpha-linked-acidic dipeptidase inhibitors [62].

Bottom–Up Approach: Pharmacotherapy of Reversal Learning

Another pharmacotherapy target that has been discovered by basic neuroscience researchers is cocaine-induced deficits in reversal learning. Reversal learning, a test of cognitive flexibility, involves an organism's ability to determine that reward contingencies have changed and act accordingly. Cocaine has been shown to produce reversal learning deficits in an odor-discriminating task in rats trained to self-administer cocaine [9]. Lesions of the orbitofrontal cortex in rats also have been shown to cause reversal learning deficits in the odor discrimination model [57] and a serial discrimination reversal learning model [5]. Cocaine, administered for 14 days, can cause a failure to signal adverse outcomes in rats that also fail to reverse their cue selectivity, suggesting a failure of plasticity mechanisms in this brain region caused by the drug [64]. Cocaine administered to Vervet monkeys for 14 days produced a reversal learning deficit of learned object discrimination [33]. Chronic cocaine users, but not amphetamine users, demonstrated reversal learning deficits in a probabilistic reversal learning task [24].

Pharmacological modulation of reversal learning is in the early stages of testing. The serotonin-6 receptor antagonist Ro 04-6790

improved reversal learning in isolation-reared rats in the Morris water maze spatial discrimination task [45]. Several serotonin-6 receptor antagonists are in clinical testing [31], suggesting that medications with this mechanism could be tested in chronic cocaine users in the probabilistic reversal learning task. The noradrenergic medications atomoxetine, desipramine, and methylphenidate improved reversal learning in a four-position discrimination task in rats and a three-choice visual discrimination task in Vervet monkeys [58] while the dopamine transporter inhibitor GBR-12909 did not alter reversal learning. The authors noted that methylphenidate impaired retention in both rats and monkeys. Since it has been demonstrated that cocaine can produce reversal learning deficits, the obvious next studies that should be performed would be to test serotonin-6 receptor antagonists and norepinephrine transporter inhibitors in cocaine-affected animals. Positive results would provide a rationale for testing these medications in human subjects in the probabilistic reversal learning task mentioned above.

Top–Down Approach

Marketed medications have been evaluated in different paradigms for efficacy in treating cocaine addiction. These medications were chosen based on different scientific rationales related to a known mechanism of action as a cocaine agonist or antagonist, and through modulating dopamine functions and the reward system. Some of these medications are direct dopamine agonists or antagonists, serotonin modulators, gamma-aminobutyric acid agonists (both A and B), and glutamate modulators.

Our understanding of the addictive processes and neurobiology has greatly improved in the last two decades, thereby impacting and helping us to fine-tune our approach to pharmacological treatment.

Data are emerging from preclinical and clinical studies that would suggest a selective role for specific medications in the addictive process. This would suggest that certain medications could be targeted at a specific phase of treatment or at a specific function involved in the addictive process—for example: (1) withdrawal phase (e.g., propranolol, amantadine); (2) active use phase (e.g., modafinil, vigabatrin); (3) abstinence maintenance and relapse prevention (e.g., topiramate, other gamma-aminobutyric acid agonists), stress modulators (e.g., corticotropin-releasing factor antagonists, lofexidine), cue-induced relapse (e.g., D3 antagonists, D-cycloserine), and priming (e.g., cannabinoid-1 antagonists); (4) improvement of cognition (e.g., nootropic agents, D1 agonists); (5) modulation of frontal inhibitory mechanisms, such as strategic thinking and impulse control (e.g., modafinil), and (6) modulation of reversal learning deficits (e.g., serotonin-6 antagonists, atomoxetine).

Clinical Trials in Cocaine Addiction

Table 1 summarizes most of the double-blind controlled trials conducted in the last decade for cocaine addiction.

Disulfiram, topiramate, modafinil, and ondansetron are leading the marketed medications as far as effect sizes and/or consistent findings in multiple trials. They currently are being pursued in larger phase III confirmatory studies. Disulfiram efficacy is thought to be related to its ability to inhibit the enzyme dopamine beta-hydroxylase, which is responsible for the conversion of dopamine to norepinephrine, in turn making more dopamine available. This may help in restoring the depleted dopamine store and the hypodopaminergic state following chronic cocaine use. The ongoing work with disulfiram is exploring the different dopamine beta-hydroxylase phenotypes and their link to the response to disulfiram. However, disulfiram also inhibits the plasma esterase that metabolizes cocaine to benzoylecgonine and leads to an increase in cocaine blood levels when co-administered with cocaine [48]. This results in an increase in heart rate and blood pressure

Table 1 Summary of data on published medication trials for cocaine dependence

Authors	Study	Outcome	Results
Dackis et al. [17]	*A double-blind, placebo-controlled trial of modafinil for cocaine dependence.* 62 randomized received a single morning dose of modafinil (400 mg) or matched placebo.	The primary efficacy measure was cocaine abstinence based on urine benzoylecgonine levels. Secondary measures were craving, cocaine withdrawal, retention, and adverse events.	Subjects treated with modafinil provided significantly more cocaine-negative urine samples when compared with the placebo group.
Kampman et al. [40]	*Effectiveness of propranolol for cocaine dependence treatment may depend on cocaine withdrawal symptom severity.* 108 randomized received 100 mg propranolol or matched placebo.	Quantitative urinary benzoylecgonine level was the primary outcome measure. Secondary included treatment retention, Addiction Severity Index results, cocaine craving, mood and anxiety symptoms, cocaine withdrawal symptoms, and adverse events.	No comparison overall between the 2 groups with the exception of cocaine withdrawal symptoms in the propranolol subjects. However, propranolol-treated subjects with more severe cocaine withdrawal symptoms responded better than their placebo counterparts.
Kampman et al. [38]	*A double-blind, placebo-controlled trial of amantadine, propranolol, and their combination for the treatment of cocaine dependence in patients with severe cocaine withdrawal symptoms.* 199 randomized received 300 mg/day of amantadine, 100 mg/day of propranolol, a combination of 300 mg/day, or matching placebo.	Cocaine abstinence was the primary outcome measure.	The odds of cocaine abstinence improved significantly over time in propranolol-treated subjects that were highly adherent to study medication but not in placebo-treated subjects.
Brodie et al. [7]	*Treating cocaine addiction: from preclinical to clinical trial experience with gamma-vinyl GABA.* 20 randomized with a titration dose (1, 1.5, 2 g) of vigabatrin.	Measuring 28 consecutive days clean (negative for cocaine).	Eight subjects successfully completed the program and were drug-free for periods ranging from 46 to 58 days.
Brodie et al. [8]	*Safety and efficacy of gamma-vinyl GABA (GVG, vigabatrin) for the treatment of methamphetamine and/or cocaine addiction.* 30 randomized.	Designed to include extensive visual field monitoring as well as outcome measures of therapeutic efficacy.	Sixteen subjects of 18 who completed the trial tested negative for methamphetamine and cocaine during the last 6 weeks of the trial. Vigabatrin did not produce any visual field defects or alterations in visual acuity.

Table 1 (continued)

Authors	Study	Outcome	Results
Kampman et al. [39]	*A pilot trial of topiramate for the treatment of cocaine dependence.* 40 randomized titrating up to 200 mg daily of topiramate.	Cocaine abstinence was the primary outcome measure verified by twice weekly urine benzoylecgonine.	The topiramate-treated subjects were more likely to be abstinent from cocaine compared with placebo-treated subjects.
Gonzalez et al. [28]	*Tiagabine increases cocaine-free urines in cocaine-dependent methadone-treated patients: results of a randomized pilot study.* 45 randomized to 12 or 24 mg of tiagabine or matched placebo.	Reduction of use as measured by cocaine-free urines.	In weeks 9 and 10, cocaine-free urines increased from baseline by 33% in subjects taking 24 mg/day, increased by 14% (12 mg/day), and decreased by 10% with placebo-treated subjects.
Carroll et al. [11]	*Treatment of cocaine and alcohol dependence with psychotherapy and disulfiram.* 122 randomized with 250–500 mg of disulfiram vs. psychotherapy control (1 of 5 treatments).	Duration of continuous abstinence from cocaine or alcohol; frequency and quantity of cocaine and alcohol use by week, verified by urine toxicology and Breathalyzer® screens.	Disulfiram treatment was associated with better retention in treatment as well as longer duration of abstinence from alcohol and cocaine use. The 2 active psychotherapies (cognitive behavioral therapy and 12-step facilitation) reduced cocaine use over time compared with the supportive treatment (contingency management).
George et al. [26]	*Disulfiram versus placebo for cocaine dependence in buprenorphine-maintained subjects: a preliminary trial.* 20 randomized to 250 mg of disulfiram vs. matched placebo.	Duration of abstinence from cocaine verified by urine test.	The total number of weeks abstinent from cocaine was higher in the disulfiram group versus placebo-treated subjects.
Petrakis et al. [51]	*Disulfiram treatment for cocaine dependence in methadone-maintained opioid addicts.* 67 randomized to 250 mg disulfiram vs. matched placebo.	Weekly assessments of the frequency and quantity of drug and alcohol use, weekly urine toxicology screens, and Breathalyzer® readings.	Cocaine use was significantly decreased in quantity and frequency in subjects treated with disulfiram as compared with placebo-treated subjects.
Carroll et al. [10]	*Efficacy of disulfiram and cognitive behavior therapy in cocaine-dependent outpatients: a randomized placebo-controlled trial.* 121 randomized to 250 mg/day of disulfiram or matched placebo.	Random regression analyses of self-reported frequency of cocaine use and results of urine toxicology screens.	Disulfiram-treated subjects reduced their cocaine use more than placebo-treated subjects.

Table 1 (continued)

Authors	Study	Outcome	Results
Martell et al. [46]	*Vaccine pharmacotherapy for the treatment of cocaine dependence.* 18 total randomized (10 received TA-DC 400 μg and 8 received 2,000 μg, vs. matched placebo).	Cocaine abstinence as verified by urine test.	The likelihood of using cocaine decreased in subjects who received the more intense vaccination schedule.
Kosten et al. [42]	*Desipramine and contingency management for cocaine and opiate dependence in buprenorphine-maintained patients.* 160 randomized to 150 mg/day or matched placebo (with and without contingency management).	Cocaine abstinence as verified by urine test.	Cocaine-free and combined opiate- and cocaine-free urines increased over time in those treated with either desipramine or contingency management, and those receiving both had more drug-free urines (50%).
Poling et al. [53]	*Six-month trial of bupropion with contingency management for cocaine dependence in a methadone-maintained population.* 106 randomized to 300 mg/day of bupropion or matched placebo (with and without voucher control and contingency management).	Reduction of cocaine use as tested by thrice-weekly urine toxicologic test results for cocaine and heroin.	Overall, voucher-based control and buprenorphine groups had fewer cocaine-positive urine drug screens than the other groups.
Ciraulo et al. [15]	*Nefazodone treatment of cocaine dependence with comorbid depressive symptoms.* 69 randomized to 200 mg (b.i.d.) of nefazodone or matching placebo.	Cocaine use measured by urine benzoylecgonine and self-report.	Median weekly benzoylecgonine declined in the nefazodone group, and scores for strength of cocaine craving decreased compared with placebo.
Winhusen et al. [68]	*A double-blind, placebo-controlled trial of reserpine for the treatment of cocaine dependence.* 119 randomized to 0.5 mg/day of reserpine or matching placebo.	Cocaine use as determined by self-report confirmed with urine benzoylecgonine, cocaine craving, Addiction Severity Index, and Clinical Global Impression scores.	No significant differences between reserpine and placebo.
Winhusen et al. [67]	*A double-blind, placebo-controlled trial of tiagabine for the treatment of cocaine dependence.* 140 randomized to 20 mg/day of tiagabine or matching placebo.	Cocaine use as determined by self-report confirmed with urine benzoylecgonine, qualitative and quantitative urine toxicology measures.	Qualitative urine toxicology results suggest a possible weak signal for tiagabine in reducing cocaine use.

Table 1 (continued)

Authors	Study	Outcome	Results
Kahn et al. [37]	*Multi-center trial of baclofen for abstinence initiation for severe cocaine dependence.* 160 randomized to 60 mg of baclofen (maximum dose).	Cocaine use as determined by self-report confirmed by urine benzoylecgonine.	No significant effect between baclofen over placebo-treated subjects.
Shoptaw et al. [61] (in preparation)	*Randomized, placebo-controlled trial of cabergoline for the treatment of cocaine dependence.* 70 randomized to 0.5 mg/wk of cabergoline or matched placebo.	Retention, self-report, cocaine use verified by urine drug screen, Hamilton Rating Scale for Depression, cocaine craving, and Clinical Global Impression rating.	Cabergoline reduced craving ratings over placebo-treated subjects.
Elkashef et al. [22]	*Double-blind, placebo-controlled trial of selegiline transdermal system (STS) for the treatment of cocaine dependence.* 300 subjects randomized to 20 mg of selegiline.	Self-reported cocaine use substantiated by urine benzoylecgonine.	There was no effect of selegiline over placebo-treated subjects.
Moeller et al. [49]	*Citalopram combined with behavioral therapy reduces cocaine use: a double-blind, placebo-controlled trial.* 76 randomized to 20 mg/day of citalopram or matched placebo (with cognitive management and cognitive behavioral therapy).	Reduction in cocaine-positive urines.	Cocaine-treated subjects showed a significant reduction in positive urines during treatment as compared with placebo-treated subjects.
Johnson et al. [36]	*A preliminary randomized, double-blind, placebo-controlled study of the safety and efficacy of ondansetron in the treatment of cocaine dependence.*	Cocaine use by urine benzoylecgonine.	The 8-mg/day group had the lowest dropout rate and a greater rate of negative urine benzoylecgonine ($p = 0.02$) compared with placebo. Ondansetron was well tolerated, with no serious adverse events.

and makes disulfiram an undesirable medication to pursue for cocaine treatment.

