For Carolina, and the beautiful dreams and great love that we share together, and the gift of our wonderful son. For Efun, and our eternal bond of family and love. For my father, whom I wish I understood better. For my mother, whom I remember, think of so very fondly, and pray for each day.

Preface

The book *Addiction Medicine: Science and Practice* is my attempt to bridge the gap between the explosion of neuroscientific and behavioral knowledge in the past three decades and treatment delivery in clinical practice. As such, it should fulfill the role of a comprehensive textbook that integrates addiction medicine from its scientific underpinnings to the treatment of patients in clinical settings.

In many ways, addiction is a spectrum of disorders that expands as our knowledge grows about the exposure and acquisition of habit-forming behaviors. This expansion shall eventually bring diseases not considered previously as addictions within its sphere. Due to our increasing use of in silico systems, technology-related behaviors might also become prominent areas of addiction research and treatment in the years to come. Our knowledge about the phenomenology and classification of addictive disorders is rising, and novel concepts related to the staging of disease are being developed.

We have learned that the neurobiological correlates of addictions related to substances, behaviors, or both appear to be similar. This discovery opens up new vistas for addiction treatments across a spectrum of disorders. Harnessing the power of understanding addiction at the level of the cell and molecular events across species with our ability to demonstrate the impact of these changes on the behavior of the organism shall usher in an era of personalized medicine. Innovative treatments and disease concepts are being advanced. New efficacious medicines for the treatment of addiction are being discovered. Indeed, our own immune system might someday be used to fight an addiction to various substances.

Culture, race, and ethnicity also have a major influence on how addictive behaviors can manifest or are expressed, and how they are viewed by society. Family traditions, religious beliefs and practices, and social setting characteristics are all very relevant and important in understanding addiction. Consequently, this book gives appropriate attention to these very relevant factors.

Taking all these essential factors into consideration, I conceptualized the bold design and challenge of a book that not only incorporated and highlighted cutting-edge science but also provided up-to-date and evidence-based treatments for addiction. This book provides a fresh approach that builds upon what the best experts know today—that for most, addiction is a

treatable disorder and the outcome need not always be poor. Modern addiction treatment is firmly in the arena of medicine, and is moving rapidly into general clinical practice, with evidence-based procedures replacing the much less well or formally evaluated and more expensive residential programs. For many individuals with an addictive disorder, an office-based approach enables optimum management of the disease whilst allowing engagement in work, play, social relationships, and the general business of daily life to continue.

I am most grateful to the distinguished group of leading experts who have come together to produce this book. These experts, united in their mission to deliver a scholarly and comprehensive book, came from the basic and clinical sciences and treatment delivery fields. I am glad for all that they have taught me through their contributions, for the knowledge they shall distill to all who read this book, and for their dedication to alleviating the suffering of those afflicted by the disease of addiction.

Charlottesville, Virginia Bankole A. Johnson, DSc, MD

Acknowledgment

I am most grateful to Robert H. Cormier, Jr., whose editorial assistance was instrumental in completing this project, and whom I also am proud to call my friend.

Part I
History, Perspectives, Epidemiology, Diagnosis, and Classification

Emerging Health Perspectives

H. Westley Clark and Linda Hutchings

Contents

Introduction

This chapter will address a few issues that are emerging as critical health issues with substance use perspectives. First, there will be a brief review of the epidemiology of substance use; this will be linked to the growing problem of prescription drug abuse. Second, the issue of screening and brief intervention for substance use disorders will be addressed. Then, the issue of new technologies as a vehicle for enhancing substance use disorder services will be reviewed. Finally, the issue of how to pay for substance use disorder services will be reviewed.

The epidemiology of substance use makes it quite clear that clinicians of any stripe will encounter patients or clients who use or misuse alcohol or psychoactive drugs. Therefore, the inter-relationship between substance use disorders, brain function, and treatment outcome should be of interest to the clinician concerned with patient and client health.

Alcohol Use

The National Survey on Drug Use and Health annually interviews approximately 67,500 persons to establish national estimates of substance use [31]. More than half of Americans aged 12 or older report being current drinkers of alcohol in the 2007 survey; this means that almost 127 million people have had at least one drink in the past month. Other than underage drinking, current drinking is not inherently problematic. However, more than one-fifth (23.3%) of persons aged 12 or older admit to binge drinking, which the National Survey on Drug Use and Health defines as five or more drinks on a single occasion. Binge drinking is associated with a number of acute adverse events, including

motor vehicle accidents, trauma, domestic violence, assaults, homicides, child abuse, suicide, fires, boating accidents, alcohol poisoning, and a number of high-risk activities which threaten the health and well-being of the consumer. Another confounding population of alcohol consumers is the heavy drinking population. It is estimated by the National Survey on Drug Use and Health that 17 million people or 6.9% of the population 12 or older admit to heavy drinking (binge drinking on at least 5 days in the past 30 days).

Naturally, alcohol consumption rates vary by—among other things—age, gender, and race/ethnicity. Among young adults aged 18–25 years of age, consumption rates are the highest in the current use, binge drinking and heavy alcohol use ranges. This age range is also associated with higher risk-taking and the consequences associated with risk-taking. Thus, physicians and other clinicians who provide primary and/or, emergency room care employment or college health practitioners are more likely to see patients in this age group for a variety of alcohol-related injuries or conditions.

Among adolescents and young adults under the age of 21, alcohol consumption rises fairly rapidly from 3.5% for those who are 12 or 13 to 50% for those who are between the ages of 18–20. Figure 1 shows the various levels of alcohol consumption for the 12–20 years olds by age grouping. It is apparent from these prevalence rates that late adolescents and young adults are likely to engage in substantial alcohol consumption. Knowing whether alcohol use is related to a presenting physical or psychiatric complaint should be helpful to the clinician. While many young adults, 18–25, will visit a clinician for very limited purposes, such as a job- or school-related physical, the epidemiology of alcohol use clearly offers the clinician an opportunity to address the issue of alcohol-related medical, social or behavioral problems. Clinicians should take advantage of such opportunities.

Illicit Drug Use

In 2007, there were an estimated 19.9 million Americans aged 12 or older who admitted to using at least one illicit drug in the past month according to the National Survey on Drug Use and Health. This represented an estimated 8.0% of the population 12 or older. For the purposes of the survey, illicit drugs included marijuana/hashish, cocaine (including crack), heroin, hallucinogens, inhalants, or prescription-type psychotherapeutics used non-medically. Marijuana is the most commonly used illicit drug by Americans, with 14.4 million people admitting to past-month use. The second category of prevalent drug use falls into the

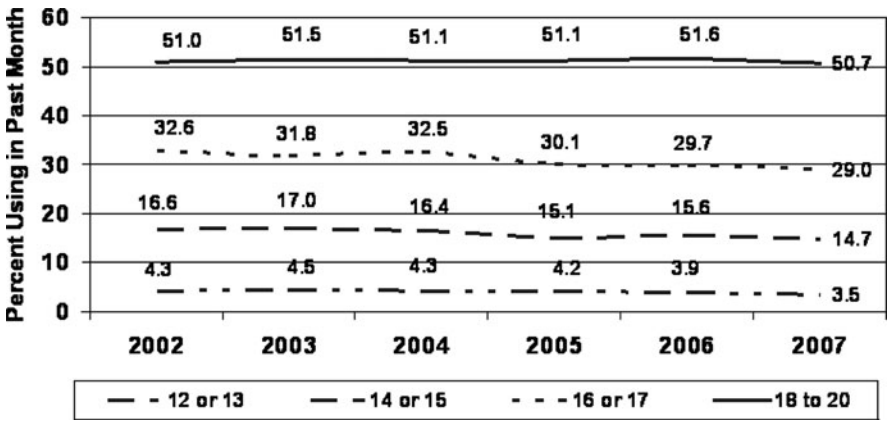

Fig. 1 Current alcohol use among persons aged 12–20: 2002–2007. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

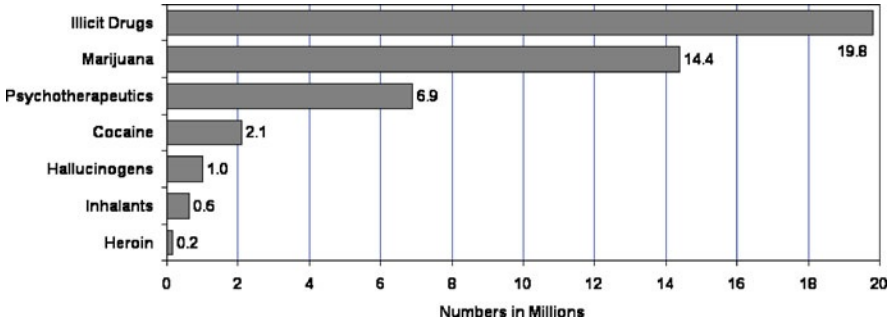

Fig. 2 Past-month use of specific illicit drugs among persons aged 12 or older: 2007. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

category of non-therapeutic or non-medical use of prescription drugs (see Fig. 2).

Specific categories of psychotherapeutics include a range of substances, including pain relievers, sedatives, tranquilizers, and stimulants. National Survey on Drug Use and Health data for those 12 and older reveal a consistent elevation of non-medical use of prescription pain relievers from 2002 to 2007 (see Fig. 3).

It has been recognized that prescription opioids are associated with higher rates of abuse and dependence than with other substances, as well as increased mortality [13]. The misuse of benzodiazepines in combination with therapeutic opioids can create problems with respiration and cardiac functioning, predisposing to respiratory depression or cardiac dysrhythmia leading to death.

Age Variations

However, as with alcohol use and misuse, there are age variations in illicit drug use. Among adolescents, National Survey on Drug Use and Health data indicate that there has been a progressive decline in the prevalence of drug use among adolescents aged 12–17 years of age (see Fig. 4). National Survey on Drug Use and Health data are supported by the Monitoring the Future Data, both surveys revealing the same basic trends [18].

It is important for primary care clinicians to recognize that the progress being made in reducing the substance use of adolescents has not resulted in an elimination of the problem of drug use. While substantial progress has been made, much effort needs to be exercised to keep up the

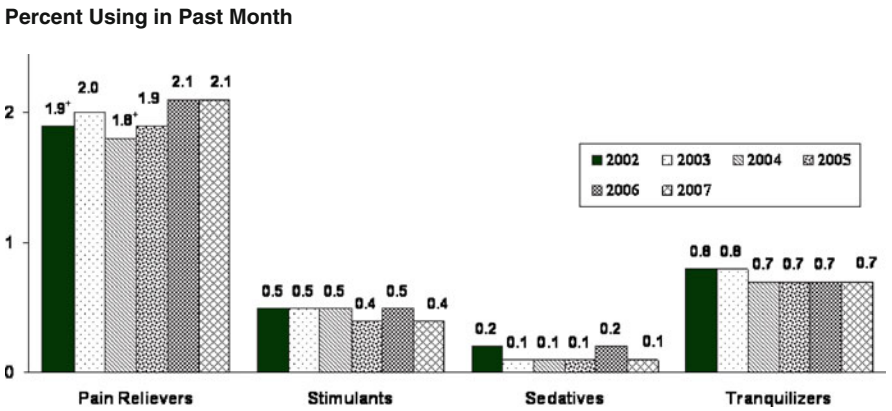

Fig. 3 Past-month non-medical use of prescription drugs (psychotherapeutics) among persons 12+: 2002–2007. +Difference between this estimate and the 2006 estimate is statistically significant at the 0.05 level. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

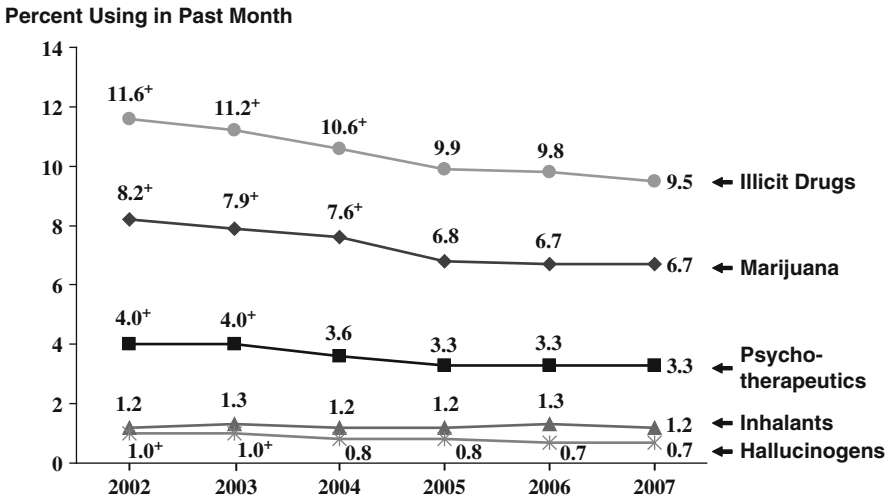

Fig. 4 Past-month use of selected illicit drugs among youths aged 12–17: 2002–2007. +Difference between this estimate and the 2007 estimate is statistically significant at the 0.05 level. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

pressure to continue to reduce the use of such substances among adolescents.

Another interesting trend seen in the National Survey on Drug Use and Health data involves adults aged 50–59. According to the 2007 National Survey on Drug Use and Health data, this age group showed an irregular increasing trend between 2002 and 2007 regarding current illicit drug use. For those 50–54, illicit drug use (past month) increased from 3.4% in 2002 to 6.0% in 2006, ending in 5.7% in 2007. There was a greater increase in past-month use of illicit drugs for those in the 55–59 age group — with an overall increase from 1.9% in 2002 to 4.1% in 2007. These trends may partially reflect the aging "Baby Boomer" population, whose lifetime rates of illicit drug use are higher than older adults (see Fig. 5).

For physicians—particularly those who specialize in the care of older patients—these trends indicate some of the challenges that may develop as the Baby Boomer population continues to age. According to the United States Census Bureau, one in five United States residents will be 65 or older in 2030. By 2050, it is projected that 88.5 million seniors will be 65 years or older, with 19 million of them 85 years or older [34].

Non-medical Use of Prescription Drugs

From an applied emerging issues perspective, the non-medical use of prescription drugs has become a major public health problem. The fact that the non-medical use of prescription drugs is now recognized as the second most prevalent pattern of illicit substance use should be of great interest to substance use disorder prevention and treatment specialists and to those in primary care, especially those who prescribe such medications.

As with alcohol misuse, there are age variations in the non-medical use of prescription drugs. National Survey on Drug Use and Health data show a gradual decline in the non-medical use of pain relievers in the past month, from 3.2 to 2.7% over the time period 2002–2007. However, when looking at young adults, 18–25 years of age, there has been a gradual *increase* in the non-medical use of prescription drugs from 4.1 to 4.6% for the same time period. Concomitantly, there has been a gradual increase for adults 26 or older from 1.3 to 1.6% during that time period. In 2007 alone, an estimated

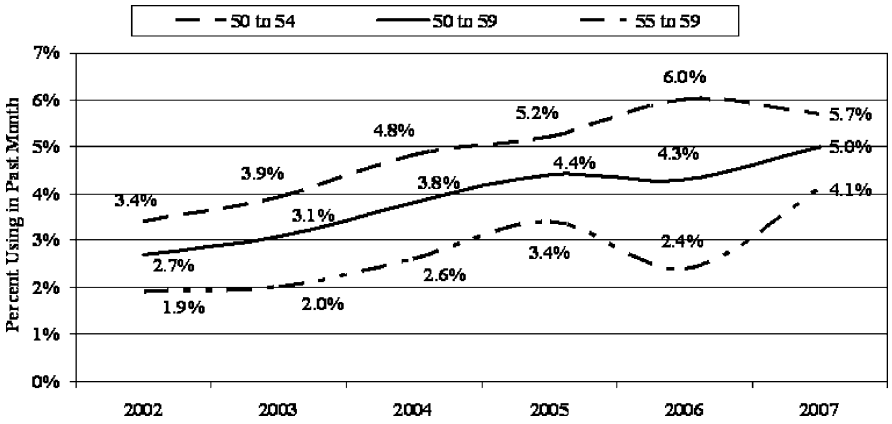

Fig. 5 Past-month illicit drug use among adults 50–59: 2002–2007. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

5.2 million individuals were currently misusing prescription pain relievers (see Fig. 6).

Additional data from the National Survey on Drug Use and Health highlight the fact that the majority of those who acquire prescription drugs for non-medical use get them free from friends and family members. Furthermore, when asked where the friends and family members got the prescription drugs, the majority of the respondents reported getting their drugs from a single physician (see Fig. 7).

It is now well established that individuals aren't just consuming prescription drugs "recreationally". Many are developing problems associated with their use. The National Survey on Drug Use and Health looked at those who meet criteria for abuse or dependence and found that figure to be more than two million individuals 12 or older. Within the prescription drug category, prescription pain relievers account for 1.7 million of the individuals who meet criteria for abuse or dependence, making prescription drugs the second most common category of drugs of misuse and the second most common category of abuse and dependence.

Thus, it is clear that the misuse of prescription drugs is a public health problem of growing proportion. However, that problem is complicated by the therapeutic need for the various agents, especially pain relievers, for clinical purposes. There does not seem to be any question about the need to treat pain adequately.

Among the implications of these findings are that prescribers of prescription drugs must assume some role in the education of patients or clients about the appropriate use of prescription drugs, and that the appropriate disposition of unused prescription drugs by patients and clients needs to be emphasized. Since prescription drug misuse is intimately tied to the

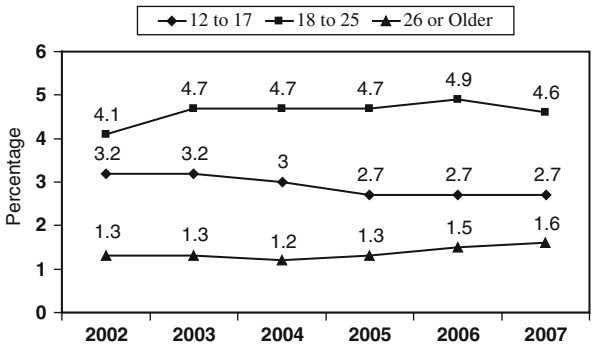

Fig. 6 Non-medical use of prescription pain relievers in the past month, by age group: percentages, 2002–2007. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

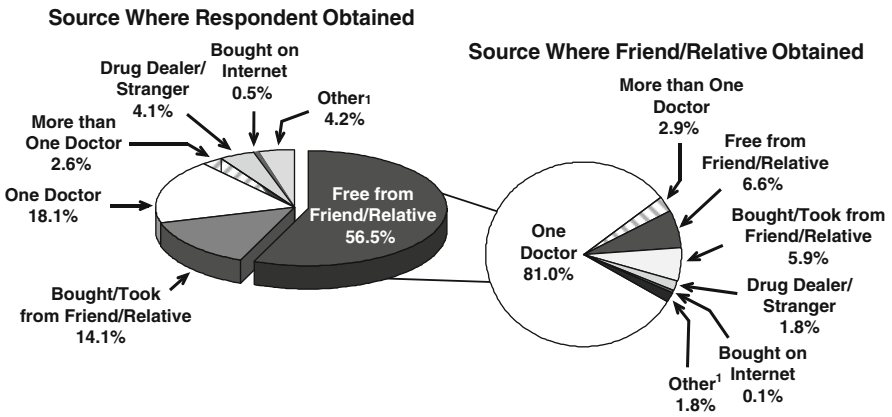

Fig. 7 Source where pain relievers were obtained for most recent non-medical use among past-year users aged 12 or older: 2007. Note: Totals may not sum to 100% because of rounding or because suppressed estimates are not shown. [1]The "Other" category includes the sources "Wrote Fake Prescription", "Stole from Doctor's Office/Clinic/Hospital/Pharmacy", and "Some Other Way". Reprinted from the Substance Abuse and Mental Health Services Administration [31]

therapeutic use of critical medications, strategies that simply address drug dealing, internet sales, misprescribing clinicians, and doctor shopping are inadequate. Nevertheless, many jurisdictions have adopted prescription monitoring programs as a way of tracking the behavior of both patients and prescribers. The Drug Enforcement Administration notes that 38 states have enacted legislation that require prescription drug monitoring programs: 29 of those programs are currently operating and 9 are in the start-up phase [25]. (The 38 states with prescription drug monitoring programs and/or enacted legislation are: Alabama, Alaska, Arizona, California, Colorado, Connecticut, Hawaii, Idaho, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maine, Massachusetts, Michigan, Minnesota, Mississippi, Nevada, New Jersey, New Mexico, New York, North Dakota, North Carolina, Ohio, Oklahoma, Pennsylvania, Rhode Island, South Carolina, Tennessee, Texas, Utah, Virginia, Vermont, Washington, West Virginia, and Wyoming. Currently, the state of Washington uses its program only for disciplinary purposes; however, legislation has been introduced to expand the program statewide.)

Prescription monitoring programs are evolving with information technology. Some programs are hampered by the fact that they are not currently operating in real time, but promise to become real time in the future. Another limitation of prescription monitoring programs is that they are often limited to specific states and do little to address patient or physician behavior across state jurisdictional lines.

As suggested above, the category of prescription drugs that ranks highest in abuse is that of analgesics, particularly pain relievers in the Controlled Substances Act schedules II and III [9]. The treatment of pain in American society is the fundamental basis for use of controlled substances, and access to appropriate pain medication is essential. Strategies designed to monitor the prescribing of pain relievers were historically not proffered as efforts to limit access to pain medication, but to discourage the misprescribing of pain medication. However, among prescribing practitioners the fear of legal consequences may have a "chilling" effect.