A recently completed multisite trial of modafinil for cocaine showed an effect only in the non-alcoholic, cocaine-addicted individuals and no effect in the dually dependent, cocaine-addicted, alcoholic individuals; this finding is very similar to the earlier pilot data conducted by Dackis et al. [17]. Two more trials for modafinil are under way, and data from these trials will help to shed more light on the role of modafinil in cocaine addiction.

Ondansetron is approved for nausea and is mostly prescribed for cancer patients receiving chemotherapy. It is thought to decrease dopamine release through the serotonin-3

receptor system in the accumbens. It has been shown to be efficacious in alcohol studies. The proof-of-concept study showed that the 8-mg dose was superior to other lower doses and placebo in helping individuals achieve abstinence from cocaine. It is currently being investigated in larger trials to study its effects on combined cocaine and alcohol addiction.

Topiramate, a gamma-aminobutyric acid agonist and AMPA antagonist anti-seizure medication, showed positive effects in treating alcohol and nicotine addiction. It also is known to cause weight loss. The dual mechanism of action makes it unique among other gamma-aminobutyric acid agonists in that it may not only reduce dopamine release through its gamma-aminobutyric acid effect but also help reduce craving and cue-induced relapse, which has been shown with other AMPA antagonists [66]. The proof-of-concept trial conducted in cocaine-dependent individuals [39] showed that topiramate's therapeutic effect was in the subgroup of participants who were able to stop using cocaine for a few days prior to randomization, making it a potential medication for low-to-moderate users with mild withdrawal symptoms and possibly for cue-induced relapse prevention. Topiramate's therapeutic effect in alcohol-dependent individuals would also make it a candidate for dually dependent individuals or for polysubstance addiction. These hypotheses are being elucidated in the ongoing larger confirmatory trials.

Cocaine Withdrawal

Amantadine and propranolol have shown efficacy in helping individuals with severe withdrawal symptoms, as assessed by the Cocaine Symptom Severity Assessment scale devised by Kampman et al. [40]. In a follow-up placebo-controlled study of either medication alone and their combination, only propranolol showed efficacy in the medication-adherent group analysis and not the intent-to-treat analysis. The combination did not prove to be superior to either medication alone [38].

Comorbid Populations

Comorbid mental illness is more common than not in the addicted population. Prevalence rates range from 20% for attention deficit disorders to 60% for bipolar disorders [54]. This adds another complexity to the treatment approach and to participant selection criteria in clinical trials. This population has been ignored either intentionally or passively by mental health and addiction medication studies. Considering how common these conditions are, it is more sensible to face this issue head on and be more inclusive of this population with a priori hypotheses to test for variations in response or in biology, based on the underlying condition, or to stratify and balance the groups in clinical trials based on a common existing mental illness—e.g., depression scores in trials where an antidepressant or a mood stabilizer is being tested for its effect on drug use. A recent meta-analysis [50] showed that treating the underlying depression or anxiety was associated with some reduction in drug use; however, complete abstinence was hard to achieve.

Participant Heterogeneity

Participant demographics and clinical characteristics including patterns of use seem to be an important factor in predicting outcome. Baseline use always has been deemed one of the strongest predictors of outcome; this was very obvious in the data from the study of topiramate for cocaine dependence and the study of bupropion for methamphetamine dependence, where bupropion was found to be efficacious only in the group with low-to-moderate use at baseline. More recently, data from alcohol and nicotine studies highlight the role of pharmacogenomics as a very promising tool in predicting outcome [18, 55].

Genetic and clinical biomarkers predicting outcome could only improve our results and are being incorporated in many ongoing addiction trials to help elucidate subgroup response.

Polysubstance Abuse

Although most drug addicts would cite a drug of choice, most use more than one drug. This could be good or bad news. Having a polysubstance dependence could lead to treatment resistance, as in the case of the recently completed modafinil study for cocaine addiction, where the alcohol/cocaine dually dependent group showed no response to modafinil.

On the other hand, the good news is that medications that address common mechanisms in addiction could help polysubstance-addicted individuals; for example, topiramate seems to be promising for alcohol, stimulants, nicotine, and food addiction. Naltrexone has shown efficacy in alcohol, opiate, and stimulant addiction. New molecular entities cited above—e.g., corticotropin-releasing factor, cannabinoid-1, and D3 antagonists—are all promising for polysubstance addiction as well. Further studies will tell.

Pharmacotherapy and Behavioral Therapy Combinations

Recent data from cocaine studies suggest that the effect of the medication could be synergized when combined with contingency management. Two separate studies, one using bupropion and one using desipramine, in opiate-dependent, cocaine-abusing populations showed an enhanced effect of the combination of medication plus contingency management compared with each treatment arm alone [42, 53].

Immunotherapy

A non-pharmacological approach of recent interest is the development of a vaccine to treat drug dependencies, in this case a vaccine for cocaine dependence. The cocaine vaccine is a new tool in early development that works by conjugating the non-antigenic cocaine molecule to a hapten that evokes an antibody response. When cocaine was used alone, the antibodies generated were able to recognize and tag the cocaine molecule, thereby preventing it from reaching the brain or other organs. Specifically, the vaccine is made by producing an immunogenic carrier through covalently linking succinylnorcocaine to recombinant cholera toxin B-subunit protein, adsorbed onto aluminum hydroxide adjuvant [32, 34, 35]. The pilot safety study showed a good dose response where the antibody titer was correlated to the vaccine dose, with a reported subjective attenuation of the cocaine high by most subjects in the follow-up, and with no reported serious adverse events [46]. In a recent human laboratory study of 10 non-treatment-seeking, cocaine-dependent men, the cocaine vaccine blunted some of the subjective effects of cocaine among individuals with the highest, but not with low, antibody titer [29]. Similarly, in a randomized controlled trial in 115 methadone-maintained, cocaine-dependent individuals, only 21 of the vaccinated subjects (38%) who achieved serum immunoglobulin G anti-cocaine antibody levels of 43 μg/mL or higher (i.e., a high immunoglobulin G level) had significantly more cocaine-free urine samples than those with levels less than 43 μg/mL (i.e., a low immunoglobulin G level) and the placebo-receiving subjects during weeks 9–16 (45% vs. 35% cocaine-free urine samples, respectively). Even among those who achieved high immunoglobulin G anti-cocaine levels, the blockade lasted only 2 months [47]. Furthermore, the present vaccination regimen (i.e., 5 vaccinations over a 12-week period) is only likely to be practical to treat cocaine-dependent individuals with quite high levels of motivation or compliance. Hence, despite the early promise of this approach, much improved vaccines requiring less frequency of injection will be needed for cocaine vaccines to be a practical and efficacious treatment for cocaine dependence. Similar vaccine-based approaches in nicotine addiction are showing very positive results in phase II studies [21].

Summary

Progress in cocaine pharmacotherapy has made some strides over the last two decades. Promising medications are being explored further in confirmatory trials. A vaccine-based approach continues to be developed. Many other new molecules are in early development. Pharmacogenomics and biomarkers will greatly improve the yield of our trials and help us better understand how to use medications for our client population.

Opioids: Heroin and Prescription Drugs

Jason M. White

Contents

Introduction

This chapter will focus on the pharmacotherapies used in the treatment of opioid dependence, including maintenance pharmacotherapies such as methadone and buprenorphine, the use of antagonists such as naltrexone and medications used in the management of withdrawal. The interest in this aspect of addiction treatment has generated a range of pharmacotherapies broader than is found in other areas of addiction treatment. In addition to the inherent interest in this area, opioids offer a window to the future development of pharmacotherapies for other types of drug dependence.

Opioid Dependence

The term "opioids" refer to drugs acting through μ-, κ-, or δ-opioid receptors, but the principal receptor of interest is the μ-opioid receptor. Opioid drugs acting through this receptor produce a variety of effects, including those regarded by users as desirable such as analgesia, relief of emotional distress and euphoria, as well as adverse effects, such as respiratory depression, sedation, nausea and vomiting. There are a variety of sources of drugs that produce these effects.

The original use was in the form of opium, with morphine as the principal active component. Opium smoking is still practiced in some parts of the world, particularly the opium growing areas such as Northern Burma, Thailand and Laos and Afghanistan. More commonly, the morphine extracted from the opium poppies is converted into diacetyl morphine, or heroin. Illicit heroin has been the primary drug leading to opioid dependence for many decades.

Recently, there has been increasing recognition of the large number of people who become dependent on prescription opioids [6, 70]. Undoubtedly, this has occurred as long as opioids have been used medically, but with the increased rate of prescribing of these analgesics, it can be expected that the number of people who become dependent on prescription opioids, either through treatment for pain relief or through illicit markets, is likely to increase.

Amongst the opioids used illicitly there is a clear preference for short-acting drugs. Morphine from the opium poppy as well as its derivative, heroin, and the preferred prescription opioids, oxycodone, hydromorphone and morphine, are all short-acting agents. The favored routes of administration are by intravenous injection and inhalation of vapor. Both routes result in very rapid onset of action with maximum effect achieved within minutes of administration. The use of short-acting opioids by these routes results in a pattern of administration in dependent users characterized by rapid onset of intoxication followed by milder and decreasing effects over a few hours before the onset of withdrawal symptoms. These symptoms can include nausea, vomiting, pain, cramps, diarrhoea, fever, lacrimation and rhinorrhoea. Re-administration of the opioid results in intoxication and elimination of these withdrawal symptoms. Thus, in the dependent user who administers heroin or another short-acting opioid multiple times per day, there is a cycling of intoxication through the day, potentially including withdrawal if administration does not occur with sufficient frequency. Both the intoxication and the withdrawal result in significant impairment in physiological, psychological and social functioning.

Maintenance Agonist Treatment

One approach to treatment of opioid dependence is immediate cessation of drug use, but this results in a withdrawal syndrome that includes both acute and protracted phases. The alternative is to stabilize the individual with an opioid that prevents the withdrawal occurring and allows relatively normal functioning. In contrast to the rapid cycling of intoxication and withdrawal that is characteristic of illicit use of short-acting opioids, the aim is to produce a slow onset and a gradual offset of action with minimal intoxication and minimal withdrawal. This includes a change in route of administration to oral or sublingual, so that onset of effect is very gradual with minimal or no euphoric effects. A long duration of action will maximize the chances of complete withdrawal suppression and allow dosing on a daily basis or less often.

In recognition of the chronic nature of opioid dependence, maintenance agonist treatment is typically of long duration, with many recommending a minimum treatment duration of one year, but for a number of individuals this may extend over many years. Longer durations of treatment are associated with higher rates of abstinence from illicit opioids. Maintenance agonist treatment aims to normalize the physiological, psychological and social functioning of the individual, and this can be achieved by a dose of agonist drug that suppresses withdrawal with minimal direct effects. However, it should also be recognized that a second role of maintenance agonist treatment is to reduce the effect of any additional opioid administered. This can occur both through receptor occupancy and through the tolerance that develops with repeated daily doses, particularly when relatively high maintenance doses are used.

While there are now a range of opioids that could be used for treatment of opioid dependence, much of the history of opioid maintenance treatment has been the use of methadone as the maintenance agent. More recently, buprenorphine has become available and there have been trials of other medications that may also play a future role.

Methadone Maintenance

Methadone has been and remains the most widely used drug in maintenance treatment of

opioid dependence. Its use is generally attributed to Dole and Nyswander working in New York in the 1960s.

Pharmacology of Methadone

Methadone binds primarily to the mu-opioid receptor, but does have some affinity for the kappa and delta receptors. In addition to its opioid action, it has some non-opioid effects, including action as a non-competitive antagonist at the *N*-methyl-*D*-aspartate receptor and an inhibitor of the re-uptake of noradrenalin and serotonin. The clinical significance of these actions is unknown, but both are of potential interest. Non-competitive antagonists at the *N*-methyl-*D*-aspartate receptor may have a role in treatment of neuropathic pain and hyperalgesia and may retard the development of opioid tolerance, but can also produce adverse effects. Inhibition of the re-uptake of noradrenalin and serotonin can result in an antidepressant effect.

Methadone is most commonly administered as a 50/50 ratio of the R and S enantiomers. The only exception is in Germany where it is also available as the pure R enantiomer. The opioid activity of methadone lies principally in the R enantiomer that has a 20-fold higher affinity for the mu-receptor. R-methadone is approximately 50 times more potent than S-methadone in producing analgesia and is effective in preventing opioid withdrawal, whereas S-methadone is ineffective. S-methadone does have non-opioid effects, such as *N*-methyl-*D*-aspartate receptor action, and could contribute to the adverse effects of racemic methadone [19, 58].

For maintenance treatment, methadone is generally administered as a solution, whereas it is normally administered in tablet form for pain relief. It is readily absorbed from the gastrointestinal tract and the bioavailability averages between 80–90 per cent, although there is significant variability between individuals. Peak plasma concentration is reached approximately 2.5–3 h after oral administration.

Methadone is extensively metabolized by the hepatic cytochromes P450 enzyme family. The primary pathway is to the inactive 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine, with CYP3A4 the major enzyme. A number of other P450 enzymes may be important, including CYP2B6, 3A5 and 2D6 [10]. CYP2B6 exhibits stereoselective metabolism so that there can be significant differences in the plasma concentrations of R and S methadone even though it is administered as a 50/50 ratio.

Clinically significant changes in methadone concentration, with consequences such as increased sedation or increased withdrawal, can arise from the co-administration of inhibitors or inducers of CYP450 enzymes. Inhibitors such as fluconazole, ketoconazole, fluvoxamine and others have been shown to increase plasma methadone concentrations, while inducers such as rifampicin, barbituates, nevirapine, efavirenz, amprenavir, nelfinavir and ritonavir decrease plasma methadone concentrations.

There is considerable variability in the pharmacokinetics of methadone between individuals [18]. This can arise through variations in absorption and metabolism and lead to different profiles of concentration change over the dosing interval. While the ideal is a low peak to trough ratio, so that effects and withdrawal symptoms are minimal, some individuals exhibit much more pronounced concentration changes, as illustrated in Fig. 1. These individuals may be at greater risk for adverse effects at the time of peak concentration, but a rapid decrease in concentration following the peak has also been associated with greater withdrawal severity [17].

Clinical Use of Methadone

Assessing Suitability for Methadone Maintenance Treatment

Most individuals who participate in methadone maintenance treatment satisfy criteria for opioid dependence and have significant physical dependence. Evidence for satisfying these criteria can be obtained through participant interview,

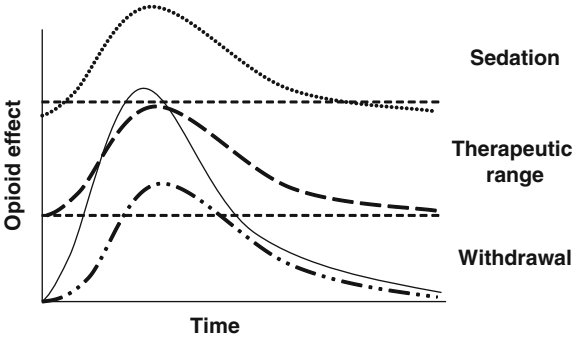

Fig. 1 Methadone effects increase over the first 3 h after administration before gradually declining. Ideally, these effects fall into the desired therapeutic range so that the individual experiences neither sedation nor withdrawal (------). High doses result in excessive sedation (· · · · · ·) and low doses excessive withdrawal (– . . – . .). In some individuals, the change in concentration is more pronounced and they may experience some sedation at time of peak concentration, but withdrawal at time of trough concentration (———). For this last group, divided doses or changing to a different medication (e.g., buprenorphine, slow-release morphine) is likely to be the best therapeutic strategy

physical examination to determine evidence of withdrawal and evidence of injecting drug use, and urinalysis. Individuals presenting for such treatment, even those who present seeking only methadone treatment, should be offered alternatives such as the use of other maintenance medications and abstinence based therapies. In addition to this group, there are some people who may not fulfill all these criteria, but who may be deemed suitable for treatment. These people are normally using at lower levels that would not necessarily be associated with strong withdrawal on cessation or a full dependence syndrome. They include users at high risk of overdose, pregnant women, prisoners with a history of opioid use (for treatment while in prison and on release) and people who may be at high risk of contracting or infecting others with HIV or other infectious diseases.

Commencement of Maintenance Treatment

As is the case with all opioid agonists, administration of methadone carries the risk of death through respiratory depression. In methadone maintenance, the maximal period of risk is during the first 1–2 weeks of treatment. While methadone maintenance is associated with an overall four-fold reduction in mortality, the risk of death rises during this induction period [81]. There are several reasons for this. First, in the absence of objective indicators of tolerance, selecting an appropriate first dose and rate of dose increase is based principally on clinical experience. Second, the long half-life of methadone means that it can take 5 days or more to reach a steady-state after each dose change. Clinicians rarely have the opportunity to wait this long before seeing the full effects of a dose change during induction. Third, when individuals experience significant withdrawal, they may self-medicate with opioids, benzodiazepines, or other drugs to relieve these symptoms. The resultant interactions may lead to mortality. The initial dose, most commonly between 20–30 mg, and the dose increments must be determined based on the balance between achieving adequate withdrawal suppression as rapidly as possible, without placing the individual at risk from methadone-induced respiratory depression. In most clinical situations, individuals are observed on a daily basis during this induction period and observations made of withdrawal signs and symptoms as well as evidence of intoxication. Dose adjustments are based on this evidence plus participant self-report. Ideally, during the induction period individuals would be observed at time of peak as well as at time of trough

concentration, but for practical reasons this is done in relatively few clinics.

Maintenance Dose of Methadone

The end of the induction phase should see the participant reach a relatively stable daily dose of methadone. In practice, over the following months dose changes are likely to occur and indeed may reoccur on an occasional basis though a history of years of treatment.

Early evidence concerning methadone dose failed to reveal marked differences in outcomes between lower doses (typically less than <50 mg/day) and high doses (frequently greater than 80 mg/day). More recent evidence from double-blind trials has suggested that higher doses are generally more effective than lower doses. The major difference lies not in treatment retention as this often similar across different doses, but in rates of illicit opioid use, which tend to be lower in those administered high doses. The result of this change of research outcomes has also been a change in clinical practice in the United States toward higher doses [11].

It is important to recognize that in these clinical trials, doses are often fixed or fixed within a range. In practice, the dose that is effective for an individual may vary over a considerable range. As the dose is increased, the proportion of individuals who are abstinent from illicit opioids increases, but even at low doses, some participants are retained in treatment and not using illicit opioids [73].

Unsupervised Dosing

Methadone for treatment of opioid dependence is normally administered as a once a day medication. Regulations in most countries require that all or a significant proportion of these doses are dispensed under supervision of a pharmacist. The major exception has been the United Kingdom, where individuals have been able to take away a week's supply or more. Where they are allowed unsupervised doses, rules are usually based on national or local guidelines or regulations. Typically, as a person is shown to be successful in maintenance treatment, the number of unsupervised or take home doses increases. The risk of take-home doses is three-fold. First, the client may administer the dose by injection with the associated risks of respiratory depression and the effects of injection of other substances in the methadone solution. Second, the drug may be sold into the illicit market. Third, there is a risk of infant ingestion of methadone doses stored in clients' homes. Against these risks is the difficulty of sustaining a normal lifestyle, particularly employment, when 7-days-per-week attendance at a clinic or pharmacy is required. It is clear that unsupervised doses allow more normality in the clients' lifestyles and are perceived as a benefit of stability while on a methadone maintenance program.

Cessation of Methadone Treatment

The timing at which an individual ceases methadone treatment is a matter of clinical judgment. Some clients may never cease treatment if they are not experiencing adverse effects and there is significant risk of relapse. In general, withdrawal from methadone is best achieved by very gradual dose reduction [69]. Even with such a gradual dose reduction, clients are often extremely sensitive to small dose changes and may require periodic stabilization of dose for some weeks before further dose reductions.

Managing Adverse Effects

Methadone, in common with other opioids, has a rang of short-term and long-term adverse effects. The long-term effects are discussed in more detail below. A number of studies have shown that adverse effects of methadone can influence client satisfaction with treatment and severe adverse effects may lead to treatment drop-out. Commonly reported effects include

excessive sedation, mood swings, sweating, constipation and decreased libido. It is important to minimize these adverse effects whilst maintaining doses of methadone that are effective in suppressing illicit opioid use. Most of these symptoms are attributable to excessive opioid effect or to breakthrough withdrawal [16]. Those attributable to excessive opioid effect, such as sedation at time of peak concentration, can be reduced by decreasing the dose, but this needs to be balanced against the potential for increasing the risk of illicit opioid use. Similarly, breakthrough withdrawal can be alleviated by dose increases, but these may result in elevated risk of opioid adverse effects at the time of peak concentration. Those individuals described in Fig. 1 who show a pronounced difference between peak and trough concentration may be particularly difficult to manage as they can potentially show significant adverse effects at time of peak concentration and breakthrough withdrawal at time of trough concentration. These individuals are much better suited by multiple daily administration. While this may be most appropriate for as many as one third of individuals on methadone maintenance [16], many clinics are reluctant to allow such split dosing because of the risk of dose diversion.

Evidence for the Effectiveness of Methadone Maintenance

There have been only two randomised placebo-controlled trials involving the effectiveness of methadone treatment. The first [62] was conducted in Hong Kong. All participants were stabilized on 60 mg of methadone in an inpatient unit. On discharge half continued on methadone maintenance with the option of dose changes, while the other group commenced a reduced dosing regime followed by placebo treatment. The results clearly showed much higher retention and lower heroin use in the methadone maintenance group.

The second, [72], compared treatment with 0, 20, and 50 mg/day of methadone. When the 50 and 0 mg groups were compared, retention was significantly higher in the 50 mg group and rates of positive urines were lower.

In addition to these two studies, there have been other randomised studies that did not include a placebo control [15, 29], that also showed positive outcomes for participants in methadone treatment groups. In addition, surveys carried out of drug treatment effectiveness have confirmed the effectiveness of methadone maintenance treatment. Together, these results show that treatment with methadone reduces illicit opioid use and retains individuals in treatment.

Other Outcomes

In addition to the effects on illicit opioid use, a number of positive outcomes have been demonstrated from the use of methadone maintenance. Illicit opioid use is associated with high rates of criminal involvement and of infectious diseases such as HIV and hepatitis C. The relationship between illicit opioid use and criminality is a complex one. Illicit opioid users may have a history of criminal involvement prior to their commencement of opioid use or they may have commenced criminal activity only as a consequence of their drug use. In addition, some aspects of the criminal involvement may be linked solely to obtaining funds to support their drug use, while other aspects of their criminal behavior are unrelated. Nevertheless, there is significant evidence that methadone maintenance treatment has an effect on rates of criminality [71].

Two prospective cohort studies in the US have shown a protective effect of methadone maintenance on HIV infection. One [56] found a much lower increase in HIV seropositivity amongst those in methadone-maintenance treatment group compared to those out of treatment. In addition, the seropositivity in the methadone treatment was due entirely to people who had dropped out of treatment. The second [59] found that clients who had spent less than a year in methadone maintenance were nearly three times more likely to be HIV positive than those who had spent more than a year in treatment.

Cost-Effectiveness

Increasingly, health care interventions need to show not only that they are effective, but also that they are cost-effective. This issue has been addressed in a number of studies for methadone maintenance. It has been shown that every year of life saved by methadone treatment incurs a cost of just under $6,000 [4]. Even with variation in the assumptions, this cost was less than $10,000 per life year. By comparison, a standard of $50,000 per life year is often judged as demonstrating sufficient cost-effectiveness to justify a medical treatment. When compared with detoxification, the costs of methadone maintenance were higher, but methadone recipients incurred lower costs for substance abuse and mental health care outside of the study [50]. Methadone maintenance also had advantages with regard to years of life saved. When a lifetime benefit model is used the benefit-cost ratio approaches 38:1 [82].

Predictors of Success in Methadone Treatment

The evidence presented above shows that methadone maintenance is a highly effective and cost-effective intervention. Nevertheless, there is room for improvement. In particular, a significant proportion of individuals never reach the 1 year duration of treatment widely regarded as a minimum for increasing the chances of long-term abstinence from illicit opioids. By examining the predictors of treatment success, it may be possible to design programs that have the best possible outcomes. There are two major sources of variability leading to differential outcomes: program-related factors and individual factors. Unfortunately, the information available on these factors provides relatively little direction. In the case of program characteristics, these have rarely been assessed quantitatively. It is generally regarded that clear program policies and protocols, well-trained staff that have empathy with the clients, and good counseling support, all contribute to good outcomes. There is also research supporting the provision of counseling and other services in addition to the basic provision of methadone (see below). The most influential of all the program factors is the dose provided. Those programs that provide only low doses of methadone have worse outcomes than those that have a dose range that includes a significant proportion of relatively high methadone doses.

Research on client characteristics that predict outcomes have yielded a range of significant findings, but little that can be used in a practical manner. For example, the most consistent client characteristic predictive of outcome is age, with older people tending to do better than younger ones. Other factors such as psychiatric comorbidity, criminal involvement and social stability have also been shown to have some influence in at least some studies.

One client characteristic that has some predictive value and that can be influenced, is the concentration of methadone achieved by the individual. The inter-individual differences in methadone pharmacokinetics, noted above, mean that dose is not closely linked to concentration. A wide range of trough plasma methadone concentrations (from 100 to 600 mg/ml racemic methadone) have been proposed as representing a suitable minimum concentration [18]. In the only prospective study that measured trough plasma methadone concentrations of subjects from commencement of methadone maintenance treatment [34] the authors identified a threshold of 220 ng/ml racemic methadone above which almost all individuals did well.

Resolution of the value of measuring a plasma concentration requires additional research on a therapeutic drug monitoring approach. It may be that concentrations will prove to be valuable predictors of outcome. At present, however, measurement of plasma concentrations is not routine in most clinics. It is often confined to determining plasma concentration changes in those individuals who seem to have an abnormal pattern of opioid effect and/or opioid withdrawal.

Problems Associated with Methadone Maintenance Treatment

While there are considerable benefits of methadone maintenance treatment, there is increasing recognition of the adverse effects of chronic opioid administration. Some problems of chronic administration have been recognized for a considerable period of time, while others such as risk of osteoporosis have emerged only in recent years. As a result, there is often inadequate information on which to base clinical decisions regarding long-term treatment. However, as further research evidence accumulates, the relative costs and benefits of extended, particularly lifetime, opioid administration in methadone maintenance will become more apparent.

Chronic opioid administration, including methadone maintenance, is associated with hypogonadism that may be more pronounced in men than in women [30, 31]. In men this may be associated with erectile dysfunction [32].