A recent study by Goldenbaum et al. notes that only 725 physicians between 1998 and 2006 were criminally charged and/or administratively reviewed for offenses associated with the prescribing of opioid analgesics [16]. This represented only 0.1% of the estimated 691,873 patient-care physicians active in 2003. Furthermore, the Goldenbaum et al. study concluded, "Practicing physicians, including Pain

Medicine specialists have little objective cause for concern about being prosecuted by law enforcement or disciplined by state medical boards in connection with the prescribing of CS [controlled substances] pain medications" [16].

The policy discussion about pain and the use of controlled substances for the management of pain in patients is an important one. With an estimated 50–60 million people within the United States suffering from chronic pain, and a larger estimate of the prevalence of various acute pain syndromes, the availability of appropriate treatment strategies is of critical importance.

The legitimate role of controlled substances in the treatment of the spectrum of pain-related conditions is often discussed. Clinicians are admonished to use clinical guidelines, transparent practices with documentation, and conservative strategies when monitoring patient compliance and dysfunctional patient behavior. Clinicians are also told to anticipate that some percentage of their patients or clients may develop substance use disorders associated with their treatment regimens or may present to treatment with pre-existing substance use disorders or vulnerabilities.

Prescription opioid dependence is also associated with other psychiatric conditions. Depression and anxiety disorders are two *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition axis I diagnoses found to be related to opioid dependence disorder in patients being treated for disabling spinal disorders who suffered from pain [11]. Managing co-occurring disorders and chronic pain conditions requires specific treatment strategies that take into account the full spectrum of the patient's conditions.

Further research will need to be done to appropriately map out the dimensions of the prescription drug misuse problem. Clinical treatment strategies for those suffering from pain and needing controlled substances will need to be refined, while substance abuse prevention and treatment programs will need to develop targeted treatment protocols.

As previously mentioned, recent survey data indicate that approximately 57% of diverted pain relievers are obtained free from friends and family members. Another 8.9% of individuals bought their pain relievers from a friend or a relative, with another 5.2% stealing their pain relievers from their friend or relative. In short, almost 71% of individuals who admit to the non-medical use of pain relievers got them from friends or family.

Clinicians, researchers and others interested in the public health implications of prescription drug abuse should obviously focus more energy on addressing the social and behavioral aspects of the social network aspects of prescription drug transactions. An emphasis on appropriate prescribing, with minimal excess, and appropriate storage with limited access, should be incorporated into clinician–patient interactions. Clinicians also should advise patients or clients about the appropriate disposal of excess controlled substances; this enlists the patient further in accepting responsibility for the medication and enhances the awareness that controlled substances can be dangerous if misused. Substance use disorders specialists should also be aware of the increase in prevalence of prescription drug abuse, with a particular recognition that prescription opioids are a growing problem among those with abuse and dependence who might present for treatment.

Combat Methamphetamine Epidemic Act of 2005

Clinicians in general should be aware that an ongoing problem of prescription drug misuse, particularly with narcotic analgesics, will produce calls for increased regulation and control of prescribing authority and patient access [22]. An example of this cause and effect is the Congressional response to the use of pseudoephedrine in recent years.

Because pseudoephedrine can be a precursor to methamphetamine production in illegal laboratories set up for methamphetamine production, the Combat Methamphetamine Epidemic Act of 2005 was incorporated into the USA

Patriot Improvement and Reauthorization Act of 2005, which was signed into law on March 9, 2006 [36]. This act banned the unmonitored over-the-counter sales of cold medicines that contain pseudoephedrine, resulting in the implementation of a comprehensive system of controls regarding the distribution and sale of drug products. It is important to realize that pseudoephedrine is found in both prescription and over-the-counter products used to relieve nasal or sinus congestion caused by the common cold, allergic rhinitis, sinusitis, hay fever, and other respiratory allergies [29].

The availability of pseudoephedrine over-the-counter made it a consumer friendly medication that was inexpensive and available in a dosage form that allowed for self-medication. Over 20% of adults in the United States suffer from allergic rhinitis requiring some form of intervention; this means that over 60 million people fall into this category. Over 30 million people suffer from sinusitis and 17.6 million people suffer from hay fever. In fact, people in the United States suffer 1 billion colds each year, according to some estimates. The Centers for Disease Control and Prevention estimate that 22 million school days are lost annually in the United States due to the common cold. This means that annually over 60 million people are affected by requirements of the Combat Methamphetamine Epidemic Act of 2005, limiting the number of tablets of ephedrine, pseudoephedrine, or phenylpropanolamine that can be purchased in a 30-day period. The Act also requires buyers to present either government issued photo identification or some form of acceptable identification and enter personal information such as name, address, date and time of sale, and signature into a logbook. It does not ban the sale of over-the-counter pseudoephedrine, however. Nevertheless, pseudoephedrine is being phased out as an over-the-counter drug by some pharmaceutical companies and replaced by less effective alternative decongestants such as phenylephrine.

Since the annual prevalence of methamphetamine use is less than 2 million people, while the current use of methamphetamine is less than 1 million [31], the authors of the Combat Methamphetamine Epidemic Act of 2005 obviously believed that some restrictions on the ability of the over 60 million people who might require pseudoephedrine to get that medication over-the-counter were tolerable in order to keep a minority of individuals from having ready access to a methamphetamine precursor. This same logic may be extended by policy makers to the phenomenon of the non-medical use of prescription drugs, with a special focus on prescription narcotics. As the over-the-counter use of pseudoephedrine is being replaced with a less effective phenylephrine, attempts may be made by supply reduction advocates and policy makers to alter the prescribing practices of clinicians in order to stem the flood of prescription drugs, particularly the opioids, into the non-medical use arena.

With one in four adults in the United States saying they suffered a day-long bout of pain in the past month, and 1 in 10 saying the pain lasted a year or more [6], the issue of treatment of pain in America is quite real. These numbers amount to 76 million people who have suffered from a day-long bout of pain in the past month and 30.5 million who have suffered from pain lasting a year or more. With 5.2 million people admitting to the non-medical use of opioid pain relievers, the larger number of individuals potentially affected by legal or regular constraints of the prescription of controlled substances for therapeutic purpose would be those who suffer from pain, not those who misuse or divert pain medications. Nevertheless, if the experience with over-the-counter pseudoephedrine is an example, organized medicine should take advantage of its head start and begin addressing the myriad of issues associated with pain medications' use and misuse.

Common chronic pain complaints include headache, low back pain, cancer pain, arthritis pain, neurogenic pain (pain resulting from damage to the peripheral nerves or to the central nervous system itself), psychogenic pain (pain not due to past disease or injury or any visible sign of damage inside or outside the nervous system). Whether all of these conditions require the

use of specific opioid medications for any specific patient should be determined by research and clinical evidence. However, concerns have produced demands for change. Already the Food and Drug Administration has issued letters to companies that make opioid drugs, including morphine, oxycodone and methadone; furthermore, the Food and Drug Administration will meet with pharmaceutical companies to review risk-management plans for medications [37].

The misuse of opioids can produce abuse and dependence requiring treatment. There are three treatment strategies: use of methadone, use of buprenorphine and the use of Naltrexone. Methadone has been used for more than 40 years in treatment of drug addiction. Its use for treatment of pain has increased in the last 5–10 years. Methadone can cause fatalities among individuals who have not developed any tolerance to opiates: children and adults who accidentally take methadone, and fatal intoxications during first weeks of treatment and adjustment of the methadone dose. Several risk factors have been identified for methadone mortality: the concomitant use of benzodiazepines and other opioids, and/or alcohol; an elevated risk of some individuals for torsade de pointes; inadequate or erroneous induction dosing and monitoring by physicians, primarily when prescribing methadone for pain; and drug poisoning that occurs as a result of diversion of the drug and its non-medical use.

It is important for the clinician to recognize that there are differences between prescribed methadone for pain and dispensed methadone for medication assisted therapy. When methadone is used for pain treatment no required risk management plan has been required. However, the Food and Drug Administration modified the labeling of methadone in 2006, and the Drug Enforcement Administration imposed a voluntary restriction on distribution in 2008.

When methadone is used for addiction treatment, the distribution is limited to certified, accredited, and registered programs. There are limits on the initial dose and restrictions on dispensing. The federal government, through the Substance Abuse and Mental Health Services Administration, recognizes the following entities as accrediting bodies: Joint Commission on Accreditation of Health Care Organizations, Commission on Accreditation of Rehabilitation Facilities, Council on Accreditation, National Commission on Correctional Health Care, and the state authorities of Missouri and Washington. There are only about 1200 opioid treatment programs licensed by the federal government. Those programs treat approximately 257,000 individuals. Incidentally, there are approximately 760,000 individuals receiving methadone for pain treated primarily outside of the opioid treatment system.

Another public health concern associated with the therapeutic use of opioids is the phenomenon of deaths associated with their use. The Centers for Disease Control and Prevention reported that there has been a significant increase in methadone-related deaths (see Fig. 8). Furthermore, there has been a steep increase in methadone-related deaths as a percentage of all poisoning deaths.

Within the opioid treatment community, there is an evolving concern about the prolongation of the rate-corrected QT interval and its

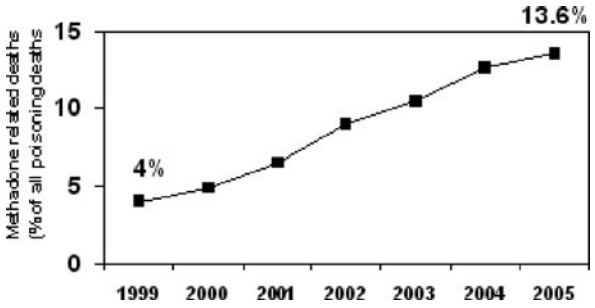

Fig. 8 Methadone-related deaths (percentage of all poisoning deaths). From 1999 to 2005, poisoning deaths increased 66% from 19,741 to 32,691. However, the number of poisoning deaths mentioning methadone increased 468% (from 786 in 1999 to 4,462 in 2005). Reprinted from Fingerhut [13]

relationship with torsade de pointes, potentially leading to sudden death. That concern is amplified by the increase in the number of methadone-related deaths. As more methadone is being used for the treatment of pain, it has become clear that even in the treatment of opioid dependence some risk exists for patients. Special concern applies to those who are being induced onto methadone.

SAMHSA's Center for Substance Abuse Treatment convened two expert panels over a 4-year period to examine associated etiologic factors related to methadone mortality. As a result of those reviews, it became clear that there were those in the medical community who believed that a routine pre-induction electrocardiogram screening should occur for all patients to measure the QTc interval and a follow-up electrocardiogram should occur within 30 days and annually thereafter. Particular sensitivity should be exhibited for those with histories of cardiac dysfunction [19].

While this advice is directed to opioid treatment programs, it applies to those who are receiving methadone for the treatment of chronic pain. Such advice recognizes that there are clinical challenges in the use of opioid medications, such as methadone, that extend beyond the issue of abuse and dependence. A preoccupation with abuse and dependence may detract from the physiological phenomenon that results from the greater use of a class of medications that play a critical role in preserving the public health.

Buprenorphine

Under the Drug Addiction Treatment Act of 2000, qualified physicians can treat individuals addicted to heroin or prescription opioids under a waiver provision administered by the Substance Abuse and Mental Health Services Administration and the Drug Enforcement Administration. To qualify, a physician must meet certain requirements (e.g., trained by a medical organization such as the American Psychiatric Association). Buprenorphine is the only Food and Drug Administration—approved medication that can be prescribed for this purpose.

In July 2005, Congress removed the 30-patient restriction on medical groups that prescribe buprenorphine for opioid dependence and addiction. The 30-patient limit was then applied to each physician's caseload, rather than to that of the entire clinic. The Office of National Drug Control Policy Reauthorization Act of 2006 increased the number of individuals a physician can treat with buprenorphine to 100 if specific conditions are met.

As of October 1, 2008, 19,000 physicians have been trained by a Drug Addiction Treatment Act–recognized medical organization and 16,000 physicians are authorized to prescribe buprenorphine. Approximately 300,000 individuals were treated in 2007, which is an 80% increase over 2006. (The Center for Substance Abuse Treatment is working with the Food and Drug Administration, the Drug Enforcement Administration, and the manufacturer to address reports of increasing diversion and abuse.)

There are a number of issues associated with the increased use of buprenorphine. Foremost is the need for medical schools, internships, residencies, and fellowships to increase the underlying issues of abuse and dependence of prescription opioids and/or heroin. Buprenorphine offers the primary care, specialist, or addiction medicine physician the opportunity to address opioid abuse or dependence at the patient level. However, training is a necessary precursor. An evolving twist in the practice of medicine is the use of buprenorphine for the treatment of pain. Of course, increased focus is also needed on those patients who have a pain condition and who suffer from addiction to opioids.

As buprenorphine gained in popularity, it was inevitable that adverse event reports would increase in occurrence. The increased use of buprenorphine magnifies the risk to children in homes in which it is used. Clinicians should remain vigilant for pediatric exposures [15]. Clinicians should *not* assume that because

Suboxone® is a combination of buprenorphine and naloxone, pediatric patients are not at risk for opioid toxicity [27]. Individuals receiving buprenorphine on an outpatient basis should be educated regarding steps they can take to ensure that it is not accessible to any young children in their homes.

In 2006, of 346,946 reported emergency department visits, 47,538 involved opioid analgesics—and only 356 of these involved buprenorphine or a combination of buprenorphine and other medications. Of those involving buprenorphine: 52 were due to adverse reactions, 63 were seeking detoxification, 225 were due to non-medical use, and 11 were due to accidental ingestion [35]. Most common pattern of abuse involves crushing the sublingual tablets and injecting the resulting extract. When injected intravenously, addicts claim buprenorphine effects are similar to equipotent doses of morphine or heroin. Indications are that buprenorphine obtained for non-medical purposes in the United States is diverted from prescriptions written for treatment of addiction or obtained through "doctor shopping" [30].

More than one-third of buprenorphine abusers reported that they took the drug in an effort to self-medicate and ease heroin withdrawal. A majority of buprenorphine abusers are young white males with extensive histories of substance abuse [8]. When asked in a National Association of State Alcohol and Drug Abuse Directors study, 33% of physicians considered Subutex® to be a significant abuse and/or diversion threat in their states [5]. In the same study, only 6% of physicians considered Suboxone® to pose a significant abuse threat, and only 8% considered it to be a significant diversion threat in their states.

Monitoring of discussions within Internet newsgroups and interviews found that the buprenorphine products are viewed primarily as medications to avoid or ease withdrawal symptoms rather than a means of getting high. There is evidence of experimental use and illegal diversion of buprenorphine; however, the extent of abuse and diversion does not come close to that of methadone or OxyContin®. Intravenous use of either Suboxone® or Subutex® appears to be rare, but it is evident from street interviews [10].

Physician Training and Buprenorphine

While the Drug Addiction Treatment Act of 2000 prescribes a minimum of 8 h of education for physicians not otherwise exempted, it became clear that additional support was needed for a number of practitioners new to the effort to provide care to those who abused or were dependent on opioids using buprenorphine. Therefore, the Center for Substance Abuse Treatment created the Physician Clinical Support System for Buprenorphine. The Physician Clinical Support System was created in collaboration with the American Society of Addiction Medicine; this public private partnership permits physicians who prescribe or dispense buprenorphine to contact the Physician Clinical Support System for support. The Physician Clinical Support System is a free, national service staffed by 45 trained physicians' mentors, a Physician Clinical Support System medical director and five physicians who are national experts in the use of buprenorphine. The Physician Clinical Support System offers support via telephone, via email, and/or at the place of the individual physician's practice. Access to information about the Physician Clinical Support System can be acquired from the Web site: www.PCSSmentor.org.

The Physician Clinical Support System has a steering committee made up of representatives from over 20 organizations, including such physician groups as the American Medical Association, the American Psychiatric Association, the American Osteopathic Academy of Addiction Medicine, the American Academy of Pediatrics, the Society of General Internal Medicine, the American Academy of Addiction Psychiatry, and the American Society of Addiction Medicine. It is believed that providing

physicians with collegial support will enhance treatment strategies and patient education, thus diminishing the prospect of adverse events and medication diversion.

Utilization of Substance Abuse Treatment Services

The National Survey on Drug Use and Health presents findings about utilization of substance abuse treatment services in addition to a comprehensive overview of substance use. In 2007, an estimated 22.3 million persons aged 12 or older were classified with substance dependence or abuse in the past year; this represented 9% of the population. Of these, 3.2 million were classified with dependence on or abuse of both alcohol and illicit drugs, 3.7 million were dependent on or abused illicit drugs but not alcohol, and 15.5 million were dependent on or abused alcohol but not illicit drugs.

In 2007, only 3.9 million of the 22.3 million persons who met criteria for substance dependence or abuse received some form of treatment for a problem related to the use of alcohol or drugs. Treatment was reported to be received in a range of settings: self-help groups, outpatient rehabilitation, inpatient rehabilitation, outpatient mental health centers, hospital inpatient, private doctor's offices, emergency room, or prisons or jails. Looking beyond the full universe of treatment options and focusing only on hospital inpatient units, drug or alcohol rehabilitation facilities (inpatient or outpatient), or mental health centers as specialty substance abuse treatment settings, the National Survey on Drug Use and Health reported that only 2.4 million people, 12 or older, who met criteria for substance abuse or substance dependence received treatment. What is striking about the findings is that 20.8 million people in 2007 who were classified as needing substance abuse treatment did not receive it.

Of the 20.8 million people who met criteria for needing treatment but did not receive it, 93.6% did not feel that they needed treatment and made no effort to get treatment. Another 4.6% felt that they needed treatment but did not make an effort to get it, while 1.8% or 380,000 people felt that they needed treatment, made an effort to get it, but did not receive it. In short, 98.2% of the 20.8 million people who met criteria for needing treatment made no effort to receive it.

These findings created the basis of two evolving concepts. The first is that the "true" waiting list is made up of only 380,000 people: the individuals who made an effort to get treatment, but who were not successful. The second is that the overwhelming majority of individuals who meet criteria are not seeking treatment despite being symptomatic (see Fig. 9). It is not clear why the overwhelming majority of individuals who

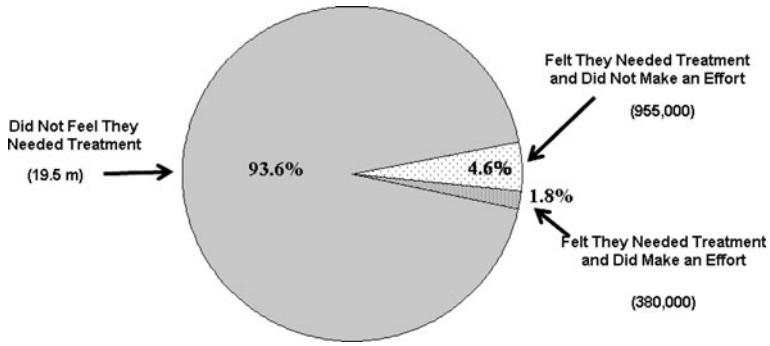

Fig. 9 Past-year perceived need for and effort made to receive specialty treatment among persons aged 12 or older needing but not receiving treatment for illicit drug or alcohol use: 2007. 20.8 million needing but not receiving treatment for illicit drug or alcohol use. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

meet criteria for needing treatment do not seek it. However, it is clear that these individuals must have some psychosocial decrements of function noticeable not only to themselves, but to those in their environment. Environmental motivators can include: family, employers, health care practitioners, law enforcement, faith leaders, friends, and associates. Therefore, from a public health perspective and a public safety perspective, it is important to determine the role of substances of misuse in the lives of individuals. It is also important to understand the developmental significance of alcohol and drugs to those in the 18- to 25-year age range, for these young adults account for the peak misuse of alcohol, traditionally illicit drugs and now prescription drugs. The data above clearly show that our efforts to reach young adults need to be intensified.

Social Determinants of Health

There are many social determinants of health, with varying influence depending upon the individual's unique condition (see Fig. 10). The use of alcohol or drugs has many cultural, biological and social precursors. The misuses, then, are similarly disposed. The question of why a substance is used beyond the obvious reality of the physiological and psychological effects remains a mystery. This is clearly seen among those who meet criteria for treatment, but who do not seek assistance. The World Health Organization has an established focus on the social determinants of health. The conceptual model depicted in Fig. 10 recognizes that there are structural determinants of health inequities coupled with intermediate determinants of health that influence the equity in health and well-being. The socioeconomic and political context of an individual's life plays a role in that individual's health. A modified version of the World Health Organization's model includes drug laws and laws governing the use of alcohol. A person's socioeconomic position in society also contributes, with material circumstances, behavioral and biological factors and psychological factors figuring into access to a health system and impacting on the health system available to a person. Health does not occur in a vacuum. Also, substance use and misuse do not occur in a vacuum. One recent survey showed that respondents feel that persons who are addicted to illicit drugs such as cocaine and heroin are much more of a danger to society than those addicted to alcohol, prescription drugs, or marijuana [33]. In fact, the

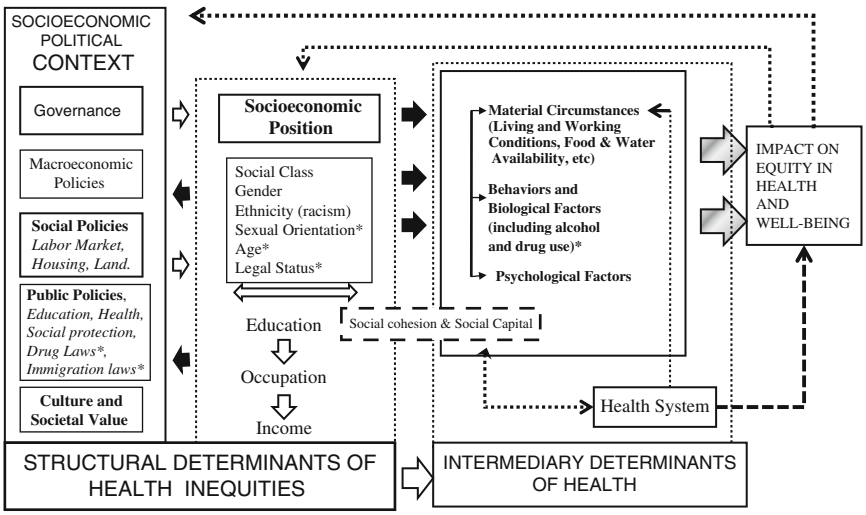

Fig. 10 The social determinants of health. Adapted from the diagram in section V.9 on p. 48 of: World Health Organization, Commission on Social Determinants of Health [38]

survey found that respondents viewed addiction to alcohol and prescription drugs to be more dangerous than addiction to marijuana. These data reflect the cultural imperatives, public opinions, and socioeconomic benefits associated with use of the substances in question.