Increasing evidence associates long-term opioid administration with low bone mineral density. One survey found that more than three-quarters of a sample of participants in methadone maintenance treatment had low bone mineral density [41]. This may be attributable to several effects of opioids, including hypogonadism, described above, and inhibition of osteoblast function. Comorbid conditions such as tobacco dependence and HIV infection may also play a role. With increasing age of many individuals on methadone maintenance, there is concern over the risks of osteoporosis and its sequelae in long-term clients.

There has been increasing evidence that methadone may prolong the QT_c interval in a minority of individuals. Such prolongation of QT_c interval is more frequent when higher doses of methadone are used, in individuals also administered drugs that inhibit CYP3A4 activity (thereby increasing methadone concentration), in those administered other QT_c-prolonging drugs, and in those with medical conditions that may predispose to such prolongation [21].

Increasing evidence is suggesting that long-term opioid administration is associated with hyperalgesia, a hypersensitivity to at least some kinds of painful stimuli [2]. Thus, for some types of pain, long-term opioid administration may actually increase the response to a painful stimulus rather than decrease it. Hyperalgesia may predispose individuals to chronic pain problems and make it difficult to achieve acute analgesia when it is required for medical treatment. Individuals being treated for opioid dependence are experienced opioid users and thus methadone treatment is not a cause of hyperalgesia, but may maintain a hyperalgesic state in someone chronically exposed to opioids.

Cognitive impairment has long been a concern for prescribers and for individuals maintained on opioids for treatment of pain and opioid dependence. Early studies suggested that there was little reason for caution unless participants had experienced a recent dose increase or were new to methadone treatment. However, recent studies have suggested that individuals maintained on methadone are significantly impaired. Impairments have been reported on a wide range of cognitive functions, such as attention, visual orientation, psychomotor speed, memory and decision making after controlling for gender, age, intelligence and pre-existing neurologic or psychiatric conditions. Reports comparing methadone recipients with people who were previously illicit opioid users also show significant impairment [13, 74]. While it is difficult to design studies of cognitive impairment that do not have at least some methodological shortcomings, this recent evidence raises concern regarding the functioning of individuals in activities such as motor vehicle operation, various types of employment and normal social and family functioning.

In summary, more recent evidence has implicated chronic opioid administration, and in particular methadone administration, in a range of adverse health impacts. For many of these impacts research findings are still accumulating and it is difficult to make definite conclusions. Nevertheless, the benefits of very long-term

opioid administration need to be balanced against these health risks.

Buprenorphine Maintenance

For approximately 30 years methadone was almost the sole opioid used in maintenance treatment. Then in 1995 the partial agonist buprenorphine began to be used in France for the same purpose. Buprenorphine had an extensive history of use as an analgesic, but there was also an increasing body of research suggesting that it would be valuable in the treatment of opioid dependence. Since that time buprenorphine has been approved for opioid maintenance treatment in a number of countries. It is available alone and in combination with naloxone in a dose ratio of 4:1.

Pharmacology of Buprenorphine and Naloxone

Buprenorphine is a partial agonist at the μ-opioid receptor where it has high affinity but low intrinsic activity. It is also a partial agonist at κ-opioid receptors and an antagonist at the δ-opioid receptor.

As a partial agonist at the μ-opioid receptor, buprenorphine would be expected to have opioid agonist effects similar to those of methadone, but a lower maximum effect. There is evidence that this is true for at least some effects of buprenorphine. For example, buprenorphine-induced respiratory depression shows a lower peak effect than the full agonist methadone [76]. Subjective responses show a similar relation. However, this may not be true for all effects of buprenorphine. Recent evidence suggests that the dose response curve for analgesic effects of buprenorphine shows a pattern similar to that of a full agonist [12].

Buprenorphine is metabolized to an active metabolite, norbuprenorphine, through the action of CYP3A4. There is evidence that norbuprenorphine acts as a full agonist at the μ-opioid receptor and that buprenorphine, with its relatively higher affinity and lower efficacy, may block the actions of norbuprenorphine [54].

Buprenorphine has very low oral bioavailability due to extensive first-pass metabolism. Bioavailability is higher by the usual sublingual route of administration. Peak plasma concentrations are reached approximately 1.5 h after administration, but this is highly variable. Buprenorphine is widely distributed in the body and readily crosses the blood-brain barrier, but there is evidence that it does not readily cross the placental barrier [60].

Following sublingual administration the terminal half-life of buprenorphine is long (approximately 26 h), but highly variable (range 9–69 h) [52]. The extended duration of action of buprenorphine is likely to be due to a combination of this long elimination half-life as well as the tight binding of buprenorphine to the μ-opioid receptor.

In subjects maintained on sublingual buprenorphine, peak plasma concentrations of buprenorphine are approximately ten-fold higher than trough concentrations, but opioid effects show relatively little change over the dosing interval [48]. Thus, compared to methadone, over the dosing interval there is greater change in plasma concentration, but less change in effect.

To date, there has been little research on drug interactions with buprenorphine. As it is primarily metabolized by CYP3A4, many of the drugs that exhibit pharmacokinetic interactions with methadone will also influence buprenorphine concentrations. There is some evidence that HIV protease inhibitors such as ritonavir and antifungals such as ketoconazole inhibit buprenorphine metabolism. The clinical impact of such interactions is yet to be determined.

Naloxone is a μ-opioid receptor antagonist. The bioavailability of naloxone via the sublingual route is very low (approximately 10%). The low bioavailability combined with the short elimination half-life of naloxone (1–2 h), means that when administered sublingually, the amount of naloxone absorbed is extremely small. In contrast, when administered via the

intravenous route, naloxone will be present in concentrations sufficient to produce an antagonist effect. For example, a person who administers 16 mg buprenorphine + naloxone via intravenous administration is receiving a 4 mg dose of naloxone with 100% bioavailability. Such a dose of naloxone is sufficient to reduce the peak effects of buprenorphine and to precipitate withdrawal in someone who is opioid dependent [55].

Clinical Use of Buprenorphine

While the criteria for buprenorphine maintenance treatment are much the same as those for methadone maintenance treatment, and there are many similarities in the way buprenorphine and methadone are used, there are also some important differences. In some countries, such as the United States, the setting may be different with buprenorphine + naloxone used largely in office based treatment while methadone treatment is centered in specialist clinics. In other countries, the settings are similar with both methadone and buprenorphine used in clinics and office-based treatment.

Commencement of methadone treatment carries significant risk of respiratory depression and therefore needs to be approached cautiously. In contrast, the relative safety of buprenorphine allows rapid escalation of dose. Even though buprenorphine has a long half-life and hence the full effects of a dose increase may take a number of days, it appears to be safe to reach a maintenance dose (such as 12 mg) on the third day of administration.

In contrast to methadone, however, buprenorphine carries the risk of precipitated withdrawal. As an agonist with high affinity but low intrinsic activity, it will displace most opioid agonists from the μ-opioid receptor, but produce insufficient activity to maintain physical dependence. Thus, buprenorphine dosing is normally commenced only when the individual exhibits mild signs of opioid withdrawal.

Buprenorphine is a more potent drug than methadone and doses tend to be considerably lower. For most clients, maintenance doses are in the range 8–16 mg/day. In contrast to methadone, there is no clear evidence of better outcomes at higher doses, at least when the dose is 8 mg/day or higher. Thus, current clinical recommendations are to titrate the dose in order to achieve effective withdrawal suppression and blockade of heroin use. In contrast to methadone, buprenorphine can be administered every second day or even every third day [49]. Clinical practice varies, with some strongly encouraging clients toward every-second-day dosing and others finding that most clients prefer daily dosing.

Regulations regarding unsupervised doses of methadone vary considerably. When implemented in France in the 1990s, buprenorphine was dispensed as a single drug and clients were not required to have doses supervised. More recently, the buprenorphine + naloxone combination has been approved in the United States without the dosing supervision associated with methadone. In other countries, the degree of dosing supervision is similar to that for methadone, even when buprenorphine is used in combination with naloxone.

Cessation of buprenorphine treatment is somewhat easier than cessation of methadone treatment. While abrupt termination of buprenorphine dosing is associated with a withdrawal syndrome and clients who gradually reduce the dose also experience some withdrawal, the intensity appears to be less than for methadone. Where a decision has been made to cease maintenance treatment with buprenorphine, gradual dose reductions may be implemented over a number of weeks.

Evidence for the Effectiveness of Buprenorphine Maintenance

There have been four studies comparing buprenorphine maintenance with placebo or active placebo. Two studies of buprenorphine compared to placebo were conducted in the United States [25, 37] and a third in Sweden [39]. In a fourth trial, conducted in the United States, buprenorphine doses of 4, 8 and 16 mg

were compared to a 1 mg dose as active placebo [45]. These four studies all showed clear evidence that buprenorphine is more effective than placebo. There were considerable variations in dose, the form of buprenorphine (with or without naloxone) and the degree of psychosocial treatment provided, but despite these variations the results are very consistent.

There have also been a number of comparisons of buprenorphine with methadone. These have been summarized in various reviews and meta-analyses [5, 9, 51]. The conclusions of these reviews are consistent in suggesting that buprenorphine and methadone are equivalent in reducing illicit opioid use. However, buprenorphine maintenance is associated with slightly lower retention rates than methadone. There may be a number of reasons for this, including use of relatively slow induction dose increases in early studies with buprenorphine.

Problems Associated with Buprenorphine Maintenance Treatment

Some of the adverse effects associated with chronic opioid administration were described in the section above titled "Problems associated with methadone maintenance treatment". As an opioid agonist, buprenorphine will have similar effects. However, as a partial agonist there is evidence that for at least some of these problems of long-term treatment, risk may be lower for buprenorphine than for methadone. There is some suggestion that hypogonadism in men may be less likely in individuals maintained on buprenorphine [31] and that they have lower rates of erectile dysfunction [33]. There is also some evidence that buprenorphine is associated with less QT_c prolongation than methadone [77]. Buprenorphine may be associated with a lower level of cognitive and psychomotor impairment than methadone [64, 65].

For many of these adverse effects a considerably larger body of research is needed to make definitive conclusions on the relative advantages of buprenorphine versus methadone. To date, the lower risk of respiratory depression has been seen as the main advantage of buprenorphine over methadone. However, if continued research on long-term effects reveals increasing problems associated with administration of full agonists such as methadone, and lesser problems with buprenorphine administration, then these advantages of buprenorphine may prove to be equally or more important.

Other Opioid Agonists

While methadone and buprenorphine are the most widely used opioid maintenance medications, other drugs have been used or are currently being used for this purpose. This section will briefly review three of those medications: levo-alpha-acetylmethadol, slow-release morphine, and heroin.

Levo-Alpha-Acetylmethadol

Research on the use of levo-alpha-acetylmethadol as a maintenance medication began in the 1970s in the United States. As a long-acting opioid, it had obvious appeal as a maintenance medication. However, final approval for registration in the United States did not occur until 1993. Subsequently, it was approved also in Europe, but by 2001 there was concern over cases of Torsades de pointes [14]. This adverse effect of levo-alpha-acetylmethadol was associated with increased QT_c interval and resulted in withdrawal of the medication by the manufacturer. As a consequence of these findings, a more thorough investigation revealed that methadone was also associated with these risks, but possibly less risk than levo-alpha-acetylmethadol.

Pharmacology

Levo-alpha-acetylmethadol is structurally similar to methadone. It differs in having two active metabolites, nor-levo-alpha-acetylmethadol and

dinor-levo-alpha-acetylmethadol, each of which has a very long half-life and contributes to the effects of the drug. The result is a long duration of action, meaning that levo-alpha-acetylmethadol can be administered every second or third day [43, 61].

Like methadone, levo-alpha-acetylmethadol is normally administered as an oral solution and is well absorbed from the gastrointestinal tract. Peak plasma concentrations of levo-alpha-acetylmethadol are reached approximately 2–4 h of administration and several hours later for nor- levo-alpha-acetylmethadol and dinor-levo-alpha-acetylmethadol. Like methadone and buprenorphine, CYP3A4 plays the primary role in the metabolism of levo-alpha-acetylmethadol.

Evidence of Effectiveness

In randomized controlled trials, levo-alpha-acetylmethadol has been shown to be about equally as effective as methadone [42, 44]. In a comparison with methadone and buprenorphine, levo-alpha-acetylmethadol showed outcomes at least as good methadone [38].

Problems

In large part, problems associated with use of levo-alpha-acetylmethadol are similar to those associated with methadone use. However, the prolongation of the QT_c interval and life-threatening cardiac arrhythmias have had a much greater impact on the use of levo-alpha-acetylmethadol. There is some evidence that the effect of levo-alpha-acetylmethadol may be due principally to the parent medication, rather than the active metabolites [40].

Slow – Release Oral Morphine

Morphine is regarded as the prototype μ-opioid receptor agonist. It is also the main active metabolite of heroin and much of the action of that illicit opioid is due to the activity of morphine. It would seem logical, therefore, to consider morphine as a maintenance medication. The main reason it was not considered at the time methadone was introduced was because of its short duration of action. However, since then a number of slow-release preparations of morphine have been developed for the relief of pain that have potential for opioid maintenance medication. There is also a slow-release morphine formulation available in eastern Europe that is marketed specifically for treatment of opioid dependence.

Pharmacology

Morphine is an opioid agonist that is highly selective for the μ-opioid receptor but has lower intrinsic efficacy than methadone. It has low oral bioavailability due to extensive first-pass metabolism and a short, variable half-life of approximately 2 h. It has two major metabolites, morphine-3-glucuronide and morphine-6-glucuronide. Both are pharmacologically active, with morphine-6-glucuronide exhibiting opioid effects and morphine-3-glucuronide excitatory effects through an unknown mechanism. Slow-release formulations of morphine developed for chronic pain treatment show varying durations of action and only some allow once daily administration.