Addressing Barriers to Treatment

Consequently, the reasons for *not* seeking treatment can also be complex, including lack of health care, lack of transportation, the fear of stigma and not knowing where to go for treatment or if any available program has appropriate treatment.

The United States government decided to embark on two different strategies to address the issue of the 20.8 million Americans who needed treatment for substance use disorders but who were not receiving treatment. The first effort, called the Access to Recovery initiative, targeted the 380,000 people who were seeking treatment but could not get it. The second effort recognizes that the overwhelming majority of people in need of care were not presenting to specialty treatment programs, but many were presenting at alternative sites of care, specifically trauma centers, community health centers, and other primary care venues.

Access to Recovery

In the Access to Recovery initiative, consumers are empowered to purchase substance abuse services using vouchers issued by state grantees. In addition to using such vouchers, increased emphasis is placed on a system of support services classified as recovery support services. Recovery support services are predicated on the notion that community support extends the reach of specialty delivery services. State or tribal grantees work with a network of public, private, and non-profit entities to help the affected individual. Thus, professional, peer, faith-based, and community-based support services were wrapped around the treatment focus. The Access to Recovery initiative served over 198,000 individuals in its first 3 years, primarily those individuals who lacked the financial resources to access treatment. Such services as transportation, child care, literacy training, self-help facilitation, recovery-based training and relapse prevention, assistance with the criminal justice system, transitional housing, and employment coaching are considered an integral part of the recovery process (see Fig. 11).

The basis for recovery support services is predicated on the work of the National Institute on Drug Abuse. The critical components of treatment are captured in the National Institute on Drug Abuse "Wheel". According to the National Institute on Drug Abuse's data, individuals without community or family supports are more vulnerable to relapse than those with such supports.

The combination of vouchers, which provide more freedom of choice, with the integration of recovery support services into the treatment plan, has proven to be effective. The Access to Recovery initiative maintains performance data for the jurisdictions participating; these data indicate that at 6-month follow-up, there was a reduction in substance use, decreased involvement with the criminal justice system, and an increase in stable housing.

The initial cohort of Access to Recovery programs involved 15 jurisdictions. The second phase of the program has increased to involve 24 jurisdictions: 18 States, Washington, DC, and five tribes or tribal organizations.

Screening, Brief Intervention, and Referral to Treatment

The second effort, Screening, Brief Intervention, and Referral to Treatment, recognizes that the overwhelming majority of people in need of care are not presenting to specialty treatment programs, but many are presenting at alternative

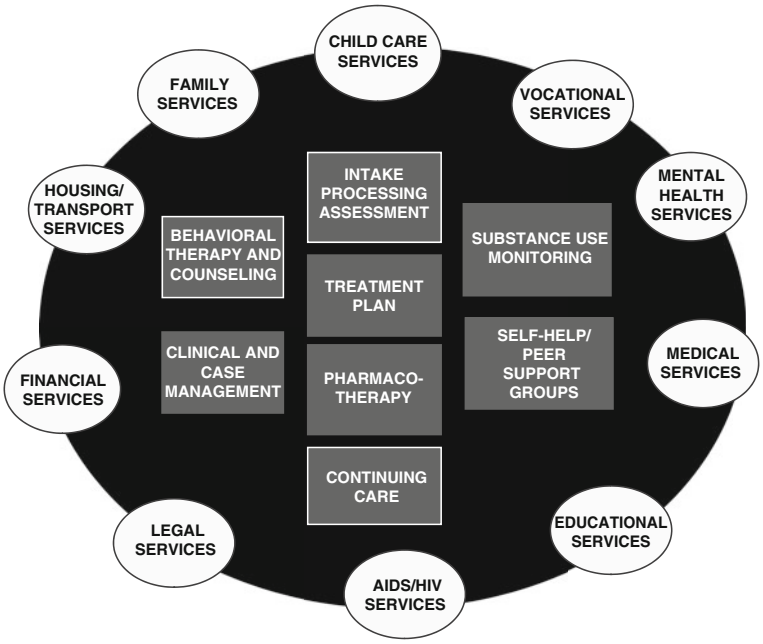

Fig. 11 Treatment services. Reprinted from the National Institute on Drug Abuse [23]

sites of care, specifically trauma centers, community health centers and other primary care venues (see Fig. 12).

Cherpitel and Ye analyzed the National Alcohol Survey for the year 2005. The Survey canvassed 6,919 adults using a random digit dial computer-assisted telephone interview with an over-sampling of blacks and Hispanics [7]. The respondents were asked if they consumed any alcohol in the 6 h prior to a reported injury (alcohol-related) and whether they felt the injury was related to their alcohol consumption (alcohol-caused). Seven percent of the respondents reported an alcohol-related injury treated in an emergency department; 6% reported receiving any treatment for their alcohol-related injury, and 5.3% reported alcohol-related injuries treated in primary care settings.

Of those seen at emergency departments who reported alcohol-related injuries, 28% reported that the injuries were alcohol caused; of those presenting to primary settings, 14.9% reported their injuries as alcohol caused; and for those presenting to any treatment, 18.9% reported their

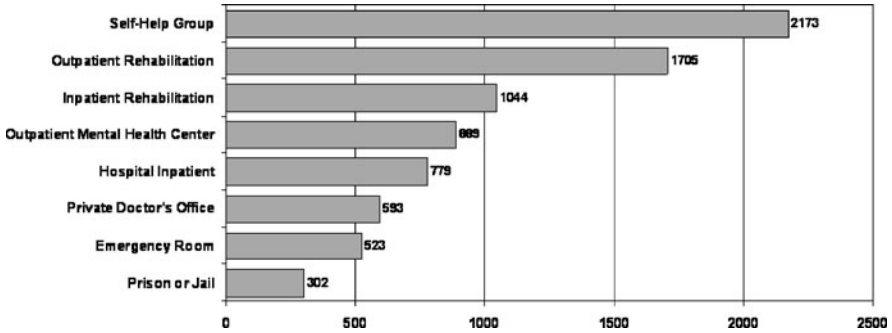

Fig. 12 Locations where past-year substance use treatment was received among persons 12+: 2007. Reprinted from the Substance Abuse and Mental Health Services Administration [31]

injuries as alcohol caused. One recent convenience sample of urban family medicine patients by Fogarty et al. found a prevalence rate of 16.7% for alcohol use disorders [14]. Fogarty et al. also noted that, inter alia, an alcohol use disorder was related to twice the odds of reporting more than one emergency department visit over the previous year, 16% fewer primary care provider visits, and 238% more non-psychiatric hospitalizations. In other words, while the prevalence of alcohol-related injuries is small in the general population, individuals presenting in the primary care setting who have an alcohol use disorder are more likely to use more expensive health care settings.

According to the National Survey on Drug Use and Health, the 19.5 million people who meet criteria for alcohol use disorders, but perceive no need for treatment and are not receiving treatment, are not going to specialty care settings. Thus, from a public health approach, if those affected by alcohol use disorders will not go to formal treatment, some form of treatment must go to them. Consequently, such entities as the World Health Organization, the United States Preventative Services Task Force, the Committee on Trauma of the American College of Surgeons, and the Academic Emergency Department Screening, Brief Intervention, and Referral to Treatment Research Collaborative all recommend routine screening for alcohol problems in various health care settings.

It has long been known that screening for problem drinking and brief counseling by primary care providers is an effective approach to reducing alcohol consumption [17, 28]. In fact, the United States Preventive Services Task Force recommends screening and behavioral counseling interventions to reduce alcohol misuse by adults, including pregnant women, in primary care settings [1]. Because it is recognized that a unique opportunity exists also to address illicit drugs in the primary health care setting, the question of whether it is practicable to screen for these substances has been raised. At this point in time, the United States Preventive Services Task Force has concluded: "for adolescents, adults, and pregnant women, the evidence is insufficient to determine the benefits and harms of screening for illicit drug use" [1]. Nevertheless, the Federation of State Medical Boards adopted a policy statement to develop "methods and/or modules of information to be used to educate medical students, residents and practicing physicians regarding the identification of substance use disorders, brief intervention and the proper prescribing of controlled substances" [12]. In addition, the Centers for Medicare and Medicaid Services added to the Healthcare Common Procedures Coding System new Level II billing codes for screening and brief intervention for alcohol and/or drugs that went into effect on January 1, 2007 [24]. The American Medical Association also has added to its current procedural terminology codes two new codes covering services related to alcohol and drug abuse screening and treatment [21].

Furthermore, researchers are exploring the utility of using screening and brief intervention as a tool to address more carefully the issue of drug abuse [2–4]. Use of such substances as marijuana, prescription drugs, and cocaine occurs with sufficient frequency to make them ideal targets for a screening effort. The epidemiology of a given community might elevate other substances of misuse to a level that makes screening in that community practical and feasible.

As noted, screening is not the only component of a process of detection and intervention. Screening, Brief Intervention, and Referral to Treatment is predicated on any of the three following strategies: brief intervention, brief treatment, or referral to treatment [32] (see Fig. 13). It became clear to the federal government that one of the engines that drive the demand for drugs is the lack of perceived need for care. At the same time, people were being seen for injuries and conditions related to drug abuse and misuse. The challenge was how to take advantage of the opportunity to provide this population with at least brief intervention or treatment.

The Center for Substance Abuse Treatment of the Substance Abuse and Mental Health Services Administration implemented a grant program in 2003 to encourage state jurisdictions and tribal organizations to initiate Screening, Brief

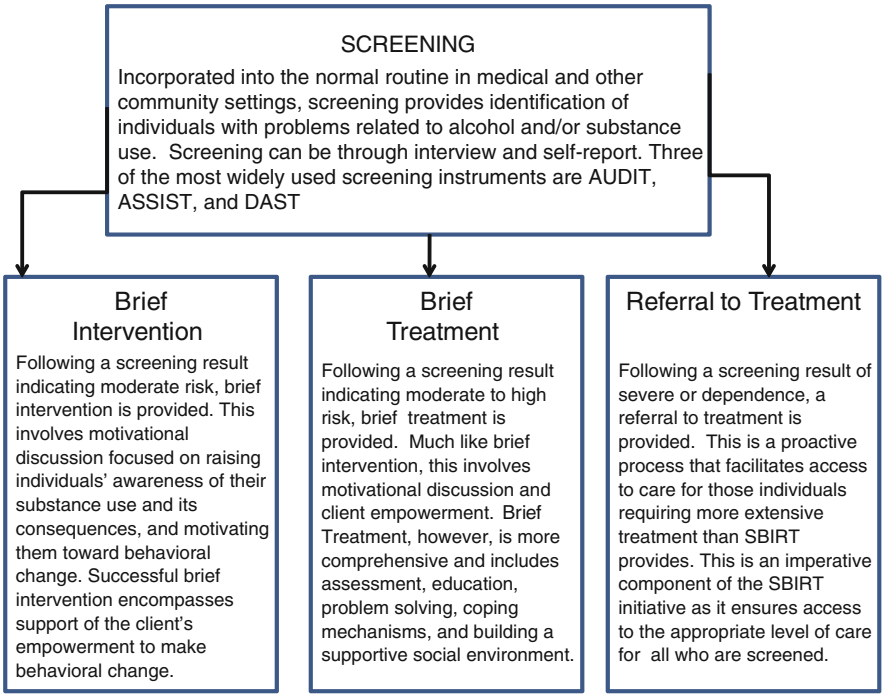

Fig. 13 Screening, brief intervention, brief treatment, and referral to treatment. Reprinted from the Substance Abuse and Mental Health Services Administration [32]

Intervention, and Referral to Treatment programs in a variety of healthcare settings, including inpatient programs, emergency departments, ambulatory care settings, community health centers and other primary care settings. The Center for Substance Abuse Treatment funded 5 state jurisdictions and one tribal organization to promote and implement Screening, Brief Intervention, and Referral to Treatment protocols in 2003 (California, Illinois, New Mexico, Pennsylvania, Texas, Washington, Cook Inlet Tribal Council of Anchorage, Alaska). Another four grants were funded in 2006 (Colorado, Florida, Massachusetts, and Wisconsin). Then, in 2008, another cohort of four grants was funded (West Virginia, Missouri, Georgia, and the Dena Nena dba Tanana Chiefs Conference of Fairbanks, Alaska). Performance data from the first two cohorts of Center for Substance Abuse Treatment Screening, Brief Intervention, and Referral to Treatment grantees revealed that by the end of September, 2008, over 700,000 individuals were screened in over 100 settings: community health centers, trauma care centers, schools and student assistance programs, occupational health clinics, and hospital emergency departments.

Recovery as a Holistic System

The Access to Recovery and Screening, Brief Intervention, and Referral to Treatment initiatives emphasize the need to move beyond the rather narrow world of treatment into the broader world of recovery. The process of change through which an individual achieves abstinence and improved health, wellness, and quality of life benefits from an integrated system of care that views the treatment agency as one of many resources needed to ensure the client's successful integration into the community. Just as each person's path toward substance misuse was different, the path to recovery will also look different for each client. The recovery system

must be person-centered and self-directed, drawing upon resources that meet the particular needs of the client. Hence, a recovery-oriented system of care model operates very much like the etiological model suggested by the model that the World Health Organization promulgates about the social determinants of health. Chronic care approaches, including self-management, family supports, integrated services, and intensive case management, improve recovery outcomes. Integrated and collaborative care not only optimizes recovery outcomes but also improves cost-effectiveness.

Health Insurance

In the health care delivery system, the cost of providing health care is a chronic issue. Total spending for health care was $2.4 trillion in 2007, or $7900 per person. Total health care spending represented 17% of the gross domestic product, with spending on substance abuse treatment rising from $9 billion in 1986 to $21 billion in 2003 and projected to increase to $35 billion in 2014. What is remarkable is that substance abuse treatment spending was only 2.1% of total health spending in 1986, and this had dropped to 1.3% in 2003, with further declines in share of total health spending in 2014 [20]. It is estimated that public payers are responsible for over 77% of the expenditures for substance abuse treatment in 2003, and this number is expected to increase to 83% of expenditures by 2014. This makes substance abuse disorder treatment unique in the pantheon of health expenditures.

In 2003, private insurers paid only 10% of the bill for substance abuse services, while state and local dollars paid for 40% of the bill for services; Medicaid paid for 18% of the substance abuse treatment services bill [20]. The burden on the public sector is demonstratively great, particularly at a time when state budgets are suffering under the weight of deficits. Yet, as with health care in general, the question is: if substance abuse treatment is to continue, "Who will pay for it?"

There are two emerging movements that shift substance abuse treatment services into a more contemporary payment scheme: health care parity and health care reform. How substance use disorder treatment services are compensated clearly plays a role in what treatment options are available to an affected individual. Furthermore, the clinical algorithm employed by the clinician will also be influenced by the patient's or client's ability to pay for services or to get services provided.

Parity for substance use disorder services was addressed in recent federal legislation, the Paul Wellstone and Pete Domenici Mental Health Parity and Addiction Equity Act of 2008 [26]. In that law, which went into effect on January 1, 2010, health plans that offer mental health and substance use disorder treatment benefits must do so on par with other health benefits. Under the law, insurance plans are not mandated to offer addiction and mental health benefits, but plans that do have those benefits must provide them on a non-discriminatory manner. Parity is also extended to coverage for out-of-network providers—increasing access to treatment for many insured individuals. Plans have the right to manage the benefit as they see fit and can decide which mental health and substance abuse treatment services they cover, as long as their decisions do not discriminate. However, they must provide to individuals and providers the medical necessity terms and conditions for any denials [26].

The law also acknowledges the fact that some states have already implemented parity laws, some of which may be stronger than the federal laws. In such cases, stronger state laws will not be pre-empted.

In short, the Wellstone/Domenici bill does not require the inclusion of substance use disorder treatment services in a health insurance benefits plan; it only requires parity of benefit structure with other health benefits if the substance use disorder treatment benefit is offered. Thus, the evolving debate about health care reform, centering on universal access to health care services, poses the greater challenge for those who require substance abuse treatment services, those

who provide such services, and those who refer patients to such services.

Critical themes in health care reform will be the issues of cost of services, the quality of the services provided, accountability for the provision of the services, and access to the services. Decision-making within the province of substance abuse treatment services will have to be transparent, with a clear view of the qualifications of the providers, and assessment tools used to determine the various treatment components necessary for treatment, documentation of services provided through electronic health records, and the appropriate use of evidence-based practices with some evidence of fidelity to those practices and verification of acceptable outcomes in choosing the relevant practices.

What is Epidemiology?

The field of epidemiology involves investigation of the distribution and determinants of health conditions in populations or population subgroups. Epidemiological investigations fall under two common domains: descriptive and analytic. Descriptive epidemiologic studies provide estimates of the incidence and prevalence of illnesses or health behaviors. Incidence refers to the proportion of new cases of a particular health outcome during a specific period of time in a specific at-risk population (i.e., among individuals free of the outcome at the beginning of the time period). Prevalence refers to the proportion of a group or population affected with a health condition at a particular point in time. This includes new cases as well as chronic cases that began earlier and continued into the period of observation. Analytic epidemiologic studies focus on identifying causes/risk factors (e.g., genetic variants, contextual circumstances) of illness, often done through retrospective comparison of cases with non-cases or prospective study of disease development among individuals exposed versus unexposed to a particular hypothesized causal factor.

This chapter covers the epidemiology of alcohol and drug abuse and dependence (referred to together as "substance use disorders"). From an epidemiologic standpoint, substance use disorders have common as well as unique characteristics. This chapter identifies common characteristics of the epidemiology of alcohol and drug use disorders, and highlights

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_2,

some important characteristics unique to specific substances.

Substance Use in the United States: A Historical Overview

Alcohol Consumption

The use of substances to alter mood states has been a part of civilization from pre-historic through modern time periods. Archeological records document the conversion of sugar into fermented beverages for recreational use, as part of religious ceremonies, and as an analgesic or disinfectant as early at 10,000 B.C. [1, 188]. Alcohol remains incorporated into the fabric of many cultures for a variety of uses, including social and recreational use, as a part of religious ceremonies, secular festivities, and as a normative aspect of daily life. Further, moderate consumption is associated with health and longevity, and is considered to be protective against several adverse health outcomes including cardiovascular disease [13].

Long-term historical information on United States alcohol consumption is available through per-capita alcohol consumption statistics derived from sales records. These records show drinking levels in the United States varied greatly over time from the early days of the United States to the twenty first century [169, 172]. Per-capita consumption levels ranged from extraordinarily high levels during the United States colonial period (from an estimated 5.8 gallons per year per capita in 1790 to 7.1 gallons in 1830) to very low levels before and during Prohibition (from an estimated 1.96 gallons in 1916 to 0.97 gallons in 1934). Prohibition refers to the time period during which the United States prohibited the manufacture, sale, and transportation alcoholic beverages were prohibited by the 18th Amendment to the Unites States Constitution. This period began in 1920, and ended in 1933 with the repeal of the 18th Amendment by the 21st Amendment. From 1935 until 1982, shown in Fig. 1, per-capita alcohol consumption increased steadily to a peak of nearly 2.8 gallons of ethanol per year in 1982 [169]. Since then, consumption has declined, leveling off at about 2.2 gallons of ethanol per year in 1993, and

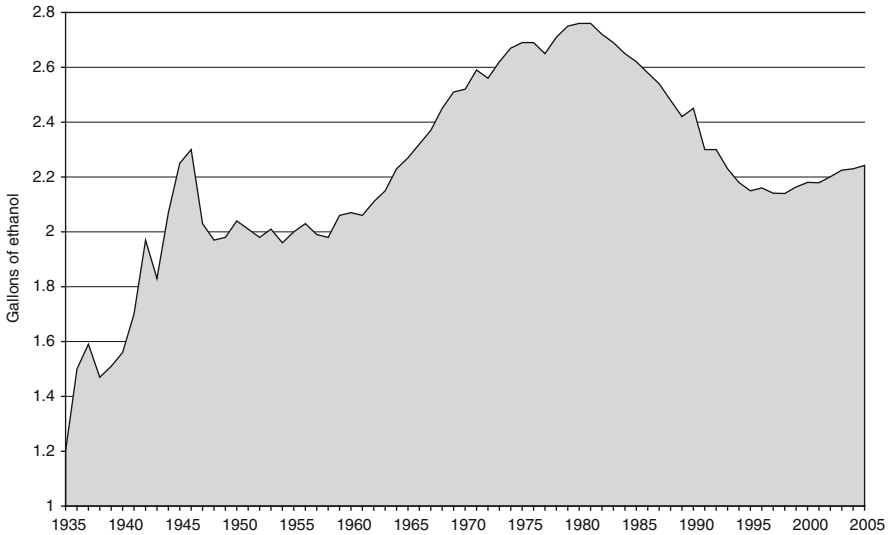

Fig. 1 Total per-capita ethanol consumption, United States, 1935–2005. Source: Lakins NE, LaVallee RA, Williams GD, Yi H (2007) Surveillance report #82: apparent per capita alcohol consumption: national, state, and regional trends, 1977–2005. NIAAA, Division of Biometry and Epidemiology, Alcohol Epidemiologic Data System, Rockville, MD, August 2007

remaining at around that level until 2005, with a slight increase from 1999 to 2005. These data are generally consistent with liver cirrhosis mortality statistics, which show similar variations over time [287].