Evidence of Effectiveness

In the one double-blind trial comparing slow-release oral morphine to methadone [20], retention in treatment and use of illicit opioids was comparable for the two medications, but morphine recipients had significantly lower depression and anxiety and fewer physical complaints. Variable outcomes have been obtained with quality of life measures [26, 78]. Morphine was shown to be an effective alternative for clients who experienced breakthrough withdrawal when maintained on methadone [58].

Problems

Use of slow-release oral morphine as a maintenance treatment is associated with two problems in addition to those resulting from long-term administration of any opioid. The first is that routine urine testing for illicit opioid use normally relies on detection of morphine. For individuals maintained on morphine, the strategy is not appropriate, and if urine testing is to be used, alternatives need to be developed. Some efforts have been made in this direction [63]. The second problem is the risk of diversion of the medication. While other opioids are associated with such risk, it is somewhat increased because of the low oral bioavailability of morphine. When a dose intended for oral administration is used intravenously, the effect may be particularly pronounced, placing the user at high risk of overdose. Individuals who are taking slow-release morphine need to be aware of this difference in bioavailability between oral and intravenous routes.

Diacetyl Morphine

While diacetyl morphine or heroin has been the main illicit opioid used, there has been interest in using it as a maintenance medication. The drug has significant disadvantages because of its short duration of action requiring multiple daily administrations. In addition, even in treatment it has been administered by the intravenous or inhalation route, resulting in rapid onset of action. Thus, heroin maintenance does not change the usual cycle of peaks and troughs of opioid effect through the day. However, the main rationale for heroin maintenance has not been to provide the maximum stability to clients, but to engage in treatment those who would otherwise be refractory or who have proven to be refractory. Thus, this treatment is intended for the minority of individuals who have not achieved substantial reductions in illicit opioid use despite multiple episodes of engagement with treatment programs.

Pharmacology

Diacetyl morphine is rapidly metabolized to 6-monoacetyl morphine and then to morphine. Both diacetyl morphine and 6-monoacetylmorphine have very short half-lives of 8 and 22 minutes respectively. 6-monoacetylmorphine and morphine are μ-opioid receptor agonists. Diacetyl morphine had been believed to be a pro-drug, but there is evidence suggesting that it may bind to a variant of the μ-opioid receptor [68]. Diacetyl morphine also differs from morphine in being considerably more lypophilic and therefore it more readily crosses the blood-brain barrier.

Evidence of Effectiveness

There have now been a number of trials of heroin maintenance, but the interpretation of the results is made difficult by the variability in trial design. Generally, methadone maintenance has been the usual comparator treatment, but in different studies this has been compared to heroin maintenance alone or heroin maintenance plus methadone maintenance. Heroin has been administered by both intravenous and inhalation routes and the frequency of administration per day has varied.

It is not surprising, therefore, that there has been considerable variability in outcomes from these trials [23]. While they have shown that heroin maintenance can be implemented safely and the results have been largely positive, heroin maintenance cannot be recommended for treatment with the same confidence as methadone or buprenorphine [79].

Adjunctive Treatment in Agonist Maintenance Programs

Maintenance treatment with methadone or buprenorphine can be little more than appropriate assessment and provision of a prescription

with periodic review. However, other aspects of treatment may be included as part of the maintenance program. This may include specific treatment focused on comorbidities such as psychiatric problems, infectious diseases, dental treatment and pain management. Psychosocial treatment may also be a significant part of the package and in many countries such psychosocial treatment is mandated.

Counseling may form part of general medical management. This is generally focused on issues of relevance to illicit drug use, such as recent drug use or abstinence, attendance in self-help groups, provision of support or efforts to reduce drug use or remain abstinent, advice for successful abstinence and feedback on urine results [24]. Two other more focused types of interventions have also been evaluated. Cognitive behavioral therapy is typically centered on drug use, the cues that lead to relapse and ways to cope with these, adjusting to the absence of drug reinforcement, drug refusal skills, and coping with withdrawal. Contingency management is a behavioral based treatment in which individuals receive rewards for drug-free urines. The reinforcers can include money, goods, or additional privileges such as take home doses.

There are a relatively small number of studies evaluating different psychosocial approaches and hence definitive conclusions are not possible. Nevertheless, it has been suggested that psychosocial treatments are effective in reducing use of illicit opioids, but have little effect on retention in treatment [1]. It should be recognised that with the small number of studies, this conclusion should be regarded as tentative only.

Maintenance Antagonist Treatment

An alternative to the use of opioid agonists is maintenance treatment with the μ-opioid receptor antagonist naltrexone. The aim of this approach is to prevent the client from experiencing opioid effects. While it is possible to overcome the effects of naltrexone with a sufficient dose of agonist, the usual dose of naltrexone makes this difficult to achieve. Naltrexone was first approved for use in opioid dependence treatment in the United States in 1984. Despite this relatively long period of clinical use, uptake of naltrexone treatment is generally low.

Pharmacology of Naltrexone

Naltrexone is an antagonist at μ-, κ-, and δ-opioid receptors, with particularly high affinity for the μ receptor. Over the range 20–200 mg naltrexone has been shown to produce dose-dependent antagonism of the euphoric effects of intravenous heroin for up to 72 h [66]. It has been suggested that the minimum plasma naltrexone concentration associated with a significant blockade of opioid effects is 1–2 ng/ml.

Naltrexone is almost completely absorbed following oral administration, but undergoes first-pass metabolism. Estimates of bioavailability have varied considerably, ranging from 5 to 60%. Naltrexone has a relatively short half-life of 2–6 h. The major metabolite, 6-β naltrexol, is a less potent antagonist but with a much long half-life. As a result, in stable maintenance clients, concentrations of 6-β naltrexol are usually higher than those of the parent medication naltrexone and 6-β naltrexol may contribute significantly to the antagonist effects of naltrexone.

Evidence of Effectiveness

While there is clear evidence that naltrexone is a potent antagonist able to block the effects of illicit opioids, outcomes from studies of effectiveness in maintenance treatment have generally been poor. Reviews of these studies have concluded that it should not be a recommended treatment option [36, 57]. A major problem with naltrexone is the low rate of retention in treatment. It is clearly an effective medication when taken on a daily basis for at least 3 months, but few individuals adhere to this treatment regimen. Clinical experience suggests that in a limited

group of highly motivated individuals, naltrexone can be very effective.

Problems Associated with the Use of Naltrexone

Naltrexone treatment is made difficult by the risk of precipitated withdrawal associated with the use of this medication in opioid-dependent individuals. Generally, individuals need to undergo withdrawal prior to administration of naltrexone. There have been attempts to shorten this process through administration of naltrexone while a person is heavily sedated or anesthetized, but there are significant safety concerns with this type of procedure (see below).

The reasons for the high dropout rate with naltrexone are not clear; however, it is possible to speculate on several possible sources. Withdrawal is not alleviated in an individual maintained on an antagonist, and indeed may made worse by administration of the antagonist medication. Naltrexone also has side effects that some individuals find uncomfortable, including nausea, headache, and dizziness. Recent evidence also suggests that naltrexone may not be a pure antagonist. Rather, in common with many other antagonists it may have inverse agonist properties that become evident in people who have been chronically exposed to opioids.

Depot and Implant Formulations

One approach to the low retention rates associated with naltrexone treatment is the development of implant and depot formulations of naltrexone. The aim is to produced sustained therapeutic plasma naltrexone concentrations for periods of weeks to months. To date, one such formulation has been approved in the United States for treatment of alcohol dependence. It produces plasma concentrations in the range 0.6–2 ng/ml and is effective over a 3–6 week period. Thus, if used for opioid dependence treatment, repeated administration would be required. Other longer acting formulations are also under development and, while not yet approved, have been widely used. These include surgically inserted implants that have a duration up to 6 months [35, 75]. While there are encouraging results from early studies with these naltrexone formulations [8], there are issues that need to be addressed, including the inter-individual variability in the plasma concentrations of naltrexone that are achieved.

Management of Opioid Withdrawal

While the main treatment option for opioid-dependence individuals is maintenance treatment with methadone or buprenorphine, some individuals have a preference or need for abstinence-oriented treatment. The major component of this may be a residential program or outpatient counseling based on relapse prevention methods. However, in order to reach abstinence, the client has to undergo withdrawal, and the discomfort associated with the acute phase of opioid withdrawal may lead to a high risk of relapse to illicit opioid use. In order to facilitate the transition to opioid abstinence, medications may be used to relieve withdrawal symptoms and psychosocial treatments may also be provided. In different contexts these may be applied on an inpatient or outpatient basis.

Management of Opioid Withdrawal with Opioid Agonists

As a result of cross-tolerance, any μ opioid agonist can potentially be used for treatment of opioid withdrawal. In practice, methadone was the most widely used opioid agonist for treatment of withdrawal, with buprenorphine becoming more common in recent years.

Protocols for methadone management of withdrawal from short-acting opioids vary

considerably. Peak doses are frequently in the range 30–40 mg/day reached in the first few days after cessation; doses are then gradually tapered at a rate of 5 mg/day or more. On an outpatient basis the tapering process may be considerably longer.

With buprenorphine, peak doses are frequently in the range 8–10 mg/day, with reductions around 2 mg/day for inpatients.

Comparisons of methadone and buprenorphine for treatment of withdrawal suggest that outcomes are similar [27]. Withdrawal symptom severity is approximately equivalent, but withdrawal symptoms may be of shorter duration with buprenorphine. This could be due to some additional withdrawal occurring following cessation of methadone treatment that does not appear to occur following cessation of short-term buprenorphine treatment.

More recently, other opioid agonist have been assessed for their efficacy in treatment of withdrawal, including tramadol [47] and dihydrocodeine [3]. Limited research to date suggests that both medications may have some role, but there is no evidence that they are superior to methadone or buprenorphine in this regard.

Use of α-2 Adrenergic Agonists

Early research on the nature of opioid withdrawal revealed that a significant component of the withdrawal syndrome is due to noradrenergic overactivity. This is manifested, in part, by signs and symptoms of sympathetic arousal, such as elevated heart rate, blood pressure and sweating. The action of α-2-adrenergic agonists in reducing this overactivity makes them potential medications for treatment of opioid withdrawal. Two such medications have been used: clonidine has been used in a number of countries over many years, while lofexidine has been used principally in the United Kingdom. The pharmacology of these medications is slightly different, with clonidine binding in a non-specific way to all three subtypes of α-2-adrenergic receptors and lofexidine binding to one subtype only. The consequence is that lofexidine has less hypotensive effect that clonidine. As hypotension is the main adverse effect from clonidine, lofexidine potentially has advantages in safety.

Comparisons of clonidine-based treatment with use of opioid agonists suggest that clonidine is considerably less effective than agonist treatment. For example, in a multi-site trial, buprenorphine + naloxone was clearly superior to clonidine for management of opioid withdrawal, whether this was carried out on inpatients or outpatients [46]. The major difference is that clonidine suppresses fewer symptoms than does methadone or buprenorphine. In clinical practice, clonidine is usually used in combination with other symptomatic medications because of its failure to alleviate symptoms such as diarrhoea and stomach cramps.

Lofexidine has recently been shown in a placebo-controlled trial to be more effective than placebo in amelioration of withdrawal [80]. In a review of earlier studies it was concluded the lofexidine had similar outcomes to clonidine, but with less effect on blood pressure [28].

Antagonist-Precipitated Withdrawal

When the goal for treatment of the individual is maintenance with naltrexone, the acute withdrawal phase may prove to be a barrier to treatment. As a means of addressing this, anesthesia and heavy sedation have been used to reduce withdrawal distress and the client is administered the first dose of naltrexone while under sedation or anesthesia. Several studies have compared anesthesia-assisted withdrawal with more conventional withdrawal management followed by naltrexone treatment. These studies show that short-term retention may be slightly higher for the anesthesia-based procedures, but at the cost of significantly higher risk of adverse events. After the first 3 months, differences in retention between groups tend to dissipate [7, 22, 53].

Conclusions and Future Directions

Compared to treatments of other types of drug dependence, development of pharmacotherapies for opioid treatment has had several advantages: a clearly defined receptor target in the μ-opioid receptor and a history of research in opioid pharmacology that has produced a range of agonist, partial agonist, and antagonist medications. Today, this has resulted in varied options for treatment of opioid dependence.

Compared to many other pharmacological treatments for a range of disorders, methadone and buprenorphine can be shown to be extremely successful. There are repeated demonstrations of marked declines in illicit drug use and increases in health status associated with treatment with these drugs. Treatment of withdrawal can also be shown to be effective with a choice between the partial agonist buprenorphine and α2 agonists, such as lofexidine and clonidine.

Despite a substantial body of research, there are many questions that remain unresolved. Further research is needed on the optimal range of psychosocial and ancillary treatments provided to individuals. While outcomes are extremely positive with methadone and buprenorphine treatment, there is significant room for improvement as a substantial minority of participants drop out during the first year of maintenance therapy. The duration of treatment is also an issue that is likely to receive increased attention with greater recognition of the potential adverse health effects of long-term opioid treatment.

One way in which the opioid treatment is likely to develop in future years is through the use of different formulations, particularly long-acting formulations. To date, naltrexone has not proven effective as a once-a-day oral medication. However, the development of depot and implant formulations may render naltrexone a much more effective medication that has a significant role in treatment of opioid dependence. Longer acting formulations are also being developed for buprenorphine, and these may result in significant changes in the way that drug is used.