Worldwide, alcohol consumption patterns vary considerably. Consumption is lowest in predominately Muslim countries (e.g., individuals in Afghanistan and Pakistan consume 0.03 and 0.31 l pure alcohol per capita, respectively) and eastern Mediterranean countries, and highest in eastern European countries (e.g., individual in Ukraine and the Russian Federation consume 15.58 and 15.23 l pure alcohol per capita, respectively) and western European countries such as France, Germany, and the United Kingdom [285].

Alcohol consumption is also heterogeneous within countries. For example, about one-third of United States adults do not drink, although per-capita consumption is 9.3 l [216, 224]. Abstainers are rare In Eastern Europe (including Russia and Ukraine), where per-capita consumption, 13.9 l, is the highest in the world [216]. After immigration, immigrants tend to retain the drinking levels of their country of origin rather changing to the patterns of their new country, for example, Mexican immigrants in the United States [89] and Russian immigrants in Israel [107, 214].

Drug Use

Drugs such as cannabis, opium, and cocaine have been cultivated and used medicinally as well as recreationally for centuries. Opium poppies are believed to have been first grown in the region near modern-day Iraq as early as 3400 B.C. Opium was used primarily as an analgesic and anesthetic, but medical use did not become widespread until the development of the hypodermic needle in the early 1800s [200]. Historical analysis also indicates that marijuana was smoked recreationally and medically in ancient China as early as 2737 B.C. [199]. In South America, societies have grown and consumed coca, the plant grown to create cocaine, for centuries. The most common mode of administration is to chew the leaves of the coca plant, or to mix the leaves into a tea [252]. In the twentieth century, innovations in pharmacological knowledge led to the development of synthetic drugs such as lysergic acid diethylamide, categorized as a hallucinogen, and methylenedioxymethamphetamine (or "ecstasy"), categorized as an amphetamine.

In Western countries prior to the 1960s, drug use was rare and the few studies that addressed prevalence focused on heroin, with widely varying results [56, 90, 243]. Morphine is believed to have been prescribed often in the nineteenth and early twentieth centuries mainly as a cough suppressant to ease the suffering of individuals with tuberculosis [199], although no data are available to empirically estimate incidence and prevalence. During the Civil War, it is believed that more than 400,000 soldiers became dependent on morphine, as it was liberally prescribed for pain associated battle wounds [199]. More systematic surveys of United States drug use began in the 1960s. A series of national household surveys on drug use conducted by the National Institute on Drug Abuse and later by the Substance Abuse and Mental Health Services Administration showed that illicit drug use, especially marijuana, increased greatly after the late 1960s (Fig. 2). Heroin use also increased in the late 1960s, when the profile of users changed from "bohemians" to inner-city, unemployed males. Yearly surveys of United States youth [140] since 1975 indicate that ~50% of 12th-grade students have used an illicit drug, with a high of 66% in 1982, a low rate of 41% in 1992, and 51% in 2004. Since 1975, over 80% of students felt that marijuana was easily available, ranging from 82.7% in 1992 to 90.4% in 1998.

Substance Use in the United States: A Public Health Problem

While alcohol and drug use is common both in the United States and in many countries worldwide, excess alcohol consumption is estimated to be the 3rd largest cause of United States

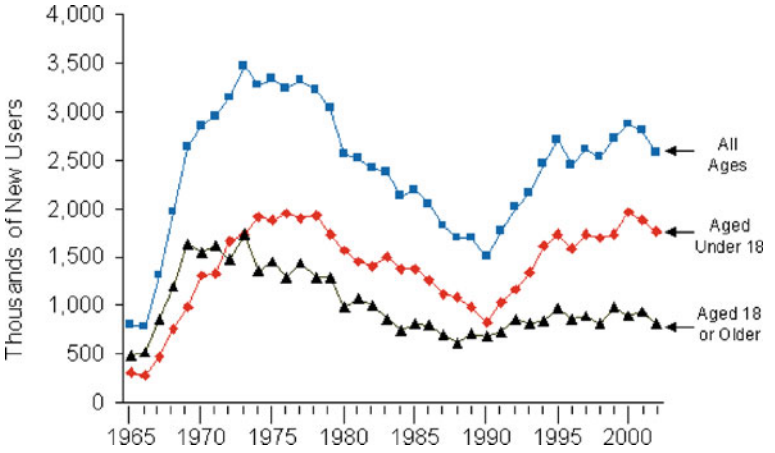

Fig. 2 New users of cannabis in the United States, 1965–2002. Source: Substance Abuse and Mental Health Services Administration (2004). Results from the 2003 National Survey on Drug Use and Health: National Findings

preventable mortality [197] and the 5th largest cause of preventable disability worldwide [66]. Excess substance use and substance use disorders are associated with a broad range of adverse outcomes including but not limited to accidents and traffic fatalities [126], domestic violence [25], fetal alcohol syndrome and other pre- and perinatal insults [211, 246], neuropsychological impairment [11], poor medication adherence (e.g., HIV) [229], economic costs and lost productivity [98], psychiatric comorbidity [21, 114], and functional disability [114]. Thus, prevention and intervention of excess substance use is an important public health priority.

When Does Use Become Pathological? Substance Abuse and Dependence

The two major nomenclatures, the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition and the International Statistical Classification of Diseases and Related Health Problems, 10th Revision, define psychiatric disorders within a common framework for individuals and groups with different training, experience, and interests. Users include medically and behaviorally trained clinicians, neuroscientists, geneticists, investigators conducting clinical trials, epidemiologists, policy makers, insurance companies and others. Both the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition and the research version of the International Statistical Classification of Diseases and Related Health Problems, 10th Revision enable diverse groups to arrive at common definitions of disorders by providing specific, generally observable criteria for each disorder. For substance use disorders, the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition and the International Statistical Classification of Diseases and Related Health Problems, 10th Revision provide diagnostic criteria for two disorders, dependence and abuse (shown in Tables 1 and 2). The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition and the International Statistical Classification of Diseases and Related Health Problems, 10th Revision also provide symptoms for diagnosing substance-specific intoxication and withdrawal syndromes, and methods for diagnosing substance-induced psychiatric disorders. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition was developed in the United States by the American Psychiatric Association and is used in the United States and internationally in research studies. The International Statistical Classification of Diseases and Related Health Problems, 10th Revision was developed by the World

Table 1 Dependence criteria: International statistical classification of diseases and related health problems, 10th revision (ICD-10) and *diagnostic and statistical manual of mental disorders*, 4th edition (DSM-IV)

Substance	ICD-10	DSM-IV
All substances	*Three* or more of the following six symptoms occurring together for *at least 1 month, or* if less than 1 month, occurring together *repeatedly within a 12-month period*: 1. Tolerance: need for significantly increased amounts of alcohol to achieve intoxication or desired effect or markedly diminished effect with continued use of the same amount of alcohol. 2. A physiological withdrawal state of the characteristic withdrawal syndrome for alcohol, or use of alcohol (or closely related substance) to relieve or avoid symptoms. 3. Difficulties in controlling drinking in terms of onset, termination, or levels of use: drinking in larger amounts or over a longer period than intended; or a persistent desire or unsuccessful efforts to reduce or control drinking. 4. Important alternative pleasures or interests given up or reduced because of drinking; *or* a great deal of time spent in activities necessary to obtain or use alcohol or to recover from its effects. 5. Persisting with drinking despite clear evidence and knowledge of harmful physical or psychological consequences 6. A strong desire or sense of compulsion to drink.	A maladaptive pattern of drinking, leading to clinically significant impairment or distress as manifested by *three* or more of the following seven symptoms occurring *in the same 12-month period*: 1. Tolerance: need for markedly increased amounts of alcohol to achieve intoxication or desired effect; or markedly diminished effect with continued use of the same amount of alcohol. 2. The characteristic withdrawal syndrome for alcohol (or a closely related substance) or drinking to relieve or avoid withdrawal symptoms. 3. Persistent desire or one or more unsuccessful efforts to cut down or control drinking. 4. Drinking in larger amounts or over a longer period than the person intended. 5. Important social, occupational, or recreational activities given up or reduced because of drinking. 6. A great deal of time spent in activities necessary to obtain, to use or to recover from the effects of drinking. 7. Continued drinking despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to be caused or exacerbated by drinking.

Health Organization and is used internationally, mainly for clinical purposes and governmental reporting.

Substance Disorders in the Diagnostic and Statistical Manual of Mental Disorders

The substance dependence criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, shown in Table 1, are based on the alcohol dependence syndrome [62], which was generalized to drugs in 1981 [286]. Dependence was considered a combination of physiological and psychological processes leading to increasingly impaired control over substance use in the face of negative consequences. Dependence was one "axis" of substance problems, and the consequences of heavy use (social, legal, medical problems, hazardous use) a different axis of substance problems. This bi-axial concept [61] led to the distinction between abuse criteria (social, role, legal problems or hazardous use, most commonly driving while intoxicated) and dependence (tolerance, withdrawal, numerous indicators of impaired control over use).

The focus on *dependence* is based on its centrality in research and on its psychometric properties. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition—defined dependence and International Statistical Classification of Diseases and Related Health Problems, 10th Revision—defined dependence have good to excellent reliability across samples and instruments [24, 26, 83, 99, 101, 108, 265], with few exceptions (rare substances; hallucinogens). Dependence validity has also been shown to be good via several study designs. These include: multi-method comparisons [40, 80, 108, 115,

Table 2 Abuse/harmful use criteria: international statistical classification of diseases and related health problems, 10th revision (ICD-10) and *diagnostic and statistical manual of mental disorders*, 4th edition (DSM-IV)

Substance	ICD-10	DSM-IV
All substances	**A**: Clear evidence that alcohol use contributed to physical or psychological harm, which may lead to disability/adverse consequences. **B**: The nature of harm should be clearly identifiable (and specified). **C**: The pattern of use has persisted for at least 1 month or has occurred repeatedly within a 12-month period. **D**: Symptoms do not meet criteria for any other mental or behavioral disorder related to alcohol in the same time period (except for acute intoxication).	**A:** Criteria for alcohol dependence have never been met. **B:** A maladaptive pattern of drinking, leading to clinically significant impairment or distress as manifested by at least *one* of the following four symptoms occurring within a 12-month period: 1. Recurrent use of alcohol resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to alcohol use; alcohol-related absences, suspensions, or expulsions from school; neglect of children or household). 2. Recurrent alcohol use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by alcohol use). 3. Recurrent alcohol-related legal problems (e.g., arrests for alcohol-related disorderly conduct). 4. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused by or exacerbated by the effects of alcohol (e.g., arguments with spouse about consequences of intoxication).

213, 226, 231]; longitudinal studies [88, 100, 101, 109, 233, 235]; latent variable analysis [16, 97, 201], and construct validation [105, 113]. Animal models of a syndrome of cocaine dependence symptoms (as distinct from use patterns) [50, 222, 266] lend credence to the dependence syndrome not only as a cross-cultural phenomenon, as suggested by a World Health Organization study [40, 101, 213], but a cross-species phenomenon as well.

Substance *abuse* is a different case. Contrary to clinical assumptions, abuse does not necessarily lead to dependence [88, 100, 109, 116, 233, 235]. Further, not all cases of alcohol or drug dependence have abuse symptoms [110, 111]. Dependence is more familial than abuse [103, 109]. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition—defined alcohol abuse is most often diagnosed in the general population based on one symptom, driving while intoxicated [104, 106, 156]; preliminary analyses of national data show this is also the case for drug abuse. A *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition—defined diagnosis of abuse may thus depend on the availability of a car, while dependence is a heritable, complex condition.

Various psychometric analyses have been conducted to examine the validity of the Edwards and Gross taxonomy of two distinct, correlated factors for substance abuse and dependence criteria. Confirmatory factor analysis on the alcohol abuse and dependence items has provided mixed evidence; several studies show that a two-factor model best describes abuse and dependence items [84, 97, 201, 202], while several others found evidence of similar model fit for one- and two-factor models, preferring the

one-factor model on the basis of parsimony and high factor correlations [187, 212]. Factor analyses of cannabis abuse and dependence items have generally found support for a one-factor model or similar fit of one- and two-factor models [3, 73, 187, 203, 257], although results from a general population survey support a two-factor model [16]. Taken together, these studies show some support for combining abuse and dependence albeit with some evidence to the contrary. Differences across study may also have occurred due to characteristics of the populations studied (e.g., general population versus community sample, adults versus adolescents). A current unresolved issue for those preferring a single substance use disorder that combines abuse and dependence criteria is a valid threshold for differentiating between cases and non-cases. This issue will need to be resolved if the criteria are to be combined, for example, in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition.

Substance Disorders: A Categorical or Dimensional Trait?

Recent psychometric analyses of the substance abuse and dependence criteria have suggested that these disorders are not categorical entities; instead, evidence supports an underlying continuum of alcohol severity across a variety of samples and populations [112, 142, 164, 185, 212, 228]. Such information may be critical when statistical power is limited, as it often is in studies of gene–gene or gene–environment interaction. If *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition—defined alcohol dependence in categorical form is psychometrically sound (i.e., reliable and valid) but dichotomizes an inherently dimensional condition, then converting its elements to a dimensional measure may produce a more informative phenotype for etiologic studies [112]. Future versions of the diagnostic nomenclature will likely incorporate a dimensional form of substance dependence [122], but further psychometric and etiologic work validating dimensional forms of substance disorders remains necessary.

Descriptive Epidemiology: The Incidence and Prevalence of Substance Disorders

Prevalence and Incidence of Substance Disorders

The most comprehensive epidemiologic United States information on the incidence and prevalence of alcohol disorders comes from the National Epidemiologic Survey on Alcohol and Related Conditions, a longitudinal survey of 43,093 respondents aged 18 years and older conducted in 2001–2002 [81, 82, 85] with a 3-year follow-up of 34,653 respondents [82]. The diagnostic interview was the Alcohol Use Disorder and Associated Disabilities Interview Schedule—*Diagnostic and Statistical Manual of Mental Disorders*, 4th edition Version [82], a structured interview for non-clinicians with high reliability and validity for substance use disorders [26, 83, 108, 227, 265].

In the National Epidemiologic Survey on Alcohol and Related Conditions, the prevalence of current (past 12 months) alcohol abuse and dependence was 4.7 and 3.8%, respectively, for a total prevalence of 8.5% for any current alcohol use disorder [114]. The prevalence of lifetime alcohol abuse and dependence was 17.8 and 12.5%, respectively, for a total prevalence of 30.3% for any lifetime alcohol use disorder [114]. Current and lifetime alcohol disorders are more prevalent in men (current: 12.4%, lifetime: 42.0%) than in women (current: 4.9%, lifetime: 19.5%). Compared with individuals of White race/ethnicity, among whom the current and lifetime prevalence of alcohol disorders was 8.9 and 34.1%, respectively, Blacks, Hispanics, and Asians have a lower prevalence of current and lifetime alcohol disorders (6.9 and 20.6% for current and lifetime alcohol disorders among

Blacks, 7.9 and 21.0% Hispanics, and 4.5 and 11.6% among Asians. Alcohol disorder prevalence is inversely related to age; those in younger age groups are most likely to have an alcohol disorder, with mean ages at onset of alcohol abuse and dependence at 22.5 and 21.9, respectively [114]. The incidence of alcohol dependence was 1.66 per 100 person-years [85], meaning 1.66 cases per year of alcohol dependence for every 100 individuals without alcohol dependence at the beginning of that year. Incidence of alcohol abuse was slightly lower at 1.03 per 100 person-years [85]. In general, predictors of incidence were similar to predictors of prevalence.

Drug disorders were substantially less common than alcohol disorders. The prevalence of current (past 12 months) drug abuse and dependence was 1.4% and 0.6%, respectively, for a total prevalence of 2% for any current drug use disorder [227]. The prevalence of lifetime drug abuse and dependence was 7.7 and 2.6%, respectively, for a total prevalence of 10.3% for any lifetime drug use disorder [227]. Current and lifetime drug disorders are more prevalent in men (current: 2.8%, lifetime: 13.8%) than in women (current: 1.2%, lifetime: 7.1%). Drug disorder prevalence is inversely related to age; those in younger age groups are most likely to have a drug disorder, with mean ages at onset of drug abuse and dependence at 19 years. There is no consistent trend by race for drug disorders [227]. In the National Epidemiologic Survey on Alcohol and Related Conditions, incidence of drug dependence was estimated at 0.32 per 100 person-years of observation [85]; incidence of drug abuse was slightly lower at 0.28 per 100 person-years. In general, predictors of incidence were similar to predictors of prevalence.

The Course of Substance Disorders

Initiation of alcohol consumption and drug use often occurs during adolescence. Onset of alcohol abuse and dependence is most likely among individuals aged 18–29, although 15% of alcohol dependence cases begin before age 18 [127]. Often, substance disorders are not lifelong conditions. Indeed, a high rate of recovery has been documented in general population samples, even among individuals who have never sought treatment. Studies of alcohol disorders in the general population also show that a high proportion of recovered individuals return to moderate drinking as opposed to abstinence [47, 277]. Data from the National Epidemiologic Survey on Alcohol and Related Conditions indicated that approximately 75% of individuals diagnosed with alcohol dependence at some point in the past did not have a current (i.e., past year) diagnosis, but that only about 20% of these individuals were abstinent from alcohol [47]. However, prospective follow-up of this sample has indicated that low-risk drinking represents a risk factor for relapse to an alcohol disorder compared with abstinence [45]. Longer term prospective follow-up of this general population sample will help to clarify the role of alcohol consumption in recovery from disorder.

The transition to adulthood represents a key developmental phase in which alcohol disorders often remit, in a process termed “maturing out” [8, 46]. Major predictors of recovery include key lifestyle components, such as employment, marriage, and childbirth. Whether or not these factors have a causal influence on recovery or reflect common factors underlying the positive lifestyle components and the recovery remains unknown.

Despite substantial progress in the development of treatments for alcohol and drug disorders, only about one-fifth of those individuals with an alcohol disorder [34, 114] and one-sixth of individuals with a drug disorder [35] seek treatment for the condition during their lifetime. Further, the delay from onset of disorder to treatment is typically 8–10 years [276]. Finally, in contrast to sharp increases in treatment utilization for disorders such as depression between 1990 and 2003 [153], a corresponding increase in the proportion of individuals seeking treatment for an alcohol and drug disorders did not occur during this period [114].

The path from first use to dependence to treatment also differs by gender. Women who

use alcohol and drugs often start using later than men, have a faster progression from first use to dependence, and enter treatment sooner than men given equal ages of dependence onset [209, 215], although no such differences have been observed for crack-cocaine users [55, 171]. This phenomenon has been termed "telescoping".

Evidence is accumulating that these well-documented gender differences in the course of alcohol disorders are converging. Studies of adolescent alcohol use have consistently shown a convergence in rates of alcohol and drug use initiation in younger birth cohorts, especially those born after World War II [139, 141]. Further, several genetically informative samples have researched gender differences in *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition—defined alcohol and drug disorders over time, unanimously finding support for such a convergence [128, 220]. Similarly, large, representative cross-sectional studies in the United States support gender convergence in rates of *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition—defined alcohol abuse and dependence [92, 155]. Finally, evidence indicates that the traditional "telescoping" phenomenon whereby women exhibit later onset of drug use and disorder but earlier treatment and shorter course may be diminishing, as women are more closely approximating men in both onset and course of disorder [129]. Searches into the causes of these shifts are ongoing, but this evidence indicates increased social acceptability of alcohol use by women in younger generations [91].

Analytic Epidemiology: The Etiology of Substance Disorders

Substance use disorders have a complex etiology involving genetic and environmental factors. These occur along a continuum ranging from the macro level consisting of broad social influences, to the micro level, consisting of molecular-level influences. These can be thought of as external to internal levels (Fig. 3). In the remainder of this chapter, we address these levels in turn. We begin with macro/external factors, including societal availability and desirability of the substances, geographic and temporal differences, pricing, laws, and advertising. We next consider externally imposed stress. Intermediate-level factors include religiosity, parental and peer social influences. Moving increasingly toward the micro and internal levels, we consider cognitive and personality variables, subjective responses to substances, and specific risk as well as protective genes. We conclude by discussing gene-by-environment interaction, addressing the idea that since etiologic influences work at various levels, a factor at any level may emerge more clearly if other levels are considered conjointly.