Future attention will also focus on the diversity of opioid-dependent individuals. While illicit heroin users have formed the greatest number of people presenting for treatment of opioid dependence, there is an increasing number of people dependent on prescription opioids. It has yet to be determined whether standard treatments developed for heroin users will be as appropriate for prescription opioid users or whether they need to be adapted in some way. In addition, there is increasing recognition of the frequency of chronic pain problems among opioid-dependent individuals [67], who may also require some differences in approach.

Contents

Clinical Use of Methamphetamine

Methamphetamine is still available on the market as a controlled substance. Manufactured under the brand name Desoxyn® (Ovation Pharmaceuticals, Deerfield, IL), it has the same control II designation and restrictions that other stimulant medications such as amphetamine and methylphenidate have [65, 66]. Methamphetamine can be used for the treatment of attention-deficit hyperactivity disorder, for short-term weight loss in obese individuals, and for narcolepsy. The Food and Drug Administration has approved its use in the treatment of attention-deficit hyperactivity disorder in children aged 6–12. (Food and Drug Administration approval in adolescents and adults with attention-deficit hyperactivity disorder has not been pursued by any company.) The parameters for Food and Drug Administration approval in treating exogenous obesity include only short-term (i.e., a few weeks) usage only in the context of a weight reduction plan of a structured diet with exercise, and only for patients in whom obesity is refractory to alternative therapy, e.g., repeated structured diets, group programs, and other medications. Also, methamphetamine use in obesity is discouraged if the patient is below age 12. Interestingly, if one reviews the current treatment guidelines from the American Academy of Pediatrics and the American Academy of Child and Adolescent Psychiatry, methamphetamine is not listed as a recommended therapy for the treatment of attention-deficit hyperactivity disorder [1, 70]. Not surprisingly, its use among practicing physicians remains sparse to nonexistent.

The dosage recommendation by the package insert for attention-deficit hyperactivity disorder starts with 5 mg given in the morning, and proceeds with weekly 5-mg increases until optimal clinical response has been achieved [65]. The usual dosing for childhood attention-deficit hyperactivity disorder is 20–25 mg given as a once- or twice-daily dose. The recommended dosage in short-term obesity treatment is 5 mg taken 30 min before meals. Desoxyn® is only available in 5-mg tablets, and no generic manufacturer

currently exists. Abbott Pharmaceuticals produced Desoxyn® since its introduction in 1942 and sold its rights to Ovation Pharmaceuticals in 2002, although Abbott still has the facilities that manufacture the product. Abbott also produced a sustained-release form of methamphetamine named Desoxyn® Gradumet, utilizing a plastic matrix for gradual release of the methamphetamine. This product was available in 5, 10, and 15-mg dosages. Manufacturing of the Desoxyn® Gradumet was discontinued in 1999 due to "manufacturing difficulties".

No clinical trials are available by PubMed search for the use of methamphetamine in attention-deficit hyperactivity disorder or obesity. Interestingly, l-deprenyl (selegiline), a common medication for Parkinson's disease that is now used for treatment of depression in a patch delivery form, has been evaluated in clinical trials, the results of which suggest that it may be a good medication for children with attention-deficit hyperactivity disorder [2, 58]. This is relevant because selegiline has two major metabolites: amphetamine and methamphetamine [32].

Although methamphetamine has not received official Food and Drug Administration approval for use in narcolepsy, this appears to be the main use for which it is prescribed in North America [59]. Methamphetamine is used along with the other stimulants and l-deprenyl to treat the excessive sleepiness symptom of narcolepsy. The last trial evaluating methamphetamine in the treatment of narcolepsy was reported in 1993 and found that daytime sleepiness was successfully treated in adults with doses of 40–60 mg/day [57].

Although methamphetamine may have proven efficacy and safety in the treatment of childhood attention-deficit hyperactivity disorder and obesity, the risks of abuse and divergence along with its current negative reputation among health care workers and the public as a drug of abuse make it unlikely that many physicians will endorse its clinical use for these indications.

Diagnosis of Methamphetamine Abuse

Similar to the abuse of other drugs, methamphetamine abuse is characterized generally as a psychological and/or physiological dependence on the drug. The diagnosis is restricted to cases in which there has been long-term abuse leading to impaired social and/or occupational functioning. Based on *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision nomenclature, methamphetamine or amphetamine abuse and dependence disorders can be primary diagnoses, or the use of methamphetamine can be associated secondarily with the induction of psychotic disorders, intoxication delirium, mood disorders, anxiety disorders, sleep disorders, or sexual dysfunction. There is some controversy about the taxonomy of substance-induced psychosis [47], which likely requires some adjustments in the symptom checklist for diagnosis.

Escalation of Methamphetamine Use

As is the case with other drugs of abuse, methamphetamine is often used in binge-like patterns that are characterized by periods of high intake, followed by "crashes" after the drug is depleted. Individuals often show a developmental trajectory from experimentation with low doses, followed by escalation to higher binge intake, although the various patterns of intake that capture methamphetamine abuse across different individuals are difficult to characterize fully due to the clandestine nature of use within the population [6, 54]. Interviews with chronic methamphetamine abusers suggest that most individuals initiate methamphetamine use by self-administering the drug at long intervals, a so-called "recreational" pattern [12]. Many individuals subsequently progress into dose escalation, with shorter intervals between

successive self-administrations, thus manifesting as a "binge and crash" pattern. The escalation into higher dose intake may reflect, at least in part, tolerance to many of the peripheral and central effects of methamphetamine [14, 22].

Animal models have been developed to characterize the nature of escalation in methamphetamine use with repeated administration. Escalation of methamphetamine use occurs when rats are given extended access to intravenous methamphetamine in an operant conditioning chamber [42]. With this procedure, rats are first trained to press a lever to self-infuse methamphetamine intravenously during daily 1-h sessions. When subsequently shifted to 6-h daily sessions, rats will escalate their intake pattern across sessions. This escalation is typically noted when comparing the intake of methamphetamine within rats across 6-h sessions, as well as when comparing the intake of methamphetamine during the first hour of the 6-h session with the intake of rats maintained on daily 1-h sessions. Escalation of methamphetamine use enhances the ability of methamphetamine to prime reinstatement of extinguished lever-pressing [74], suggesting that the development of an escalating pattern of intake may exacerbate the rate of relapse in abstinent humans.

Escalation of methamphetamine use has a host of deleterious neurobehavioral effects. Compared with non-escalating use, escalating use of methamphetamine impairs performance on the novel object recognition test in rats [74], which parallels the type of neurocognitive impairments observed in abstinent methamphetamine abusers [54]. Escalation of methamphetamine use in rats also decreases the birth of glia (astrocytes and oligodendrocytes) and neurons in the medial prefrontal cortex, as well as promoting cell death [46]. The medial prefrontal cortex is part of a complex frontal neurocircuitry known to be involved in response inhibition and self-control [40]. Damage to the medial prefrontal cortex and related frontal structures may disinhibit behavior, thus yielding a compulsive escalation of methamphetamine intake. In addition, since the medial prefrontal cortex is involved in the processing of stimulant reward [27], it may be that damage to this region reduces the rewarding effect of methamphetamine, thus leading to a compensatory escalation of intake.

With extremely high doses of methamphetamine, profound hyperthermia and neurotoxicity are observed. In rats, neurotoxic effects can be observed following 1 day of high-dose methamphetamine treatment (10 mg/kg; 4 injections at 2-h intervals), an effect characterized by a marked depletion of monoamine levels across various cortical and subcortical structures [10, 23, 93]. This neurotoxicity parallels the reductions in dopamine markers measured with positron emission tomography or with postmortem sampling in human methamphetamine abusers [11, 49, 91, 94]. However, the effects observed in rats following a single 1-day treatment may be somewhat artificial, since human methamphetamine abusers do not typically reach high levels of use until long-term use leads to escalation of intake. In particular, a recent study by O'Neil et al. [64] demonstrated that the neurotoxic effects of a methamphetamine 1-day "binge" noted earlier in rats was blunted substantially when an escalating dose procedure was used. This decrease in neurotoxicity is not related to altered pharmacokinetics, as no changes in brain or plasma methamphetamine levels were observed following a methamphetamine binge in rats treated previously with escalating doses of methamphetamine.

Pharmacokinetics of Methamphetamine

While methamphetamine is used clinically as an oral formulation, illicit use of methamphetamine more typically involves self-administration via the inhalation, intranasal, or intravenous routes.

Unfortunately, information about the precise pharmacokinetics of methamphetamine use via these latter routes is sparse. Bioavailability via the intravenous route is 100%, whereas bioavailability via the intranasal route is 79% and via the inhalation route is 67% [28]. Although there is little opportunity to obtain blood samples from methamphetamine abusers during a binge, one study reported on blood concentrations taken from individuals arrested for suspicious behavior [52]. Among individuals in which methamphetamine was detected, the blood levels were found to range between ~0.5 and 10 μM. In controlled laboratory studies, the plasma half-life of methamphetamine was found to be approximately 10 h in humans, which is considerably longer than the plasma half-life of 70 min observed in rats [28]. In rats, the plasma concentration of methamphetamine reaches a maximum level faster following intraperitoneal administration (5–10 min) than following subcutaneous administration (20–30 min); however, ~42% of methamphetamine administered via intraperitoneal injection is subject to significant first-pass metabolism, which reduces bioavailability to ~52% [24].

The major inactive metabolite of methamphetamine is p-hydroxymethamphetamine, which can be detected readily in the urine of methamphetamine abusers [31]. Methamphetamine is p-hydroxylated to p-hydroxymethamphetamine in liver microsomes. Interestingly, in both rats and humans, a significant portion of methamphetamine is N-demethylated into amphetamine [8]. Amphetamine is also a potent psychostimulant that is p-hydroxylated to the inactive metabolite p-hydroxyamphetamine [34]. Because the conversion of methamphetamine to amphetamine is faster than the elimination of amphetamine from the blood, the concentration of amphetamine can actually exceed the level of methamphetamine when sampled at a long interval following a single bolus injection of intravenous methamphetamine [12]. In humans, the plasma half-life is slightly longer for l-methamphetamine than for d-methamphetamine (~14 h vs. 10 h) [53].

Human Studies in the Treatment of Methamphetamine Abuse and Dependence

A much greater portion of recent research in methamphetamine use pertains to treatment of abuse and dependence, and not its clinical usage. Methamphetamine abuse has increased to epidemic levels globally during the last two decades (and has not been completely abolished by the restrictions on pseudoephedrine purchasing), and the need for outcome-based studies on treatment has increased greatly [48, 71]. Although many scientists and practitioners seem to assume that the more extensive experience and literature on the treatment of cocaine abuse can be extrapolated to methamphetamine, the mechanisms of action between cocaine and methamphetamine are sufficiently different, along with differences in the surrounding drug culture, to warrant independent trials and the unique treatment of people who abuse methamphetamine and wish to quit [73].

A wide range of neuropharmacological strategies are being pursued in the search for an efficacious pharmacotherapy for methamphetamine addiction. Recent evidence can be found with a search of registered clinical trials (clinicaltrials.gov), which is now required for all institutional review board-approved clinical trials. A search of “methamphetamine dependence” and “methamphetamine abuse” yielded 40 to 48 listed studies. Although many of these studies were no longer active or not testing medications, a few representative Phase II and Phase III trials are currently ongoing to evaluate the effectiveness of pharmaceutical interventions for methamphetamine abuse and dependence.

The initial stage of treatment of methamphetamine abuse for some users is the medical management of withdrawal, particularly if the user is a binge user or heavy user. This phase is characterized by increased sleep, eating, depressive symptoms, anxiety, poor concentration, and craving-related symptoms [50]. The other common scenario for withdrawal is when the user is incarcerated and unable to obtain the drug [3].

A randomized, double-blind, placebo-controlled trial of mirtazapine in 31 outpatients undergoing treatment for methamphetamine withdrawal showed no benefit in terms of withdrawal symptoms or retention [15]. Mirtazapine did improve time of sleep in the 2-week period during which it was evaluated. An open-label comparison of modafinil (400 mg/day; $n = 14$) and mirtazapine (60 mg/day; $n = 13$) with treatment as usual with pericyazine (2.5–10 mg/day) demonstrated less withdrawal severity with modafinil and mirtazapine [51]; however, these results must be interpreted with caution since this study lacked a placebo-controlled, double-blind design.

While very few double-blind, randomized, placebo-controlled trials of pharmacotherapy for methamphetamine are available in the literature, there is no doubt that the number of controlled trials will increase in the near future with the establishment of the National Institute on Drug Abuse Methamphetamine Clinical Trials Group [19]. Carefully controlled and adequately powered clinical trials are extremely expensive. Human laboratory studies have been conducted in an effort to evaluate more efficiently the efficacy of potential pharmacotherapies for the treatment of methamphetamine abuse.

Early clinical studies have pointed to the potential pharmacotherapeutic benefit of bupropion, modafinil, and baclofen in treating aspects of methamphetamine dependence including memory function [45, 90]. Initial safety studies indicated that methamphetamine administration during bupropion treatment was safe [62] and that bupropion reduced acute methamphetamine subjective effects and cue-induced craving for methamphetamine, supporting the evaluation of bupropion for the treatment of methamphetamine dependence [63]. Subsequently, perhaps the largest placebo-controlled trial thus far evaluated the use of bupropion for the treatment of methamphetamine dependence [20, 80]. Twelve weeks of treatment with sustained-release bupropion (150 mg twice daily) versus placebo followed by a 30-day follow-up in five outpatient treatment facilities ($n = 152$ participants) showed some benefit when combined with behavioral interventions. In this study, bupropion treatment increased the number of weeks abstinent, although only the male subgroup that was ranked as low-to-moderate for methamphetamine usage showed statistically significant improvement over placebo.