Availability—Temporal and Geographical

Political Events

Political events, both local and global, influence the availability of substances and thus the risk

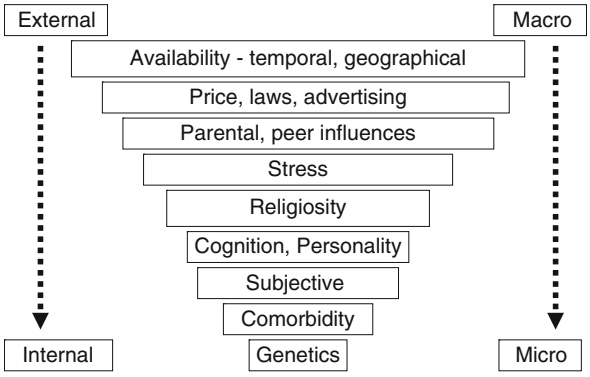

Fig. 3 Factors affecting substance use and substance use disorders

of substance use and dependence. In 2004, for example, religiously motivated attacks on alcohol retailers in Iraq (*BBC World News*, July 22, 2004) reduced the availability of alcohol locally for that region. After the Taliban government fell in Afghanistan in 2001, heroin production in Afghanistan increased greatly [165], coinciding with increased heroin use among American teenagers [255]. Political instability in South American countries such as Bolivia and Colombia, especially in the 1970s, influenced the production of cocaine and increased the availability of cocaine in the United States [251]. Thus, political events at a great geographic distance may influence local substance use availability and patterns of use.

Outlet Density

Counties, cities or states with higher density of alcohol outlets (places were alcohol is sold) have higher alcohol consumption and higher rates of alcohol-related problems, including hospital admissions, pedestrian injury collisions, and crashes and crash fatalities [33, 237, 256, 261, 262]. Ecologic and multilevel analysis controlling for individual level factors indicates that outlet density is related to higher mean group rates of consumption and drinking norms scores and to driving after drinking [93, 237]. Community-based interventions to limit access to alcohol by reducing the density of outlets have been shown to reduce alcohol-related traffic injury and self-reported consumption [130]. While information regarding outlet ("dealer") density is unavailable for drugs, the vigorous efforts of parents, schools, and law enforcement agencies to keep drug dealers away from schools are consistent with the same idea.

Pricing, Laws, and Advertising

Pricing

Alcohol taxation is the major determinant of state variation in the price of alcohol, and is thus a government intervention. An inverse relationship exists between state-level price of alcohol and per-capita consumption or adverse consequences of drinking [30]. Further, higher state-level beer tax is associated with lower prevalence of *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition—defined alcohol dependence [123]. Outside the United States, cutting the tax on spirits has been followed by increased per-capita alcohol consumption [120, 223].

Laws and Law Enforcement: Alcohol

Laws and their enforcement also affect consumption patterns. In the United States, the 18th Amendment to the Constitution outlawed the manufacture, transport, and sale of alcohol from 1920 to 1933. Figure 1 shows that in 1935, per-capita ethanol consumption was very low, but increased steadily afterwards, consistent with cirrhosis mortality rates from the same period [171, 287]. Thus, the 18th Amendment achieved its purpose, but was repealed because it was unacceptable to the public. Similar events occurred in the former Soviet Union, an area of very high per-capita alcohol consumption [285]. In the mid-1980s, the government attempted to restrict consumption. The policies were successful in reducing consumption, but so unpopular that they contributed to the downfall of the government and were eventually reversed [240].

More recently in the United States, enforcement of laws related to drinking and driving has been shown to be an important deterrent to alcohol-related crashes and fatalities. These include driver's license suspensions [268], and lowering the maximum legal blood alcohol concentration among drivers [69, 259, 269]. In addition, stricter driving-under-the-influence laws and their enforcement are consistently related to decreased hazardous use [182] and alcohol-related traffic fatalities [6, 268].

Minimum-age drinking laws influence the availability and acceptability of consumption among young people. Laws vary considerably by country both in scope and in minimum age [285]. For example, the minimum consumption

age in the United States is 21, while in Cyprus it is 12. Israel did not have a minimum legal drinking age until 2004, but public concern about increased risky drinking among young adults led to the establishment of a national minimum drinking age (18 years) at that time [248]. Some countries have separate age restrictions for consumption and purchase. For example, in Greece the minimum consumption age is 14 while the minimum purchase age is 17. In Italy, there is no age restriction on consumption in private, but a minimum age requirement of 16 to drink in public.

Minimum drinking age laws have a positive effect on community health as well as the health and safety of adolescents. Research in the United States and other developed countries has indicated that minimum drinking age laws reduce traffic crash and fatality rates [68, 241, 268, 271]; positive effects among adolescents include reducing in alcohol consumption and high risk drinking [206]. Additionally, several studies have documented an association between minimum drinking age laws and a reduction in youth suicide [15, 21].

State Distribution Policies

In the United States, states differ in the ways they control availability of alcohol. Some states exert more control through operation of state alcoholic beverage sales, while others exert less control through the licensing of alcohol outlets. This difference impacts sales and consumption patterns [270]. Compared with "wet" counties, "dry" counties, where alcohol is not sold, have lower rates of alcohol-related accidents, driving-under-the-influence arrests, and cirrhosis mortality [283]. International studies corroborate these findings; in Norway, stringent alcohol regulations, such as mandatory closing on Saturdays, led to lower detoxification admissions [223].

Grass-Roots Efforts

Mothers Against Drunk Driving was started in 1980 by a group of women after a teenage girl was killed by a repeat-offense drunk driver. Mothers Against Drunk Driving, a very active organization, national since the early 1980s, has been highly effective in influencing state legislation pertaining to intoxicated driving, such as increasing the minimum drinking age from 18 to 21, and enforcement of maximum-blood-alcohol-level laws among drivers [95]. In particular, a highly publicized media campaign called "Rate the State" in which states were graded A through D on driving-under-the-influence countermeasures, put pressure on legislators to increase the stringency of these laws, shown as an effective strategy in reducing alcohol-impaired driving [242, 267].

Alcohol Marketing and Advertising

Product development and marketing aim to increase sales and consumption [29]. Alcohol companies allocate substantial resources to researching consumer preferences, developing new products and promoting them [138]. For example, the alcohol beverage industry spent 696 million dollars on magazine advertising alone between 1997 and 2001, largely targeted to adolescents [74]. The alcohol industry does not publish the results of its marketing research, and resources necessary for definitive public health studies of advertising and other marketing effects are limited by comparison.

Public health concerns often focus on marketing that targets adolescents [28, 39]. Existing data from longitudinal studies show associations between late childhood-early adolescent exposure to advertising and subsequent drinking initiation and frequency [37, 64, 249]. Cross-sectional studies also show associations of various marketing and advertising strategies with positive attitudes about drinking and drinking frequency [71, 167]. Further, an imaging study of adolescent response to alcohol advertising indicated greater brain activation in areas linked to reward and desire among adolescents with alcohol use disorders than infrequent drinkers [254], suggesting that advertisements are especially salient to vulnerable adolescents.

Laws and Law Enforcement: Drugs

A literature on government efforts to reduce drug use by reducing availability is inconsistent. Some studies suggest the strategies are ineffective [17, 279, 284], while others find supply reductions efficacious [48, 278]. Reducing the supply of specific drugs can have unintended consequences, including increases in other substances [260]. Data from United States college studies, however, indicate that increased restrictions on alcohol use does not increase marijuana use, as has been hypothesized, but instead serves to decrease both alcohol and marijuana use [281]. Thus, the evidence is inconsistent on the efficacy of government attempts to limit drug use by reducing supply.

Parental and Peer Influences

Parental Modeling of Substance Use

Twin studies indicate that up to half the liability to alcohol dependence is environmental [225]. Parental modeling has been proposed as one such environmental factor affecting subsequent substance use in their children [65]. Adoption studies do not support this, however, since rates of alcoholism in adoptive children of alcoholics are not elevated [132]. One etiologic model with empirical support from twin studies posits that influential factors for substance use and the progression to dependence change over time; environmental and social factors mediate the initiation and use of substances in childhood and adolescence, while genetic factors become more influential in the adult substance use and dependence [151].

Parenting Practices

Poor parental monitoring increases association with substance-abusing peers [117], a risk factor for alcohol misuse (see below, peer influences). Harsh, inconsistent parenting predicts earlier initiation of alcohol use, conduct problems and poor regulatory competencies [166, 217]. On the other hand, warm yet authoritative parenting styles protect adolescents from alcohol problems [207].

Peers

Peer influence is a strong predictor of adolescent drug and alcohol use and problems [143, 250, 272]. Twin studies show that shared environmental influences such as peers have a significant effect on initiation of alcohol and any drug use [157, 219]. Two models have been proposed to explain peer influence on adolescent substance use, social selection, and socialization [144]. The social selection theory proposes that young adolescents selectively "mate" with friends; those children who display deviant behavior as children will be prone to choose deviant friendships in adolescence [70]. This can lead to initiation of drug use (especially marijuana use) and may be a factor in the transition to "heavier" drugs. It has been further proposed that an underlying trait such as sensation seeking (see below) influences both the selection of peers and substance use [53]. In contrast, the socialization theory proposes that adolescents can be influenced to use substances by peers in their environment [49] via modeling, offers, development of expectancies, and social norms [18, 236]. Substance use by older siblings is also associated with individual substance use [23, 75, 136, 190]. Studies that could examine these various environmental effects while controlling for genetic influences are needed to resolve the social selection/causation debate.

Peers may also be protective. Some United States ethnic/immigrant groups use substances less than the norm [89]. Adolescents from these groups with ethnically homogeneous peers encounter less pressure to use substances [22].

Stress

Drug disorders are often preceded and accompanied by disruptive behavior and conduct

problems [168] that have a shared genetic vulnerability with drug disorders [149]. These behaviors evoke negative reactions from the environment, resulting in stressful life events that are not always independent of the individuals, making a causal direction between stress and disease onset difficult to discern. In animal studies where stress can be experimentally applied, cause and effect are clearer, as is also the case in studies of early stressful experiences in humans that antedate the onset of substance use disorders.

Animal Models

In animal studies, the timing of stress relative to normal development can be experimentally manipulated. In adult animals, substance use increases after physical stressors [76, 210] and social stressors [44, 85, 96, 194].

Early life stressors also contribute to drug-using behaviors in animals. Neonatally isolated rats are more likely to acquire stimulant self-administration behaviors [134, 160, 179] and show higher dopamine levels in response to cocaine than handled rats, suggesting that early stress leads to greater cocaine reward [20, 161]. Early-life rearing stressors predict ethanol seeking in primates [10]. Isolated rearing led to increased drinking of morphine solution under various conditions [5, 184]. Recently developed animal models of Δ9-tetrahydrocannabinol self-administration [19] may allow similar studies for cannabis.

Early Stressors and Drug Use in Humans

Childhood stressors, including parental separation, neglect and abuse (physical and sexual) are associated with later substance use, problems and dependence [54, 150, 152]. However, most studies failed to control for parental history of substance abuse, a potential confounder given that substance abuse is associated with poor parenting [174]. One informative study showed that among adolescents with a substance-abusing parent, strong family cohesion (the opposite of neglect) protected against drug problems [133]. Twin studies allow the study of environmental stressors while controlling for genetic influences and have shown that childhood sexual abuse is an environmental risk factor for substance use disorders [147, 204]. Effects of other childhood adversities (e.g., neglect, physical and emotional abuse) have not been examined in twin studies.

Religiosity

Religiosity has been called "one of the more important environmental factors that affect the risk for substance use and dependence" [148]. An inverse relationship between religiosity and drinking is cross-cultural [4, 7, 208]. Longitudinal studies of adolescents, college and professional students show that religiosity protects against later heavy drinking [9, 183]. Religiosity is strongly correlated within twin pairs due to shared environmental effects [148, 158, 263]. Heritability of drinking differs between religious and non-religious twins, an example of gene-environment interaction [159]. In twins studied longitudinally [148], religiosity predicted later drinking more than drinking predicted later religiosity, suggesting that religiosity is more likely to influence drinking than the reverse. These studies indicate that religiosity is largely environmental and protects against alcohol use disorders. Religiosity also protects against drug disorders [31, 198], although this literature is less extensive.

Cognition, Personality

Substance Expectancies and Motivations

Positive substance expectancies constitute an important risk factor for the development of alcohol dependence [78, 238]. For example, alcohol expectancies are considered the beliefs that drinking alcohol will result in decreased

negative emotions or enhanced positive emotions [77, 245]. These expectancies can be derived from parents and peers, and are believed to be environmentally influenced rather than genetically influenced [244]. Motivations for drinking often fall under four main domains: (1) drinking to obtain social rewards or enhance social interactions; (2) drinking to enhance positive mood; (3) drinking to reduce negative mood, and (4) drinking to avoid social rejection and conform to social norms. While individuals with alcohol disorders often rate all motivations highly, reduction of negative affect and enhancement of positive affect have been prospectively associated with heavy use and alcohol and drug disorders [14, 27, 137].

Personality Traits

No single personality trait predicts alcoholism [239], but traits associated with the development of alcohol use disorders include novelty seeking [32] and sensation seeking [186, 289], traits that are often associated [58, 282]. The heritability of sensation seeking is unclear, with some twin studies suggesting that approximately half of the variance can be attributed to genetic factors [119, 121, 135], and another suggesting a much weaker influence of genetic factors [195]. Additional personality traits related to alcohol use disorders, albeit less consistently, are neuroticism/negative emotionality [288], impulsivity/disinhibition [191], and extraversion/sociability [125]. Similar traits have been examined in relation to drug use disorders. For example, research has shown that impulsivity/inhibition is reliably lower among individuals with drug abuse/dependence [38, 190], whereas negative emotionality tends to be higher [253, 282].

Subjective Reactions

Level of response to alcohol indicates the quantity needed to obtain an effect. Individuals with a low level of response need to drink more to obtain an effect. This is a genetically influenced characteristic associated with enhanced risk for alcohol use disorders [234]. Level of response varies by ethnicity. Several groups at high risk for alcohol use disorders show low response, including children of alcoholics, Native Americans, and Koreans [63, 198, 273], while high response is found among Jews [234], a group with relatively low levels of alcohol disorders [107, 174]. A low level of response predicts later onset of alcohol dependence in young adult males [232], and may contribute to transition from lighter to heavier drinking in individuals in a heavy-drinking environment [230]. Several chromosomal regions have shown suggestive linkage results to level of response [280] and an association with variations in the ADH1B gene (one of the genes that influences metabolism of alcohol in the liver) has been documented [57], but replication is needed.

Subjective reactions can also be characterized by whether they are positive or negative. A stimulating (reinforcing), rather than sedating, effect of alcohol has been identified in moderate/heavy drinkers [131], as well as untreated alcoholics [258]. In contrast, a flushing reaction to alcohol includes unpleasant physical sensations [124], found among Asians. A strong flushing reaction precludes drinking, while moderate flushing protects against alcohol dependence. Individuals also vary in their subjective responses to marijuana, and positive and/or negative responses are moderately heritable [180].

Psychiatric Comorbidity

Individuals with substance use disorders exhibit higher rates of mood, anxiety, and personality disorders as compared with the general population [35, 86, 87, 114, 154, 221]. For example, national surveys indicate that individuals with an alcohol disorder are approximately 3.0 times more likely to be diagnosed with major depression; the association between drug disorders and major depression is even stronger,

with odds ratios around 7.0 [36, 102]. A strong association has also been documented between substance disorders and antisocial personality disorder. The National Epidemiologic Survey on Alcohol and Related Conditions survey estimates that 39.3 and 72.4% of individuals with antisocial personality disorder meet criteria for lifetime drug disorders and alcohol disorders, respectively [79].

The strong and consistent relationships between substance disorders and other psychiatric disorders have prompted etiologic researchers to evaluate evidence for an underlying vulnerability to psychiatric disorder in general. Adult twin studies indicate at least moderate genetic heritability across disorder [146, 149, 182], and recent genetic studies have indicated specific genes associated with the transmission of several psychiatric disorder in general, rather than particular disorders [52, 274]. "Internalizing" and "externalizing" domains have been proposed as a means of organizing individual disorders into larger, more meaningful groups. Internalizing disorders are often characterized by the anxiety and depression domains, whereas externalizing disorders are often characterized by alcohol, drug, and antisocial personality disorders. Research into the validity and utility of broad versus narrow categorizations of disorder has been a major area of psychiatric research for decades [192], and remains ongoing [162, 163].

Genetics

Family and Twin Studies of Alcohol and Drug Dependence

Alcoholism [41, 205] and drug disorders [193] are familial. Genetic epidemiology studies of heritability use twin samples to compare concordance for a disorder between monozygotic (identical) vs. dizygotic (non-identical) twins. In these studies, significantly higher concordance in identical twins, who share 100% of their genes, compared with non-identical twins, who share only an average of 50% of their genes, indicates genetic heritability for a disorder. Twin studies of alcohol dependence show substantial heritabilities (50–60%) [118, 218]. Heritability estimates from studies of illicit drugs are more variable, perhaps due to more varied phenotypes (use, heavy use, abuse and dependence); for drug dependence, heritability estimates are similar to alcohol dependence [72, 147, 219]. For all substances, environmental factors appear to influence initiation and continuation of use, while genetic factors move individuals from use to dependence. Also, as noted above, environmental and social factors mediate the initiation and use of substances in childhood and adolescence, while genetic factors become more influential in the adult substance use and dependence [151]. Some twin studies investigating shared heritability of dependence on different substances showed high shared genetic variance between substances [149, 264] while other studies suggest that dependence on different classes of drugs is not genetically interchangeable [264]. Molecular genetics studies may be able to clarify these issues.

Genetics in Epidemiology Studies and Gene × Environment Interaction

The last 5 years have seen considerable progress in the genetics field in general, as well as in identifying genes whose variants show replicated results on relationships to the risk for alcohol and drug dependence. Some of the genes involved include those that affect the process of alcohol metabolism in the liver such as alcohol dehydrogenase 4 (*ADH4*), related to both alcohol [60, 94, 175, 177] and drug dependence [175, 177, 178]. Other well-replicated findings on genes related to the risk for substance dependence involve processes linked to neurotransmission. These include genes influencing gamma-aminobutyric acid, the major inhibitory neurotransmitter in the brain. Genetic variants in *GABRA-2* predict alcohol dependence in United States [42, 43, 59], Russian [170], and German [67, 247] samples, and the outcome of a behavioral treatment for

alcohol dependence in a multi-site study [12]. *GABRA-2* variants were also related to the risk for drug dependence [2]. The functioning of muscarinic cholinergic receptors underlies many brain functions, including attention, learning, memory, and cognition, all potentially related to addictive disorders. Genetic variants influencing this process include *CHRM2*, shown to affect the risk for alcohol and drug dependence [51, 176, 275] and related personality traits [60].

Although twin studies show that genetic and environmental factors are both important, few studies have addressed whether the relationship of specific genetic variants to alcohol and drug dependence is modified by environmental circumstances. This type of research question could be addressed by appropriately designed epidemiologic studies that collect DNA as well as interview information on risk factors. Until recently, a limitation on such studies was the need to extract DNA from blood samples, a difficult task in survey research due to many practical considerations. Fortunately, methods have recently become available to collect DNA through the use of saliva samples, making the inclusion of genetic variables much more feasible in epidemiologic research. An example of this approach includes a study showing that being exposed to childhood maltreatment interacted with a gene influencing stress reactions to predict early onset of drinking among adolescents [145]. Additional studies of this type are under way in Israel [248] and are being planned in the United States.

Studying the interaction between certain genes and specific environmental factors has important implications for the prevention and treatment of alcohol and drug use disorders. First, better knowledge in this area may help early identification of individuals who are unlikely to be able to use drugs or alcohol in moderation for early education, additional support or supervision. Second, the knowledge may help identify individuals exposed to particular stressors that would particularly benefit from intervention. Finally, clearer knowledge of the interaction of environmental with genetic effects may suggest new lines of investigation to determine the biological mechanisms of protective or risk-enhancing environmental events or conditions, which may eventually aid in developing better treatments.

Conclusion

In summary, a number of factors influencing the risk for substance dependence have been identified. Through trans-disciplinary research, epidemiologists and others can work together in the future to address multi-level factors conjointly.

United States Federal Drug Policy

Angela Hawken and Jonathan D. Kulick

Contents

Introduction

The United States federal government takes an active role in setting and implementing drug-control policy, directly and in concert with state and local authorities and with international partners—even as the other polities' policies may be widely at variance with federal policies. Over the last century, the government's formal policies, budgetary commitments, and actions reflect enduring tensions between different conceptions of the problem of drug abuse: civil liberties versus public order, public health versus criminal justice, use reduction versus harm reduction, and demand driven versus supply driven. Accordingly, the balance among the three pillars of treatment, prevention, and law enforcement has shifted with changes in drug use; public sentiment; external political, economic, and social forces; and research findings. Even so, the span of federal drug-control policy is best characterized as periods of perfervid law enforcement, driven by acute concern about the menace of particular drugs, alternating with periods of routine management of one of many social ills.

This chapter addresses the development of federal drug-control policy, and current policies and functions of the federal government. In particular, it considers the role of research in influencing policy. It is necessarily synoptic, and the interested reader is referred to more detailed source materials.

History

The use of some drugs that are now illicit, especially cannabis and opiates, was commonplace and uncontroversial in the United States before the late nineteenth century [56] (milestones in federal drug-control policy are outlined in Table 1). Opium appeared in many patent medicines, and the medical benefits were considered to outweigh the acknowledged harms [6]. Morphine and, later, heroin, were introduced in the 19th century, and were widely prescribed into

Table 1 Milestones in federal drug-control policy

Year	Measure	Effect or goal
1906	Pure Food and Drug Act	Required medicines to have labels of ingredients.
1909	Smoking Opium Exclusion Act	Prohibited import of opium for smoking.
1912	Hague Convention	Required signatories to pass domestic legislation to combat international drug trade.
1914	Harrison Narcotics Tax Act	Regulated trade in opium and coca products; effectively prohibited their use.
1918	Rainey Committee	Found illicit drugs to be a serious threat; called for stricter law enforcement.
1919	Heroin Act	Prohibited trade and possession of heroin, even for medical purposes.
1922	Narcotics Drugs Import and Export Act	Prohibited non-medical use of opiates and cocaine; established Federal Narcotics Control Board.
1925	*Linder v. United States*	Allowed for prescription of illicit drugs for addiction treatment.
1928	*Nigro v. United States*	Upheld constitutionality of Harrison Act.
1929	Porter Act	Created Public Health Services Narcotics Division and prison hospitals for addicts.
1930	Federal Bureau of Narcotics	Created enforcement structure in Treasury Department, under a Narcotics Commissioner.
1932	Uniform State Narcotic Act	Encouraged state governments to control marijuana use in line with 1922 Act, in lieu of federal legislation.
1936	*Reefer Madness*	Documentary about the dangers of marijuana distributed by government.
1937	Marihuana Tax Act	Effectively criminalized distribution of marijuana.
1942	Opium Poppy Control Act	Prohibited growing opium poppies without a license.
1951	Boggs Act	Established mandatory-minimum prison sentences, with uniform penalties for opiates, cocaine, and marijuana.
1956	Narcotic Control Act	Increased penalties under the 1951 Boggs Act.
1960	Narcotics Manufacturing Act	Placed controls on legal manufacturers of opiates and cocaine.
1961	Single Convention on Narcotic Drugs	Consolidated earlier drug-control treaties, and added cannabis; superseded 1912 Hague Convention.
1963	President's Advisory Commission on Narcotics and Drug Abuse (Prettyman Commission)	Called for using all resources of federal government to combat trafficking.
1965	Drug Abuse Control Amendments	Placed controls on stimulants and depressants, and restricted research into hallucinogens.
1966	Narcotic Addict Rehabilitation Act	Diverted some addicts to treatment as an alternative to incarceration. Authorized support to states' rehabilitation programs.
1968	Bureau of Narcotics and Dangerous Drugs	Created from merger of Federal Bureau of Narcotics and Bureau of Drug Abuse Control.[a]
1969	Operation Intercept	Closed Mexican border and searched vehicles crossing it.
1970	Controlled Substances Act[b]	Consolidated many drug-control laws, placing all controlled drugs into one of five schedules. Addressed prevention and treatment, and interdiction. Repealed mandatory-minimum penalties.
1971	War on Drugs	Comprehensive policy announced by White House to combat domestic and international production, distribution, and use.
1972	National Commission on Marihuana and Drug Abuse	Federal study recommended marijuana decriminalization [56].
	Drug Abuse Office and Treatment Act	Established national network of treatment programs. Created Special Action Office for Drug Abuse Prevention in Executive Office of the President.

Table 1 (continued)

Year	Measure	Effect or goal
	Drug Abuse Warning Network and National Household Survey on Drug Abuse	Surveys initiated under the Special Action Office for Drug Abuse Prevention.
1973	Methadone Control Act	Established federally funded clinics for prevention and treatment of heroin addiction.
	Heroin Trafficking Act	Increased penalties for drug traffickers and established strict bail procedures.
	Drug Enforcement Administration	Created to supersede the Bureau of Narcotics and Dangerous Drugs.
	Alcohol, Drug Abuse, and Mental Health Administration	Created to oversee the National Institute of Mental Health, the National Institute on Drug Abuse, and the National Institute on Alcohol Abuse and Alcoholism.
	National Institute on Drug Abuse	Established as focal point for research, treatment, prevention, training, services, and data collection.
	National Drug and Alcohol Treatment Unit Survey	Initiated at the National Institute on Drug Abuse to characterize prevention and treatment programs.
1975	Monitoring the Future Survey	Initiated at the National Institute on Drug Abuse to measure use and attitudes in young adults.
1976	Comprehensive Alcohol Abuse and Alcoholism Prevention, Treatment, and Rehabilitation Act Amendments	Directed attention to prevention and treatment for women and youth.
1978	Drug Abuse Education Amendments	Coordinated state and federal education programs. Established Office of Alcohol and Drug Abuse Education in Department of Education.
1980	Drug Abuse Prevention, Treatment, and Rehabilitation Amendments	Encouraged foreign cooperation in eradication and interdiction. Strengthened federal leadership in prevention, education, treatment, and rehabilitation. Reimposed mandatory-minimum sentences.
1982	National Research Council marijuana-policy study [41]	Called for allowing states to decriminalize.
1986	Controlled Substances Analogue Enforcement Act	Established controls for enforcement of "designer drugs" (e.g., 3,4-methylenedioxymethamphetamine); allowed for immediate scheduling.
	Drug-Free Workplace	Executive order required federal agencies to institute urine-testing programs.
1988	Drug Free Workplace Act	Required federal contractors to institute urine-testing programs.
	Anti-Drug Abuse Act	Authorized funds for school-based prevention programs. Established different penalties for powder and crack cocaine.
	Office of National Drug Control Policy	Created in Executive Office of the President.
1991	National Commission on Acquired Immune Deficiency Syndrome	Report called for expansion of treatment and decriminalizing needle sale and possession.
1992	Substance Abuse and Mental Health Services Administration.	Established in the Department of Health and Human Services. Transferred the National Institute on Drug Abuse, the National Institute of Mental Health, and the National Institute on Alcohol Abuse and Alcoholism to the National Institutes of Health. Abolished the Alcohol, Drug Abuse, and Mental Health Administration.

Table 1 (continued)

Year	Measure	Effect or goal
1993	Departments of Labor, Health and Human Services, and Education FY 1994 Appropriations Act	Prohibited funding for sterile-needle programs.
	Domestic Chemical Diversion Control Act	Instituted Drug Enforcement Administration registration requirement for many precursor chemicals for controlled substances.
	International Counternarcotics Policy (Presidential Decision Directive 14)	Provided policy framework for international drug control.
1995	Heroin Control Policy (Presidential Decision Directive 44)	Provided policy framework for source-country eradication and trafficker-financing efforts.
1996	Methamphetamine Control Act	Established new controls over methamphetamine precursor chemicals, and increased penalties for their possession.
1997	Drug-Free Communities Act	Provided funds to community anti-drug coalitions.
1998	Drug-Free Workplace Act	Provided federal funds to small businesses for mandatory employee drug testing.
	Drug Free Media Campaign Act	Required the Office of National Drug Control Policy to conduct a national youth-targeted media campaign.
	Office of National Drug Control Policy Reauthorization Act	Expanded the Office of National Drug Control Policy's mandate and elevated it to cabinet status.
2000	Drug Addiction Treatment Act	Allowed physicians to provide opiates to addicts outside of drug-treatment clinics.
	Ecstasy Anti-Proliferation Act	Increased penalties for trafficking in 3,4-methylenedioxymethamphetamine.
	Children's Health Act	Repealed the Narcotic Addict Rehabilitation Act. Waived parts of the Controlled Substances Act of 1970 to permit office-based treatment of opiate dependence. Authorized expansion of National Institute on Drug Abuse research on methamphetamine and 3,4-methylenedioxy-methamphetamine.
	Plan Colombia	Emergency Supplemental Act funded counter-drug activities of Government of Colombia.
2001	National Prevention Research Initiative	National Institute on Drug Abuse effort to promote science-based prevention strategies.
	National Research Council comprehensive federal policy study [47]	Found that data and research are "strikingly inadequate" to support policymaking.
2002	Vulnerability to Ecstasy Act	Provided for prosecution of owners and managers of facilities hosting drug use, trade, or manufacturing.
2004	Anabolic Steroids Control Act	Significantly expanded list of scheduled anabolic steroids.
2005	Combat Methamphetamine Epidemic Act	Regulated retail sales of medicines used in the manufacture of methamphetamine.
	Gonzales v. Raich	Upheld right of Congress to ban marijuana use, under the Commerce Clause.

[a]Formerly the Federal Bureau of Narcotics had been responsible for heroin, cocaine, and cannabis, and the Bureau of Drug Abuse Control (in the Food and Drug Administration) had been responsible for depressants, stimulants, and hallucinogens

[b]The Controlled Substances Act of 1970 was Part II of the Comprehensive Drug Abuse Prevention and Control Act

the 1920s. Cocaine appeared first in beverages, and then in many prescription medicines around the turn of the century [41].

The anti-alcohol temperance movement grew in force in the late 19th century, leading to calls for the prohibition of alcohol, but the movement leaders were not concerned with other drugs, which they did not regard as degrading to character [67]. Nonetheless, the success of the temperance movement established a precedent that "prohibition was the only logical or moral policy when dealing with such a great national problem" [42].

Until the turn of the century, the federal government had not exercised general police powers over public health. The rise of the progressive movement and public concerns about the depredations of the patent-medicine industry led to the passage of the Pure Food and Drug Act of 1906, which imposed labeling and purity requirements. While it did not prohibit any ingredients, it is regarded as having reduced the rate of opiates addiction [34].

The first federal prohibition against drug use addressed opium, driven by concerns about opium smoking by Chinese immigrants, by foreign-policy interests in China and the Philippines, and by the observation that merely restrictive laws had spurred smuggling without much reducing supply. A 1905 law that prohibited the import and sale of opium in the Philippines, then a United States colony, was the first federal law to prohibit trafficking in a drug, although opium for smoking had been subject to a special duty since 1862 [25]. The Smoking Opium Exclusion Act of 1909 prohibited the import of opium for smoking, but did not cover other forms of opium, which was widely used for medicine and recreation throughout the United States. The United States was also signatory to several international conventions restricting the trade in opium.

As opium smoking was associated with Chinese immigrants, so did cocaine snorting become associated with poor blacks around the turn of the century, even as whites dominated cocaine consumption [74]. Similarly, marijuana became associated with Mexican immigrants, and concern about its use was highest in the border regions where they were concentrated [42].

The Harrison Narcotics Tax Act of 1914 [26] was positioned as a revenue measure, rather than as prohibition, and as required for the United States to comply with the Hague Convention of 1912 [30]; the congressional debate on the act saw almost no mention of moral concerns. The Act required that any party involved in the distribution of opiates or coca products register with the federal government and pay a tax. It allowed for selling small quantities of the controlled drugs over the counter, and for larger sales authorized by a physician, so doctors (and the American Medical Association) did not feel that it threatened the practice of medicine [42]. Soon after passage, however, the act was interpreted to prohibit a physician from supplying the controlled drugs to addicts (who—as addiction was not considered a disease—were not legitimately patients). Under this interpretation, federal agents arrested many physicians, and made it clear that the government was not going to tolerate treatment of addicts that maintained their addiction [16]. The Narcotics Division of the Prohibition Unit of the Internal Revenue Service (Treasury Department) was given enforcement authority, which was transferred to the Prohibition Bureau in 1927.

There followed a series of committees to investigate the effects of the Harrison Act and the scope of the drug problem. A 1918 committee finding called for stricter law enforcement and greater coordination of state laws with federal statutes [34].

Many court rulings on whether Congress had the power to regulate physicians and punish drug possession established federal authority by 1925 [6], and a 1928 Supreme Court ruling affirmed that the Harrison Act was constitutional [48]. Alcohol prohibition, established by the Eighteenth Amendment in 1919, was by this time hotly debated, but the Harrison Act occasioned little controversy, despite the fact that drug violations accounted for a greater number of federal prisoners than any other class of offenses [48].

The growing scope of prosecutions under the Harrison Act spurred Congress to build an institutional structure to manage the consequences. The Porter Narcotic Farm Act of 1929 established two facilities where addicts could be held and treated. In 1930, the Federal Bureau of Narcotics was established in the Treasury Department, under the direction of Commissioner Harry J. Anslinger, who would go on to dominate federal drug-control policymaking and implementation for decades. (Anslinger was the nephew of the Treasury Secretary, Andrew J. Mellon; it is not apparent that Mellon shared what turned out to be his nephew's zeal for drug control [58].) Initially, the Federal Bureau of Narcotics focused its efforts on heroin, and Anslinger publicly downplayed the threat from marijuana [21]. In the 1930s, advances in the processing of hemp fiber threatened powerful petroleum and timber interests, who lobbied Congress for the prohibition of hemp and used their influence in the newspaper business to demonize marijuana users [56]. (As industrial hemp and marijuana are the same plant—albeit very different strains—it is difficult to distinguish between cultivation of the two in the law.)

The Federal Bureau of Narcotics responded to these pressures with the Marihuana Tax Act of 1937, and a media campaign to stir fears of marijuana use. The Act did not explicitly prohibit the possession or sale of marijuana, but imposed registration and transaction tax obligations on anyone trafficking in it, with heavy fines and prison terms up to 20 years. (The transfer tax was a contrivance, as a measure under treaty powers was infeasible and a revenue measure would be difficult to enforce [74].)

Drug use declined during World War II, and rose again thereafter [74]. The wartime decline was due, in part, to supply reductions from countries embroiled in conflict. The shortage of legal supplies spurred the growth of the black market, especially for heroin [33]. In response to the growing public perception that marijuana use led to the use of opiates, and urged on by the Federal Bureau of Narcotics, Congress responded with reinforcements of the Harrison Act. The Boggs Act of 1951 [8] was the first to impose mandatory-minimum sentences and to lump together marijuana, opiates, and cocaine, with uniform penalties [57]. National medical and legal associations questioned this stricter regime, and called for a Congressional study of the government's drug policy. The Daniel Committee found that drugs posed a great threat to the country, and recommended increased powers for the Federal Bureau of Narcotics and harsh measures, including denial of bail, making smuggling and heroin trafficking capital offenses, and the closing of treatment clinics [33]. The Narcotic Control Act of 1956 [43] implemented these recommendations.

The Narcotics Manufacturing Act of 1960 [44] established licenses and quotas for drug manufacturers, to bring the United States into compliance with international conventions on the medical and scientific uses of natural and synthetic opiates and cocaine. By the language of the conventions, barbiturates, amphetamines, and tranquilizers were not covered by the Act [26].

As public concern over drug abuse (including prescription drugs) grew in the 1960s, the White House established the President's Advisory Commission on Narcotics and Drug Abuse (Prettyman Commission). Its 1963 report called for marshaling all the powers of the federal government to combat drug use and trafficking [51]. In particular, it recommended: (1) that enforcement and investigative responsibilities be transferred to the Department of Justice, (2) a substantial increase in federal agents, and (3) extension of federal control over all drugs "capable of producing serious psychotoxic effects when abused".

Following on the report, the Drug Abuse Control Amendments of 1965 placed restrictions on the manufacture of prescription drugs with a potential for abuse, with the establishment of the Bureau of Drug Abuse Control in the Food and Drug Administration. As previous prohibitions had done for opiates, the Drug Abuse Control Amendments created shortages that drove up the street price (especially of amphetamine) and spurred the involvement of criminal organizations in manufacturing and

trafficking [16]. In 1968 the Bureau of Drug Abuse Control was merged with the Treasury Department's Federal Bureau of Narcotics to form the Bureau of Narcotics and Dangerous Drugs, in the Department of Justice.

Despite these efforts to control drugs (and similar measures in other countries), the use of marijuana and heroin continued to increase. Under President Nixon, the United States government redoubled its campaign against drug trafficking and abuse, formally declaring a "War on Drugs"; in 1971, President Nixon declared that drugs were "public enemy number one" [7]. In 1969, the United States closed the border with Mexico and instituted searches of vehicles crossing the border. The National Commission on Marijuana and Drug Abuse was created in 1970.

The Controlled Substances Act of 1970 [14] supplanted the Harrison Act as the basis of federal drug-control policy, and remains so today. Extant federal laws were reformulated under the federal power to regulate interstate commerce, and drugs were placed into five categories ("schedules") according to their medical utility and potential for abuse. (See Table 2 for a summary of the current schedules.) In earlier decades, courts had found that Congress did not have the authority to regulate the local production and distribution of drugs under its interstate-commerce powers, but opinions had shifted by the mid-1960s. Following the 1965 Drug Abuse Control Amendments model, the Controlled Substances Act of 1970 established administrative procedures for scheduling new drugs. The ongoing tension within the government over which agencies would have control over drug policy was evident in the drafting of the Controlled Substances Act of 1970. In the Senate version of the bill, the Attorney General was required only to "request the advice" of the Secretary of Health, Education, and Welfare (now Health and Human Services) and of a (non-binding) scientific-advisory committee before amending the schedule; in the House version, which was finally adopted, the Attorney General was not allowed to override the Secretary's determination *not* to schedule a new drug, and he was required to accept the Secretary's recommendation regarding medical and scientific considerations [59].

Drug control was a less visible priority under the Ford and Carter administrations. President Ford endorsed the findings of the Domestic Council Drug Abuse Task Force that the federal government could at most contain the problems of drug abuse, and should not operate under the model of eliminating them [23]. President Carter went so far as to publicly entertain the notion of marijuana decriminalization, but this idea gained no traction in Congress and public sentiment was against it [41].

The Drug Abuse Prevention, Treatment and Rehabilitation Act of 1979 [17] reflected the latest, slight swing of the pendulum away from law enforcement. It imposed minimum requirements on the National Institute on Drug Abuse for spending on prevention, and identified high-risk populations to be targeted with intervention programs.

The 1980s saw another escalation of the War on Drugs. President Reagan created the position of the White House Drug Policy Advisor in 1982, which was supplanted by an even more powerful Director of the Office of National Drug Control Policy in 1988, under the National Narcotics Leadership Act. (These officials are commonly known as the "Drug Czars". The Director of the Office of National Drug Control Policy has held cabinet-level rank, until the appointment of Gil Kerlikowske by President Obama [15]. For a comparative assessment of the performance of the Drug Czars, see [39].)

A series of measures increased federal penalties for many offences, increased drug-control spending, and improved the coordination of federal drug-control efforts. The Comprehensive Crime Control Act of 1984 [13] amended the Controlled Substances Act of 1970 to allow for fast-tracked scheduling of newly emerging "designer drugs" and when there exists an imminent public-safety hazard. Rising public concern about crack cocaine, catalyzed by the overdose death of a star college basketball player, led to the Anti-Drug Abuse Act of 1986 [2], which reinstated mandatory-minimum sentences for possession (large amounts were considered

Table 2 Schedule of controlled substances

Schedule I	
Criteria	• high potential for abuse • no currently accepted medical use in treatment in the United States • no safety for use under medical supervision
Major drugs	• cannabis • heroin • gamma-hydroxybutyric acid • lysergic acid diethylamide • 3,4-methylenedioxymethamphetamine (Ecstasy) • methaqualone (Quaalude) • peyote[a] and mescaline • psilocybin mushrooms
Schedule II	
Criteria	• high potential for abuse • currently accepted medical use in treatment in the United States • abuse may lead to severe psychological or physical dependence
Major drugs	• amphetamines • barbiturates—short acting • cocaine • methamphetamine • methylphenidate (Ritalin) • opiates (e.g., methadone, morphine, oxycodone, fentanyl)
Schedule III	
Criteria	• potential for abuse less than in schedules I and II • currently accepted medical use in treatment in the United States • abuse may lead to moderate or low physical dependence or high psychological dependence
Major drugs	• anabolic steroids • barbiturates—intermediate acting • codeine • ketamine • synthetic tetrahydrocannabinol (Marinol)
Schedule IV	
Criteria	• low potential for abuse relative to schedule III • currently accepted medical use in treatment in the United States • abuse may lead to limited physical dependence or psychological dependence relative to schedule III
Major drugs	• barbiturates—long acting • benzodiazepines (e.g., Valium, Xanax)
Schedule V	
Criteria	• low potential for abuse relative to schedule IV • currently accepted medical use in treatment in the United States • abuse may lead to limited physical dependence or psychological dependence relative to schedule IV
Major drugs	• codeine cough suppressant • opiate anti-diarrheals

[a]Members of the Native American Church are allowed to use peyote in their rituals

prima facie evidence of intent to distribute) and allowed for the death penalty for some offenses.

Sentencing requirements were based on weight (see Table 3), with crack and powder cocaine treated dramatically differently; Congress justified the 100:1 powder-to-crack ratio on the basis of the social harms associated with crack, despite the identical chemical composition of the two forms. Whatever the original intent of Congress, this sentencing distinction

Table 3 Federal penalties for drug trafficking

Drug (Schedule)	Quantity	Penalties	Quantity	Penalties
Cocaine (II)	500–4,999 gm	1st Offense: 5–40 years. If death or serious injury, 20 years–life. ≤$2 M if an individual, $5 M if not. 2nd Offense: 10 years–life. If death or serious injury, life. ≤$4 M if an individual, $10 M if not.	≥5 kg	1st Offense: 10 years–life. If death or serious injury, 20 years–life. ≤$4 M if an individual, $10 M if not. 2nd Offense: 20 years–life. If death or serious injury, life. ≤$8 M if an individual, $20 M if not. 2 or More Prior Offenses: Life.
Cocaine Base (II)	5–49 gm		≥50 gm	
Fentanyl (II)	40–399 gm		≥400 gm	
Heroin (I)	100–999 gm		≥1 kg	
Lysergic acid diethylamide (I)[a]	1–9 gm		≥10 gm	
Methamphetamine (II)	5–49 gm		≥50 gm	
Phencyclidine (II)	10–99 gm		≥100 gm	

Drug	Quantity	Penalties
Other Schedule I and II	Any	1st Offense: ≤20 years. If death or serious injury, 20 years–life. $1 M if an individual, $5 M if not. 2nd Offense: ≤30 years. If death or serious injury, life. ≤$2 M if an individual, $10 M if not.
Schedule III	Any	1st Offense: ≤5 years. ≤$250 k if an individual, $1 M if not. 2nd Offense: ≤10 years. ≤$500 k if an individual, $2 M if not.
Schedule IV	Any	1st Offense: ≤3 years. ≤$250 k if an individual, $1 M if not. 2nd Offense: ≤6 years. ≤$500 k if an individual, $2 M if not.
Schedule V	Any	1st Offense: ≤1 year. ≤$100 k if an individual, $250 k if not. 2nd Offense: ≤2 years. ≤$200 k if an individual, $500 k if not.