A recently reported open-label study evaluated a sequential dosing algorithm consisting of hydroxyzine (a sedating antihistamine), flumazenil (a benzodiazepine antagonist), and gabapentin (an anticonvulsant) to treat methamphetamine dependence [88]. In that study, 50 adults with a diagnosis of methamphetamine dependence were administered hydroxyzine (50 mg), followed 1 h later by flumazenil (0.1–0.3 mg intravenously over 30 min) and gabapentin (initial dose 300 mg/day up to 1,500 mg/day), for 4 weeks, and were followed up for 8 weeks. Results showed a 47% reduction in methamphetamine use for the entire subject sample and a 65% reduction for the 36 subjects who completed the 8-week evaluation, suggesting efficacy of the sequential medication regimen [88]. Caution is needed, however, due to the open-label design employed and the fact that a placebo comparison was not included in the study design. In contrast, a previously reported study evaluating 16 weeks of treatment with either gabapentin (800 mg twice daily; $n = 26$), baclofen (20 mg 3 times daily; $n = 25$), or placebo ($n = 37$) using a randomized double-blind, placebo-controlled design showed that neither medication was superior to placebo, indicating a lack of efficacy in the treatment of methamphetamine abuse [33].

A recent placebo-controlled, cross-over study investigating the effects of another anticonvulsant, topiramate, showed that acute administration (up to 200 mg) enhanced, rather than attenuated, the positive subjective effects of methamphetamine [37]. More recently, a Phase II double-blind, placebo-controlled trial proof-of-concept study determined the safety and efficacy of chronic topiramate for the treatment of methamphetamine addiction [21]. Subjects ($n = 140$) meeting the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition criteria for methamphetamine dependence were

randomized to receive topiramate or placebo at 50 mg, escalating to 200 mg daily during weeks 1–5 and 200 mg daily during weeks 6–12. The primary outcome measure was abstinence from methamphetamine during weeks 6–12. Results showed that generally topiramate was well-tolerated and safe, although no significant topiramate treatment effect was found. However, exploratory data analyses indicated that subjects ($n = 35$) whose baseline use was less than 18 days out of the previous 30, or who had negative urine prior to randomization ($n = 26$), experienced a topiramate treatment effect ($p = 0.03$ and 0.02, respectively). Thus, despite the failure of the primary protocol outcome variable, a subset of "light" methamphetamine users were identified as positive responders to treatment.

A small open-label study of 11 methamphetamine-dependent veterans showed decreased use with risperidone (average dose, 3.6 mg/day) over a 4-week treatment period [55]. A randomized, double-blind trial evaluating 80 participants with concurrent *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition-defined bipolar I or II and methamphetamine or cocaine dependence showed that both quetiapine and risperidone, serotonin-2 and dopamine D2 receptor antagonists, improved the manic, mixed, and depressive symptoms, as well as reducing drug craving; however, this interpretation is limited by the lack of a placebo control group [60].

A recent small preliminary, randomized, double-blind, placebo-controlled trial of ondansetron, a serotonin-3 receptor antagonist, has been reported for participants seeking treatment for methamphetamine dependence [36]. This 8-week trial evaluated ondansetron (0.25, 1, or 4 mg twice daily) vs. placebo along with cognitive behavioral therapy and found no benefits of ondansetron on any measured markers of methamphetamine use, withdrawal, or craving. Another trial demonstrated that sertraline, a serotonin transporter inhibitor (50 mg twice daily), actually worsened some parameters of methamphetamine abuse treatment over placebo [81].

Aripiprazole, a dopamine D2 receptor partial agonist approved by the Food and Drug Administration for the treatment of schizophrenia, has been evaluated in human laboratory studies in which volunteers learned to discriminate the interoceptive effects of 15 mg of d-amphetamine [84]. Aripiprazole at 20 mg, but not at 10 mg, attenuated the discriminative stimulus effects of d-amphetamine; however, the high dose alone also produced performance decrements. The low dose of aripiprazole attenuated some of the subject-rated effects of d-amphetamine and did not impair performance, suggesting that aripiprazole may have therapeutic benefit [84]. In a subsequent double-blind inpatient study employing 16 methamphetamine-dependent subjects, treatment with aripiprazole (15 mg orally) was associated with significantly higher ratings on the Addiction Research Center Inventory subscales, reflecting euphoria and amphetamine-like effects following the administration of methamphetamine (15 and 30 mg intravenously) [61]. Further, aripiprazole was found to have no effect on abstinence-induced and cue-induced craving over the time course of treatment, suggesting that this dopamine D2 receptor partial agonist is not likely to be an effective treatment for methamphetamine dependence.

A double-blind, placebo-controlled, between-groups study employing a human laboratory model of intravenous methamphetamine self-administration evaluated the effect of rivastigmine, an acetylcholinesterase inhibitor, as a treatment of methamphetamine abuse [17]. In this study, 0 or 30 mg of intravenous methamphetamine or placebo was sampled initially. Subsequently, subjects chose either to self-administer a 3-mg dose of methamphetamine or placebo or to receive a monetary alternative ($0.05–$16). The number of choices for methamphetamine infusion was greater than for placebo, and the number of money choices was greater when placebo was available than when methamphetamine was available. Rivastigmine (1.5 or 3 mg; $n = 6–9$) did not alter the total number of methamphetamine infusions compared with placebo ($n = 7$); however,

the higher dose of rivastigmine reduced the positive subjective effects of self-administered methamphetamine. Thus, as has been reported previously for other drugs of abuse, a reduction in methamphetamine-induced subjective effects does not necessarily predict a reduction in drug self-administration.

There is a general consensus that any medication for methamphetamine abuse will be most effective in the context of concomitantly delivered behavioral therapies, much like other drugs of abuse [77]. The most common therapies employed and studied have included cognitive behavioral therapy, contingency management, or both [43]. Outcome-based studies on cognitive behavioral therapy have shown reductions in methamphetamine abuse and relapse of abuse [9]. Contingency management procedures, though effective when individuals are actively in drug treatment, have not been shown to have benefits once the individuals are "on their own" [75].

Mechanisms of Methamphetamine Reward

In addition to the clear evidence of abuse on the "street", methamphetamine has been shown to be a potent reinforcer in humans tested under highly controlled laboratory conditions. Methamphetamine reward is manifest both as a subjective report of "liking" and as a behavioral choice of methamphetamine self-administration over placebo. (We use the term "reward" to refer to both subjective and behavioral effects, whereas "reinforcement" is a more specific term that refers to behavioral effects only.) Hart et al. [30] evaluated healthy research volunteers in a residential laboratory facility for their response to oral methamphetamine (5 or 10 mg) or placebo. Over an 8-day choice procedure, subjects had the opportunity to self-administer the dose of methamphetamine that they most recently sampled or to receive a $1 voucher. As expected, methamphetamine was chosen significantly more than placebo, and the sampled methamphetamine (10 mg) increased subjective ratings indicative of drug liking, demonstrating that oral methamphetamine is rewarding in humans. In another study from this same laboratory, Comer et al. [13] evaluated the effects of repeated oral methamphetamine or placebo administration in humans in a residential laboratory. Relative to placebo baseline, tolerance developed to methamphetamine's positive subjective effects across repeated administrations, which may be a factor leading to escalating use among at-risk individuals.

Methamphetamine reward may be dependent to some extent on the pharmacokinetics of the drug. As discussed by Lile [44], drug reward is enhanced when there is a rapid onset of effect, which may explain why methamphetamine abusers tend to prefer the inhalation and intravenous routes of delivery over the oral route. In addition, the rate of self-administration may be determined by the offset (elimination half-life) of the drug effect, with longer offset durations leading to less frequent self-administrations. These general principles may be important points to consider in attempts to develop effective pharmacotherapies for methamphetamine abuse. In particular, therapeutic agents designed to substitute for or block the rewarding effect of methamphetamine should ideally have a slow onset of action and a prolonged duration of action in order to minimize their potential for abuse. Nonetheless, it may be desirable for pharmacotherapeutic agents to have some rewarding effect because this will enhance patient compliance.

To better understand the neurobiological basis of methamphetamine reward and to develop new potential pharmacotherapies, a number of laboratory animal models have been developed. One widely used model is drug self-administration, which is based on fundamental principles of operant conditioning. In this model, rodents or non-human primates are trained to make an operant response (e.g., lever press) in order to receive a drug infusion. Responding is reinforced typically on a fixed ratio schedule in which a fixed number of responses lead to an

infusion. Alternatively, a progressive ratio schedule can be used in which the number of responses required to earn an infusion increases incrementally after each infusion until a "break point" (cessation of responding) is achieved; the progressive ratio schedule is thought to estimate the relative effectiveness of the drug to serve as a reinforcer. As expected based on human literature, both rats and non-human primates self-administer methamphetamine avidly and in a dose-dependent manner [4, 29, 72].

Another model for measuring methamphetamine reward in rodents is the conditioned place preference preparation. This is a Pavlovian procedure in which the drug is paired with one distinct context and placebo is paired with a different context. When allowed to choose between the two different contexts in a drug-free state, rats show a preference for the drug-paired context. This preference is thought to reflect a secondary rewarding effect of the context due to its association with the drug, and it may be a model of contextual control of drug seeking, rather than a direct measure of the primary reinforcing effect of the drug per se [5]. Similar to self-administration, methamphetamine conditioned place preference has been demonstrated in both rats and mice [23, 26, 41].

A third animal model for evaluating methamphetamine reward is the brain stimulation reward preparation. In this model, a bipolar stimulating electrode is implanted chronically into the lateral hypothalamus, a region through which courses the medial forebrain bundle. The medial forebrain bundle connects dopaminergic cell bodies in the ventral tegmental area to the limbic terminal fields of the nucleus accumbens and prefrontal cortex, and stimulation of this pathway is highly reinforcing. Rats are first evaluated for their brain stimulation reward threshold by adjusting the frequency of stimulation pulses in a series of ascending and descending increments. When a drug of abuse is subsequently administered, the brain stimulation threshold is lowered, thus providing an index of rewarding strength. Corroborating the findings with self-administration and conditioned place preference, methamphetamine has been shown to decrease the threshold for brain stimulation reward [83].

Animal models, coupled with neuroimaging technologies in humans, have uncovered some of the basic neural mechanisms that underlie methamphetamine reward. While the reward circuitry is complex, involving multiple circuits and neurochemical systems [39], dopaminergic neurotransmission in the mesocorticolimbic dopamine pathway undoubtedly plays a critical role in the psychostimulant effects of methamphetamine [35, 68, 79]. Methamphetamine reward results from increased dopamine release in limbic terminal fields, which is regulated by the vesicular monoamine transporter [87]. Methamphetamine increases extracellular dopamine concentrations by inhibiting the action of the vesicular monoamine transporter, which sequesters dopamine into vesicular stores, as well as by inhibiting monoamine oxidase, which diminishes dopamine metabolism, thereby making cytosolic dopamine more available for methamphetamine-induced reversal of the plasmalemma dopamine transporter [18, 85]. In addition to these dopamine-regulating cellular targets in the limbic terminal fields, a number of other systems impinge on reward-relevant dopamine neurons, including gamma-aminobutyric acid (GABA)-ergic, glutamatergic, and nicotinic acetylcholine receptors localized within the midbrain ventral tegmental area region [16]. In addition, prefrontal cortical regions are thought to provide descending input into both the dopaminergic cell body and terminal regions [39]. Consistent with this latter view, functional magnetic resonance imaging analyses in humans indicate that, in addition to increasing neural activity in the nucleus accumbens, methamphetamine increases activity in the orbitofrontal and anterior cingulate cortices [92]. Further, using functional magnetic resonance imaging and positron emission tomography imaging, abnormalities in brain structure and chemistry are observed in individuals using methamphetamine, including reductions in the density of dopamine transporters, dopamine D2 receptors, serotonin transporters, and vesicular

monoamine transporters, particularly in the striatum [11].

A greater understanding of the components of the neurocircuitry involved in methamphetamine reward has provided new opportunities for targeting the development of medications to treat methamphetamine addiction [89]. As mentioned previously, the dopamine transport inhibitor bupropion has been shown to be effective in a double-blind, placebo-controlled clinical trial [20]. However, since bupropion also is a nicotinic acetylcholine receptor antagonist [56, 82], it is not clear whether its efficacy is due to blockade of the dopamine transporter, blockade of nicotinic receptors, or blockade of both mechanisms concomitantly. Preclinical studies have also provided evidence that blockade of the vesicular monoamine transporter with lobeline or related synthetic analogs may be a useful new approach [18, 29]. Moreover, although direct blockade of dopamine D2 receptors is not a likely approach to treat methamphetamine abuse due to the induction of extrapyramidal side effects, effort has focused on atypical antipsychotics that work at either serotonin-2 receptors [86] or dopamine D3 receptors [83].

In addition to the direct effects of medications on the plasmalemma and vesicular dopamine transporters and receptors, an alternative approach is to target systems that modulate mesocorticolimbic dopamine neurons. For example, preclinical work has indicated that medications that enhance gamma-aminobutyric acid transmission by blocking the metabolic enzyme gamma-aminobutyric acid transaminase may be useful to treat methamphetamine abuse [25]. At least one study has shown that the gamma-aminobutyric acid transaminase inhibitor, γ-vinyl gamma-aminobutyric acid, is safe in human abusers, even among those who continue to use methamphetamine [7]. Gamma-aminobutyric acid receptor selective agonists are also under investigation [26, 72], as are glutamate receptor antagonists [38].