Cannabis	Quantity	Penalties
Marijuana	50–99 kg or plants	1st Offense: ≤5 years. ≤$250 k if an individual, $1 M if not. 2nd Offense: ≤10 years. ≤$500 k if an individual, $2 M if not.
	100–999 kg or plants	1st Offense: 5–40 years. If death or serious injury, 20 years–life. ≤$2 M if an individual, $5 M if not. 2nd Offense: 10 years–life. If death or serious injury, life. ≤$4 M if an individual, $10 M if not.
	≥1,000 kg or plants	1st Offense: 10 years–life. If death or serious injury, 20 years–life. ≤$4 M if an individual, $10 M if not. 2nd Offense: 20 years–life. If death or serious injury, life. ≤$8 M if an individual, $20 M if not.
Hashish	≤10 kg or 1 kg hashish oil	1st Offense: ≤5 years. ≤$250 k if an individual, $1 M if not. 2nd Offense: ≤10 years. ≤$500 k if an individual, $2 M if not.
	>10 kg or 1 kg hashish oil	1st Offense: ≤20 years. If death or serious injury, 20 years–life. ≤$1 M if an individual, $5 M if not. 2nd Offense: ≤30 years. If death or serious injury, life. ≤$2 M if an individual, $10 M if not.

[a]Lysergic acid diethylamide weights include the carrier medium (e.g., blotter paper)

has had hugely disproportionate racial impacts, as the majority of offenders sentenced for crack have been black, and the majority sentenced for powder have been white [32]. Congress has rejected repeated recommendations by the U.S. Sentencing Commission that the crack-powder distinction be eliminated, and has let die in committee every bill that would reduce or eliminate sentencing disparities [19].

The Anti-Drug Abuse Act of 1988 [3] states that "it is the declared policy of the United States Government to create a drug-free America by 1995." It established the White House Office of National Drug Control Policy to be the principal architect of national drug-control strategy. The Act also requires some federal contractors and all grantees to meet requirements for providing a "drug-free workplace," and extends mandatory-minimum sentencing requirements to conspiracy convictions. Under the statute, the Office of National Drug Control Policy is to set priorities, implement a national strategy, and certify federal budgets. The strategy is to be comprehensive and research based, with measurable objectives. Subsequent executive orders, reauthorization bills, and other legislative initiatives have added to the Office of National Drug Control Policy's authority and responsibilities, to include media campaigns, grants to communities, and cabinet-department budget assessments [65]. Smarting from criticism that the office was politically driven and insufficiently evidence based, it asked the National Research Council to establish a Committee on Data and Research for Policy on Illegal Drugs, which found that:

> [N]either the data systems nor the research infrastructure needed to assess the effectiveness of drug control enforcement policies now exists. It is time for the federal government to remedy this serious deficiency. It is unconscionable for this country to continue to carry out a public policy of this magnitude and cost without any way of knowing whether and to what extent it is having the desired effect [36].

The subsequent presidential administrations have seen smaller-bore legislative initiatives and less rhetorical emphasis on drugs, even as the War on Drugs has continued apace. At the same time, conflicts between federal law and state- and local-level statutes and enforcement have increased. In President Clinton's first term, he decimated the Office of National Drug Control Policy staff, appointed a low-key Director, and made almost no mention of drugs, occasioning criticism even from Democratic officials [5]. President Clinton reversed these positions during his reelection campaign and appointed a very visible Director.

In the same election season, voters in Arizona and California approved measures that legalized the use of marijuana for medical purposes, in direct contravention of the federal Controlled Substances Act. (Other state initiatives to allow for the medical use of marijuana date back to 1978, but were ineffective [37].) Top administration officials vowed to enforce federal laws and sought to prosecute physicians who prescribed marijuana. The George W. Bush Administration continued to campaign against increasingly lenient state laws and local decisions to make marijuana arrests a low priority, and went after (locally legal) sellers of drug paraphernalia [9].

Nonetheless, despite Drug Enforcement Administration raids on dispensaries, a few prosecutions of prescribing doctors, and a Supreme Court ruling upholding the federal government's authority to prohibit the use of cannabis [27], medical marijuana has proved popular, and the new Obama Administration has announced that it will no longer prosecute marijuana dispensaries that are operating legally in the 13 states that allow for them [38]. Meanwhile, states and localities have become laboratories for experimenting with reforms of drug policy—with sentencing, needle-exchange programs, and marijuana decriminalization. An accurate understanding of drug policy *as practiced* in the United States requires closer attention to state and local drug policies [53].

Federal Drug-Control Operations

The federal government budgets over 14 billion dollars to drug-control efforts, divided among twelve federal agencies with drug-control

Table 4 Federal drug-control fiscal year 2009 budget and activities

Agency	Drug-control programs and functions	Budget ($ million)
Department of Health and Human Services	National Institute on Drug Abuse (drug-abuse and addiction research), the Substance Abuse and Mental Health Services Administration (substance-abuse treatment and prevention), Indian Health Services (treatment and prevention), Centers for Medicare and Medicaid Services (screening and intervention for at-risk beneficiaries)	3,799
Department of Homeland Security	Office of Counternarcotics Enforcement, Customs and Border Protection, Immigration and Customs Enforcement, Coast Guard	3,696
Department of Justice	Drug Enforcement Administration, Interagency Crime and Drug Enforcement, Office of Justice Programs, Bureau of Prisons	2,896
Department of State	Bureau of International Narcotics and Law Enforcement Affairs, United States Agency for International Development	1,489
Department of Defense	Interdiction, intelligence, state and local assistance, prevention, and treatment programs	1,061
Department of Veterans Affairs	Veterans Health Administration	465
Office of National Drug Control Policy	High Intensity Drug Trafficking Area Program, Drug Free Communities program, National Youth Anti-Drug Media Campaign, Counterdrug Technology Assessment Center	422
Department of Education	Safe and Drug-Free Schools and Communities Act programs	218
Department of the Treasury	Internal Revenue Service, Office of Foreign Assets Control, Financial Crime Enforcement Network	59.2
Department of the Interior	Bureau of Indian Affairs	6.3
Department of Transportation	National Highway Traffic Safety Administration	2.7
Small Business Administration	Drug-free workplace grants	1.0
	Total	14,114

functions (unless otherwise noted, all budget figures are for fiscal year 2009). The lion's share of these resources (92%) is controlled by five cabinet departments: Health and Human Services, Homeland Security, Justice, State, and Defense (see Table 4). The Department of Health and Human Services has the largest share ($3.8 billion). It houses the National Institute on Drug Abuse, the largest supporter of drug-abuse and addiction research, and the Substance Abuse and Mental Health Services Administration, which funds substance-abuse treatment and prevention services. The Department of Homeland Security ($3.7 billion) enforces drug control at the borders, via Customs and Border Protection, Immigration and Customs Enforcement, and the Coast Guard. These agencies are responsible for cross-border protection, intercepting the movement of drugs and drug-related funds, and money laundering. Following the attacks of September 11, 2001, the drug-funds interception functions of the Department of Homeland Security were increased with the passing of the USA Patriot Act, which gave the Department of Homeland Security and federal security agencies additional authority to investigate and preempt future terrorist activities.

The Department of Justice budget is $2.9 billion. The Department of Justice supports prison- and community-based drug treatment through the Bureau of Prisons; enforces federal illicit-substance laws and regulations through the Drug Enforcement Administration, targets drug-trafficking and money-laundering organizations through the Interagency Crime and Drug Enforcement account, and manages drug-control–strategy programs through the Office of Justice Programs.

The State Department budget is $1.5 billion, for the Bureau of International Narcotics and Law Enforcement Affairs and the U.S. Agency for International Development. Roughly two-thirds is for eradication and interdiction efforts, and one-third for promoting alternatives to drug production in source countries.

The Defense Department budget is $1.1 billion, for drug-related threats to national security. The Department of Defense oversees interdiction and the disruption of illegal-drug flows toward the United States, collects and disseminates intelligence on drug activity, and trains American and foreign drug-enforcement agents (including foreign militaries). The Department of Defense's drug-control efforts include a demand-reduction program (random drug testing with sanctions, anti-drug education, and treatment) for the military.

Policymaking and Budgeting

While drug-control policy is implemented in many agencies of the executive branch, it is directed from, and coordinated by, the White House Office of National Drug Control Policy. Responsibility for drug-control legislation is spread across many House and Senate subcommittees (see Table 5 for those subcommittees with principal responsibility, and Table 6 for bills introduced in recent sessions).

When the Office of National Drug Control Policy was created in 1988, it was tasked with compiling a federal drug-control budget. Each year federal agencies submit drug-control–budget data to the Office of National Drug Control Policy, which produces a single federal budget. The Office of National Drug Control Policy has no budget-enforcement authority, so its budget is not prescriptive.

Federal agencies and the Office of National Drug Control Policy have some discretion in what they identify as drug-control expenditures, so the federal budget (and the balance between demand- and supply-side control measures) is sensitive to assumptions about what constitutes drug control [40]. In 2004, the Office of National Drug Control Policy changed its methodology for assembling the federal drug-control budget [77]. The Office of National Drug Control Policy's stated purpose was to more directly measure efforts targeting drug use itself, rather than its consequences [60]—that is, to exclude expenditures that were considered ancillary to drug control. Critics of this revision regard it as a manipulation by the Bush Administration to hide the costs of the War on Drugs. Previously, the

Table 6 Recent congressional bills

Bill Number	Title	Purpose
110th congress		
H.R. 79	Powder-Crack Cocaine Penalty Equalization Act of 2007	To amend the Controlled Substances Act and the Controlled Substances Import and Export Act with respect to penalties for powder cocaine and crack cocaine offenses.
H.R. 174	Public Housing Drug Elimination Program Reauthorization Act of 2007	To reauthorize the public and assisted housing drug elimination program of the Department of Housing and Urban Development.
H.R. 970	Dextromethorphan Distribution Act of 2007	To amend the Federal Food, Drug, and Cosmetic Act with respect to the distribution of the drug dextromethorphan, and for other purposes.
H.R. 1118	Drug Trafficking Elimination Act of 2007	To amend the Controlled Substances Act to enhance criminal penalties for drug trafficking offenses relating to distribution of heroin, marijuana, and methamphetamine and distribution to and use of children, and for other purposes.
H.R. 1199	Drug Endangered Children Act of 2007 (enacted)	To extend the grant program for drug-endangered children.
H.R. 2294	Enhanced Participation in Drug Courts Act of 2007	To amend the Omnibus Crime Control and Safe Streets Act of 1968 to revise the definition of "violent offender" for the purpose of participation in drug courts.
H.R. 2425	Stop Marketing Illegal Drugs to Minors Act	To amend the Controlled Substances Act to provide enhanced penalties for marketing controlled substances to minors.
H.R. 3749	Methamphetamine Prevention Enhancement Act of 2007	To amend the Public Health Service Act to provide for the establishment of a Drug-Free Workplace Information Clearinghouse, to authorize programs to prevent and improve treatment of methamphetamine addiction, and for other purposes.
H.R. 4545	Drug Sentencing Reform and Cocaine Kingpin Trafficking Act of 2007	To target cocaine kingpins and address sentencing disparity between crack and powder cocaine.
H.R. 5035	Fairness in Cocaine Sentencing Act of 2008	To amend the Controlled Substances Act and the Controlled Substances Import and Export Act to eliminate increased penalties for cocaine offenses where the cocaine involved is cocaine base, to eliminate minimum mandatory penalties for offenses involving cocaine, to use the resulting savings to provide drug treatment and diversion programs for cocaine users, and for other purposes.
H.R. 5842	Medical Marijuana Patient Protection Act	To provide for the medical use of marijuana in accordance with the laws of the various States.
H.R. 5843	Act to Remove Federal Penalties for the Personal Use of Marijuana by Responsible Adults	To eliminate most federal penalties for possession of marijuana for personal use, and for other purposes.
H.R. 6281	High School Sports Anti-Drug Act	To provide States with the resources needed to rid our schools of performance-enhancing drug use.
S. 1011	Recognizing Addiction as a Disease Act of 2007	To change the name of the National Institute on Drug Abuse to the National Institute on Diseases of Addiction and to change the name of the National Institute on Alcohol Abuse and Alcoholism to the National Institute on Alcohol Disorders and Health.
S. 1211	Saving Kids from Dangerous Drugs Act of 2008	To amend the Controlled Substances Act to provide enhanced penalties for marketing controlled substances to minors.

Table 6 (continued)

Bill Number	Title	Purpose
S. 1383	Drug Sentencing Reform Act of 2007	To reduce the disparity in punishment between crack and powder cocaine offenses, to more broadly focus the punishment for drug offenders on the seriousness of the offense and the culpability of the offender, and for other purposes.
S. 1685	Fairness in Drug Sentencing Act of 2007	To reduce the sentencing disparity between powder and crack cocaine violations, and to provide increased emphasis on aggravating factors relating to the seriousness of the offense and the culpability of the offender.
S. 1711	Drug Sentencing Reform and Cocaine Kingpin Trafficking Act of 2007	To target cocaine kingpins and address sentencing disparity between crack and powder cocaine.
S. 2137	Methamphetamine Kingpin Elimination Act of 2007	To amend the Controlled Substances Act to expand the threshold criteria for designating an individual as a principal administrator, organizer, or leader of a continuing criminal enterprise involving methamphetamine.
S. 2274	Dextromethorphan Abuse Reduction Act of 2007	To amend the Controlled Substances Act to prevent the abuse of dextromethorphan, and for other purposes.
S. 3351	Drug Trafficking Interdiction Assistance Act of 2008	To enhance drug trafficking interdiction by creating a Federal felony for operating or embarking in a submersible or semi-submersible vessel without nationality and on an international voyage.
S. 3598	Drug Trafficking Vessel Interdiction Act of 2008 (enacted)	To amend titles 46 and 18, United States Code, with respect to the operation of submersible vessels and semi-submersible vessels without nationality.
111th congress		
H.R. 68	No More Tulias: Drug Law Enforcement Evidentiary Standards Improvement Act of 2009	To increase the evidentiary standard required to convict a person for a drug offense, to require screening of law enforcement officers or others acting under color of law participating in drug task forces, and for other purposes.
H.R. 265	Drug Sentencing Reform and Cocaine Kingpin Trafficking Act of 2009	To target cocaine kingpins and address sentencing disparity between crack and powder cocaine.
S. 97	Drug Free Families Act of 2009	To amend title IV of the Social Security Act to require States to implement a drug testing program for applicants for and recipients of assistance under the Temporary Assistance for Needy Families program.

Source: GovTrack.us

drug-control budget reflected consistent annual increases in spending, and a stable 2-to-1 ratio between supply- and demand-side expenditures over the years. The revised methodology yielded a much smaller drug-control budget, with 90% of the apparent reductions appearing on the supply side. The most significant change was the exclusion of costs associated with prosecuting and incarcerating drug users [75].

The 1980s and 1990s saw a shift in spending from treatment to law enforcement. In real terms, the federal drug-control budget increased by 600% between 1981 and 2000, from about three to 18 billion dollars [68]. This increase was driven primarily by criminal-justice expenditures. The change in budgeting approach makes it difficult to track the federal budget over time. The Office of National Drug Control Policy recalculated earlier budgets using their new methodology, but only as far back as 1996. Figure 1 shows the federal drug-control budget from 1996 to 2009, which is the longest series for which consistent budget data are available (i.e., comparable budgeting methodologies were used). The federal drug-control budget

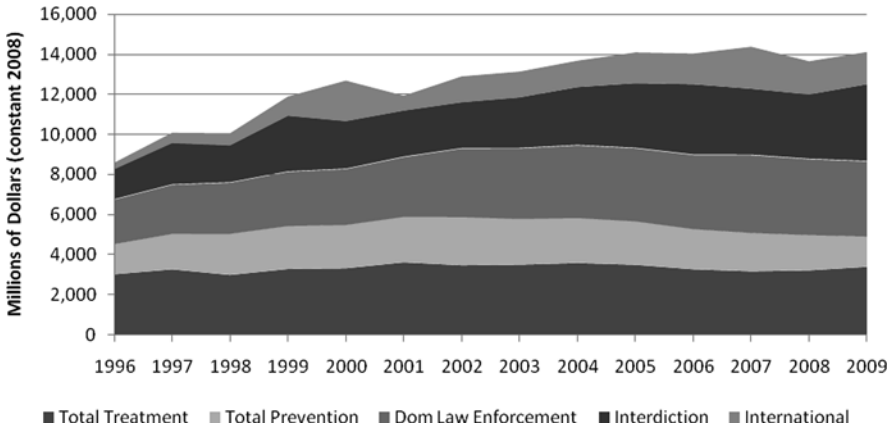

Fig. 1 Federal drug-control budget 1996–2009 (constant 2008 dollars). Data for 1996–2001 are from [61]. Data for 2002–2009 are from [62]. All data reflect budgets using the revised Office of National Drug Control Policy methodology. To correct for changes in the purchasing power of the dollar, we have adjusted the data to constant 2008 dollars, using the Consumer Price Index. Dom = Domestic

increased steadily over this period (even after controlling for inflation). The two lowermost areas in Fig. 1 represent the total demand-reduction budget, with the three uppermost representing the total supply-reduction budget. Demand-reduction spending has remained relatively stable over the period, while supply-reduction spending has increased substantially. Therefore, in spite of accounting revisions, demand-reduction spending has declined as a share of the total (from 43% in 2004, the first year of the revised methodology, to 35% in 2009).

Law Enforcement

The enforcement of federal drug laws entails the seizure of illicit drugs, and the arrest, prosecution, and punishment of traffickers and users. In addition to targeting the drug-supply chain, federal law-enforcement agencies also seek to reduce ancillary harms of the drug trade through, for example, Project Safe Neighborhoods, a national program to reduce gun and gang violence. Disrupting the supply chain increases the price of illicit drugs and reduces the quantity available for sale. Targeting users deters drug use by imposing consequences for purchasing drugs (through the probability of arrest and the severity of the sanction imposed). The federal government spends more than $9.2 billion (65% of the drug-control budget) on domestic and international law enforcement and interdiction [63]. These strategies target the entire supply chain, but federal agencies focus primarily on international and interstate actors.

Domestic law enforcement accounts for 42% of enforcement and interdiction spending [63]. Under the revised budget methodology, the drug-control budget no longer includes the (substantial) cost of prosecuting and incarcerating drug offenders; 52% of the 200,000 federal inmates were sentenced on drug charges [22]. The costs of investigations, intelligence, assistance to state and local authorities, and law-enforcement research are included. The Office of National Drug Control Policy highlights two programs that assist state and local authorities: the High Intensity Drug Trafficking Area and Organized Crime Drug Enforcement Task Force programs.

The Director of the Office of National Drug Control Policy has the authority to designate qualifying jurisdictions in the United States as High Intensity Drug Trafficking Areas, centers of production or distribution that have

harmful effects on other areas. When a jurisdiction is identified as a High Intensity Drug Trafficking Area, federal resources are provided to facilitate investigations and information sharing across enforcement agencies and to fund strategic intervention initiatives to reduce the production and distribution of drugs, and drug-related money laundering. As High Intensity Drug Trafficking Area initiatives are tailored to the needs of the jurisdiction, activities differ across sites. As such, there is no cross-site evaluation of a High Intensity Drug Trafficking Area. Each jurisdiction is responsible for developing and monitoring performance measures relevant to its High Intensity Drug Trafficking Area program. The Organized Crime Drug Enforcement Task Force coordinates federal, state, and local efforts against high-value drug trafficking and money-laundering organizations (Consolidated Priority Organization Targets), with the goal of disrupting the chain of command within these organizations. Key measures used to monitor the performance of the Organized Crime Drug Enforcement Task Force are the number of organizations that are disrupted or dismantled, and the number of defendants convicted:

> From 2002 to 2008, a total of 110 CPOTs [Consolidated Priority Organization Targets] have been identified, of which 81 percent have been indicted, 53 percent have been arrested, 25 percent have been extradited from other countries, and 3 percent have been killed either by other gang members or as a result of resisting arrest. Of the 110 existing CPOTs, 26 percent are linked to Foreign Terrorist Organizations [63] (pp. 23–24).

Other domestic law-enforcement efforts include the Drug Enforcement Administration Mobile Enforcement Teams and the U.S. Immigration and Customs Enforcement Border Enforcement Security Task Forces. The Drug Enforcement Administration focuses on major drug organizations involved in international and interstate trafficking. In 1995, Mobile Enforcement Teams were established to assist with lower-level enforcement efforts, by giving technical and investigative help to local law-enforcement agencies to fight traffickers and the violent crime related to trafficking, especially gang violence. Mobile Enforcement Teams are rapid-response teams, deployed in response to requests by local sheriffs, police, or district attorneys.

Border Enforcement Security Task Forces were established in response to the growing threat from trafficking across the Mexican border and drug-gang–related violence associated with the Mexican drug cartels. The Border Enforcement Security Task Forces facilitate information sharing among local, state, federal, and foreign law-enforcement agencies. Border Enforcement Security Task Forces have been responsible for many arrests and convictions, and seizures of drugs and weapons, equipment, and currency that support trafficking [71].