Several other novel, albeit unproven, approaches for treating methamphetamine abuse are in the pipeline. For example, novel congeners of the iboga plant alkaloid ibogaine may be useful [67], although the potential utility of these alkaloids awaits characterization of their neuropharmacological mechanisms of action. Additionally, a recent study indicates that medications that suppress the endogenous opioid peptide nociceptin may attenuate methamphetamine reward [78]. Another approach is a therapeutic vaccine to treat methamphetamine addiction [69]. Regardless of the mechanism, however, any pharmacotherapeutic approach for treating methamphetamine abuse should be considered an adjunct to behavioral therapies. As mentioned earlier, the utility of contingency management and cognitive behavioral therapy to maintain abstinence rates among methamphetamine abusers has been demonstrated [9, 43, 75, 76], and further work is needed to determine whether the combination of pharmacotherapy and psychosocial interventions has a synergistic effect.

Conclusions

Methamphetamine abuse has increased to epidemic levels during the last 20 years, and the need for outcome-based studies on treatment has greatly increased. Currently, no medications have been approved by the Food and Drug Administration for the treatment of methamphetamine abuse. Recent advances in the understanding of the neurocircuitry involved in methamphetamine reward have provided new opportunities and rational targets that can be exploited for the development of pharmacotherapies to treat methamphetamine addiction. The efficacy and safety of these candidate pharmacotherapies require evaluation in adequately powered, double-blind, placebo-controlled trials; however, human laboratory studies have the potential to evaluate more efficiently candidate treatments and provide information on whether the more expensive clinical trials are warranted. Currently, a wide range of neuropharmacological strategies are being pursued in the search for an efficacious pharmacotherapy for methamphetamine abuse.

Potential Pharmacotherapies for Cannabis Dependence

Carl L. Hart and R. Douglas Shytle

Contents

Introduction

Cannabis, which comprises Δ^9-tetrahydrocannabinol-containing products including marijuana and hashish, is the most widely used illicit drug in the world [2], with nearly 150 million people reporting annual use [122]. In the United States alone, an estimated 14.8 million individuals report current marijuana use, defined as use within the past 30 days [111]. Most users of cannabis consume the drug infrequently and without apparent negative consequences. There are, however, a small proportion of users who experience problems related to frequent cannabis use. It has been estimated that 9% of cannabis users will become dependent [3]. Although this number is low compared with dependence rates for tobacco consumers (about a third of tobacco users will become dependent), rates of cannabis dependence in several countries have increased substantially over the past decade [11, 111] as well as the number of individuals seeking treatment for cannabis-related problems [109, 112]. The terms "dependence" and "dependent" encompass the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition, text revision) and the International Statistical Classification of Diseases and Related Health Problems, 10th revision.

Although the total number of cannabis-dependent individuals who seek treatment is higher than the number of those who seek treatment for other illicit drugs, the relative proportion of those seeking treatment for cannabis dependence is low. For example, in the U.S., the percentage of regular drug users who received treatment for a cannabis use disorder (includes cannabis abuse and dependence) in 2006 was less than 10%, whereas this number was nearly 40% for cocaine users [111]. There are several possible explanations for the relatively low percentage of cannabis treatment seekers including the fact that many individuals perceive cannabis as a relatively innocuous drug [134]. However, several investigators have reported that heavy, daily cannabis use is associated with an

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_53,

abstinence syndrome upon cessation of the drug (for review, see [19]). Although cannabis withdrawal is not life threatening, the accompanying symptoms such as irritability, anxiety, sleep disruptions, aches, and pains can be quite unpleasant. In addition, many individuals seeking treatment for cannabis dependence reported that these symptoms made it more difficult to maintain abstinence [110, 16, 30].

Heavy cannabis use has also been reported to produce adverse effects on cognitive functioning (e.g., [101, 102, 108]). For example, Bolla and colleagues [12] reported that heavy use of cannabis was associated with poorer cognitive performance on a wide range of tasks (e.g., memory and executive functioning) and that decreased performance persisted as long as 28 days of abstinence. Regular cannabis smoking is also associated with pulmonary dysfunction similar to that which is seen in regular tobacco smokers (for review, see [73, 125]). Finally, recent data indicate that cannabis smoking can precipitate psychosis in individuals susceptible to developing a psychotic disorder (e.g., [5, 64, 92]; see also [4]).

Some investigators have speculated that the low percentage of individuals seeking treatment for cannabis dependence may be related to the fact that there are relatively few specific treatments for cannabis dependence [109], although this issue does not appear to deter treatment-seeking cocaine abusers. Regular cannabis users may also be reluctant to participate in treatment programs dominated by alcohol-, cocaine-, and opioid-dependent individuals. There are data indicating that some cannabis dependence-specific therapies are successful in decreasing drug use and many associated negative consequences (for review, see [85, 88]). Other data, however, show that cannabis-dependent individuals exhibit high rates of relapse similar to those found with other substances of abuse [91]. To date, the majority of treatment studies have investigated behavioral/psychosocial therapies. The high relapse rate and the sheer number of cannabis-dependent individuals, however, underscore the importance of developing pharmacotherapies for those individuals who may be less responsive to other treatments. Pharmacotherapies may be used alone, in combination with behavioral/psychosocial therapies, or in a staged manner following inadequate response to behavioral/psychosocial therapies. In general, the problem in treating substance-dependent individuals has been less that of treating withdrawal and more of preventing relapse. However, treating withdrawal symptoms continues to be an important first step in eventual success and one that clinicians often need to begin this therapeutic endeavor. The treatment of cannabis dependence in this regard is similar to efforts under way for decades for opioids, cocaine, and alcohol dependence.

This chapter represents an update of Hart [61]. It reviews findings from recent research on cannabinoids (a group of compounds related to $\triangle^9$-tetrahydrocannabinol, the primary psychopharmacologically active constituent of marijuana smoke) that may be relevant for the development of pharmacotherapies for cannabis dependence. Data from studies that assessed the ability of medications to attenuate cannabinoid-related abstinence symptoms in laboratory animals and in humans will be reviewed. In addition, results from studies that have investigated the effects of pharmacological agents on response to cannabinoids are reviewed because these data may prove useful in informing the development of cannabis relapse prevention medications. The review begins with a brief overview of the different phases of the dependence cycle that cannabis pharmacotherapies might target as well as cannabinoid relevant neuropharmacology.

Detoxification and Relapse Prevention or Maintenance Phase

Medications are typically initiated at two different phases of the dependence cycle: during detoxification and prevention of relapse. Detoxification is usually an *initial and immediate goal* during which medications are administered in order to assuage unpleasant abstinence symptoms that may appear following abrupt

cessation of drug use, e.g., the administration of a benzodiazepine during alcohol withdrawal. Medications used in the detoxification phase are also sometimes used in the relapse prevention or maintenance phase, e.g., nicotine replacement medications. Thus, the distinction between a detoxification medication and a relapse prevention medication is sometimes less clear.

Maintenance medications can be viewed as a *longer-term strategy* used to help the dependent individual avoid relapsing to the abused drug. There are at least three major maintenance strategies. First, agonist or substitution therapy is used to induce cross tolerance to the abused drug. For example, methadone, a long-acting μ-opioid agonist, and nicotine replacement medications have been used for opioid dependence and tobacco dependence, respectively, as agonist maintenance treatments to prevent relapse and cravings in individuals attempting to maintain abstinence. Agonist maintenance agents typically have safer routes of administration and diminished psychoactive effects, relative to the abused drug. Second, antagonist therapy is used to produce extinction by preventing the user from experiencing the reinforcing effects of the abused drug. For example, the naltrexone blocks opioid mu receptors and agonists' associated effects, and is therefore used as an antagonist therapy for opioid dependence. Finally, punishment therapy produces an aversive reaction following ingestion of the abused drug. For example, disulfiram (Antabuse®) is used in the treatment of alcohol dependence. Disulfiram inhibits aldehyde dehydrogenase, a major enzyme involved in alcohol metabolism, thereby preventing the complete breakdown of alcohol, and the resultant accumulation of aldehyde produces unpleasant symptoms including headache, vomiting, and breathing difficulties.

Cannabinoid Neuropharmacology

Over the past two decades, data from basic research have contributed to an increased understanding of neuronal mechanisms involved in the effects of cannabinoids. Although a comprehensive review of cannabinoid neuropharmacology is beyond the scope of the current manuscript and such reviews have already been published (e.g., [42, 70]), a brief overview might be informative for the rationale regarding some of the medications presented in this review. Cannabinoids bind to two types of receptors: cannabinoid receptor 1 and cannabinoid receptor 2 (CB_1 and CB_2). These receptors are much more abundant than opioid receptors [105] suggesting that the potential actions of cannabinoids are widespread. CB_2 receptors are found mainly outside of the brain in immune cells, suggesting that cannabinoids may play a role in the modulation of the immune response. CB_1 receptors are found throughout the body, but primarily in the central nervous system. The regions in which central nervous system CB_1 receptors reside may provide some clues about their functions. For example, the highest density of CB_1 receptors has been found in cells of the basal ganglia, which primary components include the caudate nucleus, putamen, and globus pallidus (for review, see [65, 98]). Cells of the basal ganglia are involved in coordinating body movements. Other regions that also contain a larger number of CB_1 receptors include: the *cerebellum*, which coordinates fine body movements; the *hippocampus*, which is involved in aspects of memory storage; the *cerebral cortex*, which regulates the integration of higher cognitive functions; and the *nucleus accumbens*, which is involved in drug reinforcement. This suggests that endogenous cannabinoid activity modulates a broad range of behaviors.

Data from microdialysis studies have revealed that dopaminergic transmission is increased in the nucleus accumbens following acute administration of cannabinoid agonists [26, 114], and this effect is blocked by the CB_1 antagonist rimonabant (SR 141716A). While it is possible that cannabinoid-induced dopamine elevations are a result of direct stimulation of dopamine neurons, accumulating evidence suggest a more likely mechanism of action is via disinhibition of dopamine-containing neurons that are under tonic gamma-aminobutyric

acid-ergic inhibition [113]. Consistent neurochemical correlates during withdrawal from cannabinoids include reduced dopaminergic activity along the ventral tegmental area-nucleus accumbens pathway [34, 115] and upregulated expression and release of corticotropin-releasing hormone in the central nucleus of the amygdala [22, 104]. This growing body of knowledge, coupled with increasing numbers of individuals seeking treatment for cannabis dependence, has prompted research on the effects of cannabinoid antagonism on cannabis-associated reinforcement and research on the effects of cannabinoid agonists, as well as medications that decrease the stress response, on cannabis withdrawal.

Abstinence Symptoms Treatment Medications

Studies of Laboratory Animals

Prior to the availability of a cannabinoid antagonist, findings from investigations of cannabinoid-related withdrawal symptoms in laboratory animals were inconsistent. Some researchers found evidence of withdrawal symptoms upon abrupt cessation of drug administration [9, 77], while others failed to observe signs of withdrawal when drug administration was terminated (e.g., [33, 57]). Administration of the cannabinoid antagonist rimonabant, however, produces a reliable withdrawal syndrome in laboratory animals undergoing chronic cannabinoid treatment (e.g., [8]). Behaviorally, this syndrome is most consistently characterized in rodents by wet-dog shakes, paw tremors, piloerection, and increased grooming.

The fact that cannabinoid-related withdrawal symptoms are reliably produced in laboratory animals not only provided evidence for physiological cannabinoid dependence, but it also provided an opportunity to examine systematically pharmacological agents for effectiveness in attenuating these symptoms. Table 1 summarizes selected studies that have employed laboratory animals to evaluate medication effects on precipitated cannabinoid withdrawal symptoms. Although the number of studies conducted evaluating potential cannabinoid treatment medications continues to grow, compared with medications development research for other drugs of abuse, this number is conspicuously low. In one earlier study, Verberne et al. [127] administered intravenous Δ^9-tetrahydrocannabinol in escalating doses for five consecutive days to rats; on day six, an acute dose of Δ^9-tetrahydrocannabinol or placebo was given 30 min prior to an intraperitoneal injection of clomipramine, a serotonin reuptake inhibitor. The investigators reasoned that clomipramine would precipitate withdrawal in animals chronically exposed to Δ^9-tetrahydrocannabinol because fluoxetine,

Table 1 Published studies that have employed laboratory animals to evaluate medication effects on precipitated cannabinoid withdrawal symptoms

Investigators	Species	Medication (dose)	Precipitant (dose)	Outcome
Verberne et al. [127]	Rat	Δ^9-THC (6 mg/kg, i.v.)	Clomipramine (15 mg/kg, i.p.)	Δ^9-THC reduced withdrawal symptoms.
Lichtman et al. [83]	Mouse	Δ^9-THC (30 mg/kg, i.v.)	Rimonabant (10 mg/kg, i.p.)	Δ^9-THC reversed withdrawal-related paw tremors.
Lichtman et al. [83]	Mouse	Clonidine (0.125 – 1 mg/kg, i.p.)	Rimonabant (10 mg/kg, i.p.)	Clonidine reversed withdrawal-related paw tremors and head shakes.
Anggadiredja et al. [1]	Mouse	Prostaglandin E_2 (1, 3.2 μg, i.c.v.)	Rimonabant (10 mg/kg, i.p.)	Prostaglandin E_2 lessened withdrawal symptoms.
Cui et al. [31]	Rat	Lithium (4, 8, 16 meq/kg)	AM281 (3 mg/kg, i.p.)	Lithium blocked withdrawal symptoms.