Suppressing drug production and trafficking in other countries, and preventing illicit drugs from entering the United States, are top priorities of federal drug enforcement; 58% of the law-enforcement budget is for international programs and interdiction. The United States provides direct assistance to foreign countries (primarily through the Departments of State and Defense), as well as multilateral assistance through international organizations, such as the United Nations Office on Drugs and Crime [69]. United States efforts target the Andean region (Plan Colombia [72], and the Andean Counterdrug Initiative [73], for Bolivia, Peru, Ecuador, Brazil, and Panama) and Afghanistan, with small initiatives in Pakistan and Haiti. Increasing attention and resources are being devoted to Mexico as violence associated with the major Mexican drug cartels has spilled over the border.

Foreign assistance consists primarily of bolstering law enforcement and anti-trafficking efforts, and crop eradication. Relatively little emphasis is placed on alternative development and crop-substitution programs. Most illicit-drug crops are in poor countries, tended by peasant farmers; eradication programs have been criticized for leaving locals without alternative livelihoods, sometimes threatening state stability and reversing eradication successes, as with coca eradication in Bolivia in the 1990s [21].

Colombia is the largest recipient of foreign assistance for drug control [10]. The United States has aided Colombia's military in countering drug production and trafficking since the 1970s, but by the late 1990s Colombia led the world in cocaine production and was a major supplier of heroin to the United States. In 1999 the Colombian president announced the six-year Plan Colombia, which aimed to halve drug cultivation, production, and distribution, and increase security in Colombia by taking back areas controlled by militia groups that used drug profits to finance their activities. United States funding was approved in 2000, and more than six billion dollars has been spent since, 74% for military support [24]. The plan has helped Colombia improve its security situation, but has done little to curb the flow of cocaine to the United States. The production-reduction goals of the plan were not met; coca production has increased since 2000 as producers moved into more-remote areas [24].

The many billions of dollars spent on international drug-law enforcement has yielded meager results; the mechanics of drug production and distribution militate against enforcement efforts bringing about lasting reductions in supply. Focused efforts that reduce drug production in one area are offset by increased production elsewhere. Also, since most of the profits accrue to actors at the end of the supply chain, street prices are relatively insensitive to supply shocks as retailers have latitude to adjust their profit margins [21].

Prevention

Preventing the initiation of drug use precludes later physiological and social harms, and so may be cost effective, but only 10% of the federal drug-control budget goes to prevention programs. This is due, in part, to the difficulty of appropriately targeting these programs, and to the lack of documented success of those existing prevention programs. In 2007, an estimated 8% of American youth aged twelve or older were using illicit drugs (according to the National Institute on Drug Abuse's Monitoring the Future Survey and the Substance Abuse and Mental Health Services Administration's National Survey on Drug Use and Health), making youth prime targets for prevention programs.

Among the better-known prevention programs are Drug Abuse Resistance Education (D.A.R.E.) and school-based random drug testing. Drug Abuse Resistance Education involves a uniformed police officer visiting classrooms and educating students on how to resist drug use. Successive evaluations of Drug Abuse Resistance Education have found no meaningful differences in knowledge, attitudes, or drug use for those students participating in Drug Abuse Resistance Education, compared with those who did not [31]. When it became apparent that Drug Abuse Resistance Education was an ineffective use of drug-control resources, the program was "retooled" into what became the New-Drug Abuse Resistance Education (New-D.A.R.E.) program [54]. New-Drug Abuse Resistance Education provides a more interactive curriculum, where students are exposed to brain imaging as proof of how drug use impairs brain functioning, provides data on actual levels of drug use among youth, and teaches refusal skills [35]. Evaluations of New-Drug Abuse Resistance Education fail to show any improvements over its predecessor [1]. The federal government has had a rocky relationship with Drug Abuse Resistance Education, and negative findings have led it to almost eliminate financial support for the program. In 2001, the Surgeon General identified Drug Abuse Resistance Education as a program that "Does Not Work" [55], and, in 2003, the U.S. Government Accountability Office concluded that Drug Abuse Resistance Education was potentially counterproductive in certain populations (i.e., it was associated with *increased* drug use) [31]. Remaining federal support for Drug Abuse Resistance Education is largely rhetorical; it continues to be listed as a model prevention program on the Office of National Drug Control Policy Web site [64], and President Obama declared a National Drug Abuse Resistance

Education Day to celebrate the work of the program [49].

The Office of National Drug Control Policy directly manages two prevention programs: The National Youth Anti-Drug Media Campaign and the Drug Free Communities Support Program. The National Youth Anti-Drug Media Campaign was created by Congress in 1998 with the goal of preventing and reducing drug use through radio, television, and other media. National Institute on Drug Abuse-funded evaluations have shown that, while it has positively affected parents' beliefs and behaviors, there has been no measurable impact on initiation or reduced use among targeted youth [50].

The Drug Free Community Program, funded by Congress in 1997, supports local initiatives to address drug use. The Drug Free Community Program is managed jointly by the Office of National Drug Control Policy and the Substance Abuse and Mental Health Services Administration and the program currently supports 769 community coalitions. An ongoing evaluation suggests that communities receiving support through The Drug Free Community Program have reduced drug use at a greater rate than non-recipient communities [4]. There are many inherent difficulties in drawing conclusions about the causal effect of this type of program. As communities have to apply for Drug Free Community Program support, selection bias can muddy findings: communities that opted into the program may be different from those that did not, in ways that may affect outcomes. Nonetheless, the evaluation findings warrant cautious optimism.

Other federal prevention programs are spread across several executive agencies [64]. For example, the Student Drug-Testing Institute in the Department of Education provides technical support for schools interested in establishing a school-based testing program. Random drug testing ostensibly serves a double function—it deters drug use and detects early drug involvement, thereby disrupting the path to addiction. By 2008, 16% of secondary schools had implemented drug-testing programs [52]. An assessment of school drug testing found no differences in student drug-use outcomes between schools with drug testing (whether for cause or at random) and those without [76]. To overcome the methodological limitations of the research design used in this study, a randomized controlled trial of school drug-testing programs is under way [29].

Despite some troubling instances of persisting support for unproven or even discredited programs, there are federal government efforts to bring research-based evidence to bear on prevention [12].

Treatment

In 2009, drug-treatment services (excluding treamtent research) account for 20% of the federal drug-control budget (about $2.4 billion) and are provided primarily through the Substance Abuse and Mental Health Services Administration. Implementation is mostly left to the states, as 86% of the Substance Abuse and Mental Health Services Administration's drug-treatment funding is distributed via block grants (lump sums allocated to states, with very few stipulations on how resources are to be spent). The Center for Substance Abuse Treatment within the Substance Abuse and Mental Health Services Administration works with states and local groups to improve and expand effective treatment services provided under the block grants.

The remaining 14% of the Substance Abuse and Mental Health Services Administration's funds are issued on a discretionary basis, under Programs of Regional and National Significance: capacity programs, which identify needed system changes and extend evidenced-based care, and science and service programs, which identify practices that might improve services and disseminate information about these practices. The federal government has made strides toward promoting treatment practices that are grounded in evidence [46], but the quality of the federally endorsed evidence base on "what works"

remains weak, and the standards for considering a treatment program "evidence-based" are low [20].

Research

Seven percent of the budget (about one billion dollars) goes to research. Of this, 60% goes to treatment and 40% to prevention. The National Institute on Drug Abuse, created in 1974, is the principal federal agency funding basic, clinical, and epidemiological research into drug abuse and addiction; the National Institute of Justice and the National Institute of Mental Health also fund research. National Institute on Drug Abuse-funded research has made major contributions to the science of addiction and has led to a number of innovations in drug treatment, including the clinical development of levo-alpha-acetylmethadol and naltrexone (medications used to treat opioid dependence). Despite being effective treatments for opioid addiction, levo-alpha-acetylmethadol and naltrexone faced market barriers to distribution and were ultimately of little policy significance. Levo-alpha-acetylmethadol is no longer produced and naltrexone is provided to few addicts [28]. The National Institute on Drug Abuse disseminates research findings to promote science-based practices and policies, through its *Research Monograph Series* (first issued in 1975) and the bi-monthly newsletter *NIDA Notes* (first issued in 1985). The National Institute on Drug Abuse accounts for some 85% of global biomedical research on drugs and addiction [70].

The National Institute on Drug Abuse's billion-dollar budget gives it high visibility, and the Institute has on occasion come under scrutiny for its role in shaping federal drug policy, through both the types of research it funds and the targeting of its research dissemination. The Institute has been criticized for promoting politically expedient research messages and a research agenda that reinforces the War on Drugs, to maintain its funding, while paying little attention to harm-reduction strategies [49]. However, Nora Volkow, a neuroscientist who was appointed director of the National Institute on Drug Abuse in 2003, maintains that its agenda is divorced from politics and is driven by science.

Issues in Policymaking

In the next decade, budget constraints may yield a welcome scrutiny of federal drug-control policies and programs. If outcomes are to improve, federal drug-control policymakers will have to take resource allocation seriously and prioritize their efforts. What will this mean for federal drug control?

Picking Battles

Drug policymakers will need to pick their battles, which will require clearly elaborating the mission and goals of the federal drug-control strategy. This may entail focusing on particular drugs and drug-control activities.

The stated goal of the national drug-control policy is "to reduce illicit drug use, manufacturing, and trafficking, drug-related crime and violence, and drug-related health consequences" [66].

It seems reasonable, then, that the strategy should focus on those drugs associated with the most severe crime, violence, and health consequences—and, further, that policymakers establish that the program's fiscal and social costs are outweighed by the benefits obtained. Under current law, alcohol—the costliest drug by far—is legal, while the scheduling of illicit and controlled substances is only loosely determined by social harms. As alcohol is legal, it is usually divorced from the drug-policy debate. If public health is to be the driving principle, the policy for each drug should reflect its social costs.

Setting Minimum Standards for "Evidence"

Few people will object to a call for "evidence-based" practices; indeed, the Office of National Drug Control Policy is required to "develop and implement a set of research-based principles" for drug-abuse–prevention programs [45]. But this desideratum compels stakeholders to justify their existence and continued funding by demonstrating that their programs "work," which may have the perverse effect of stifling progress. A low bar for "effectiveness" renders many ineffective programs "evidence-based," and makes it difficult to identify worthy programs. Good programs get lost in the mix, and weak programs persist. Clear, strict standards for the quality of evidence would shield policymaking from some of the malign influences of politics [35].

The Muddled "Wars"

Afghanistan, the world's leading producer of illicit opium poppies [69], is also a central front of United States counterterrorism operations. As the War on Drugs has become inextricably linked with the Global War on Terror, terrorism-related drug-control efforts (trafficking and money laundering) have received greater federal support. Conflating these two "wars" reduces policymakers' ability to optimize resource allocation toward programs that are most effective at reducing drug-related social harms. If national-security concerns are to drive drug-control policymaking, then it should be made explicit. Whatever the operating principles are, if they are not made clear and adhered to, the resulting policies are not likely to be effective.

The new Obama administration's top drug-policy appointments have been received with guarded optimism by advocates of reform, and are not identified as ardent drug warriors (although Vice President Biden has long been so), but no official changes of policy have been implemented. Whatever their orientation, previous administrations have called for evidence-based policymaking, but the political process has trumped science and program evaluation. Should policymakers be committed to thoroughgoing reform, there is ample evidence to inform their efforts.

Appendix

The Controlled Substances Act of 1970 created five schedules under which drugs of abuse are classified [18].[1] Scheduling of a drug determines, in part, federal penalties for possession and distribution, and the terms under which it may be prescribed.

The legislation created the initial listing, but the Drug Enforcement Administration and the Department of Health and Human Services determine adjustments to the Schedules, based on a drug's potential for abuse, accepted medical use in the United States, and potential for dependence. The Drug Enforcement Administration begins or accepts petitions for investigations, and then passes its findings to the Department of Health and Human Services, for a recommendation based on scientific and medical evaluations. The Drug Enforcement Administration then makes the scheduling decision.[2]

See Table 2 for the scheduling criteria and major scheduled drugs.

[1] Some states impose controls on the sale and use of substances not covered under the federal schedules, such as nitrous oxide and amyl nitrite [11]. Pseudoephedrine is widely used in the manufacture of methamphetamine, and medicines containing pseudoephedrine are separately regulated under an amendment to the USA Patriot Act [18].

[2] The scheduling procedure may be bypassed when an international treaty requires controlling a drug, or "to avoid an imminent hazard to the public safety" [2].

Historical Perspectives of Addiction

Howard I. Kushner

Contents

Histories of Addiction

In the past quarter century, historians of addiction have focused on contextualizing the political, social, and cultural meanings of addiction. Building on Harry Gene Levine's classic 1978 article, "The Discovery of Addiction," historians have suggested that the classification of certain substances as illicit or licit tells us more about social norms and power relationships than about the psychopharmacological properties of the substances themselves [32]. Historians have contextualized the definitions of addiction, alerting us to the extent to which alcohol prohibition and the criminalization of narcotics and stimulants reflected dominant cultural values rather than robust scientific findings. These studies pose an *intellectual* challenge to the treatment and control of addiction. So far, however, they have made a less significant impact on addiction policy and treatment. In a recent article, I argued that historians of addiction should take biology seriously [44]. Here I hope to persuade addiction scientists and practitioners of the value of these recent histories for their research and practice.

Doing so requires an appreciation of historical methods. Academic historians are not simply engaged in telling a chronological story; nor, since the late nineteenth century, have they assumed that they can uncover "facts" that recreate the past as it was. Rather, academic historians insist that historical sources do not speak for themselves, but are subjects of contested interpretations framed by current and past cultural and political contexts. From this perspective, there can never be one final "factual" reading of the past; today's landmark interpretation is regularly subjected to tomorrow's reinterpretation because, odd as it may sound to the non-academic historian, the past is always subject to change as historians redefine the contexts in which events occur. The current scientific paradigm that addiction is a brain disease [56] is placed in social and cultural contexts. The implicit message is that, whatever its biological substrates may be, by acknowledging social, cultural, and political forces, addiction scientists,

policy-makers, and practitioners can develop more effective policies and interventions.

Brain Disease Redux

Often, writes historian Nancy Campbell, what has been learned in addiction science has been ignored in succeeding paradigms. More than a half century ago, Campbell finds, addiction researchers Maurice S. Seever and Abraham Wikler had independently concluded that addiction was a chronic relapsing/remitting condition, a view presented in 2000 by then-National Institute on Drug Abuse director, Alan Leshner, as novel [48]. Campbell also points to a rhetorical resilience of a traditional "moral lexicon" of addiction. Citing the work of current National Institute on Drug Abuse director, Nora Volkow, and her colleagues as exemplars, Campbell finds that their notion of "disrupted volition" parallels nineteenth century constructions of addiction "as a 'disease of the will' subject to voluntary control." Thus, writes Campbell, with "amnesiac gesture toward its own repressed past, the addiction enterprise comes full circle into the present" ([12], pp. 221, 237).

As Campbell suggests, the claims that addiction is a brain disease would sound familiar to nineteenth century neurologists. In many respects, current views resemble degeneration theory as expounded by the French physician Théodule Ribot in his 1883 study *Les Maladies de la Volonté* (which was reissued in 32 subsequent editions in French and English) [64]. Degeneration theory offered a hereditarian explanation for a variety of disorders including retardation, depression, depravity, and sterility. Behaviors that today would include addictions such as alcoholism, diet, and sexual addictions were alleged to have a cumulative destructive impact on the nervous system that was inherited by succeeding generations [24]. Practitioners took extensive family histories and prepared elaborate pedigrees that sought to explain a current disorder by uncovering patterns of disease and behavior in a patient's family. Adherents sought to portray degeneration as organic, but much like addiction practices today, treatment revolved around an array of psychological and moral interventions under the rationale that alterations in habits had a direct physiological influence on the nervous system [24, 53, 58, 61].

Degeneration theory meshed with the views of the influential neurologist James Hughlings Jackson, whose "dissolution theory" was based on his claim that lesions in the neo-cortex reversed the evolutionary process in which the "higher" cortical structures restrained the "lower" emotive, limbic functions. Jackson's hydraulic theory reinforced the assumptions that addictions reflected a hijacking by these more primitive structures, often referred to as the "reptilian brain." Thus, addiction was a brain disease because the behaviors were enabled by the damage to cortical censors [32]. Because these behaviors appeared to run in families, it was a small step to connect Jackson's dissolution with degeneration.

Both degeneration and dissolution were translated into early twentieth century popular scientific explanations of the physical effects of alcohol and other drugs. For instance, historian Susan Speaker writes of Richmond P. Hobson, a retired naval officer and three-term congressman from Alabama, who published *Alcohol and the Human Race* in 1919 and portrayed it as based on the best "evolutionary science" of the time [35]. Hobson, who founded the American Alcohol Education Association in 1921, wrote that alcohol was a toxin that paralyzed white blood cells, making them unable to "catch the disease germ" that was "devouring" the drinker. This led to the destruction of the "centers of the brain upon whose activities rest the moral sense," resulting in what Hobson labeled "retrograde evolution." For Hobson, "alcoholic beverages, even in moderation reverse the process of nature." Ninety-five percent of "all the acts of crime and violence committed in civilized communities," Hobson claimed, "are the direct result of men being put down by alcohol to the plane of savagery" ([72], p. 214).

Hobson's "science" both influenced and was influenced by early twentieth century prohibitionist sentiments. With the end of Prohibition, a

new science of alcoholism emerged. Americans, according to Speaker, ceased "demonizing alcohol after Prohibition, and chose to deal with its risks largely through regulation, education, and harm-reduction strategies." However, she writes, "they have resisted" treating users of most other psychoactive drugs in a similar manner [72]. What emerged were distinct attitudes, policies, and sciences that separated alcohol from other addictive substances. However, Speaker implies, these distinctions were based less on objective evidence than on the cultural, social, and economic attitudes toward alcohol and other mind-altering substances. I begin with historians' interpretations of the science of alcohol addiction and then move on to other substances.

Alcohol and Other Drugs

The federal government has created two separate divisions for addiction research: (1) the National Institute on Alcohol Abuse and Alcoholism, which has focused exclusively on alcohol, and (2) the National Institute on Drug Abuse, which has studied the use of all other addictive substances. Despite this official separation of alcohol from other drugs, in a recent collection, *Altering American Consciousness: The History of Alcohol and Drug Use in the United States, 1800–2000*, historians Sarah W. Tracy and Caroline Jean Acker argue that bringing them together is justified: "Despite the chasm created by law, which separates them into legal and illegal categories, all psychoactive drugs share important commonalities" ([78], p. 22). "America's drug habits cannot be understood, nor effective drug policy made," they insist, "until we have a clearer picture of the range of drugs used yesterday and today, and the ways in which specific historical circumstances have shaped their use and regulation" ([78], p. 2).

The theme that runs through *Altering American Consciousness* is best summed up by historian Alan Brandt, who writes that although the addictive nature of nicotine may today be seen as an undisputed fact of its chemical properties, nicotine's classification as an addictive substance is rooted more in the history of attitudes toward smoking than in its neurochemical mechanisms [7]. Brandt believes that the history of nicotine provides a window to understanding the meaning of addiction. He rejects what he calls "universal, transhistorical approaches to the mechanisms of addiction" in favor of "specific historical contexts" that illuminate "the social processes by which addictions are created and experienced, categorized, and treated" ([7], p. 383).

The history of nicotine provides a context for the increased labeling of a variety of substance uses and behaviors—from carbohydrates and coffee to shopping and sex—as addictions. Perhaps this has occurred because, as William L. White [84] points out, there continues to be no consensus on the language and meaning of addiction itself [37, 69, 83]. "The rhetoric of addiction," White believes, "grew out of the multiple utilities" of the constituencies it served ([84], p. 43). Deconstructing the various definitions of inebriety, intemperance, drunkenness, and alcoholism, White argues that the contested rhetoric of addiction served as "a means of staking out professional territory." At stake was which institutions and professions could claim "legitimate ownership of the problem" ([84], p. 50).

Taking White's view further, anthropologist Helen Keane's *What's Wrong With Addiction?* focuses on how addiction rhetoric is constituted in current discourses [37]. Like Brandt, Keane eschews a universalist view, arguing instead that what has become characterized as addiction "is tied to modernity, medical rationality and a particular notion of the unique and autonomous individual" ([37], p. 6). Although addiction has been portrayed as restricting freedom and individual autonomy, Keane argues that discourses of addiction have tended to limit freedom as they have authorized the prohibitive power of the family, the state, and the corporation.

Keane's and White's claims are best examined in historical context. We begin with histories of alcohol use and then move on to other substances.

Alcohol: Predisposed or Culturally Determined

The histories of alcohol addiction have much in common with those of other drug addictions, but unlike illicit and (still) legal drugs such as nicotine, alcohol putatively poses a danger only to predisposed alcoholics. The prevailing view in America is that moderate consumption of alcohol by those without a predisposition is safe and not addictive. In contrast, the dominant media and scientific view today holds that, although some people are more prone to addictive behaviors than others, no predisposition is necessary for addiction to illicit substances and nicotine; any exposure potentially places any user at risk [19, 56].

Connected to the risk dichotomy is the widely accepted belief that alcoholism is a disease. Although a number of historians have pointed to a long genealogy supporting the notion that excessive and seemingly uncontrollable drinking was driven by forces beyond an individual's power, most agree with Griffith Edwards [25], former chairman of the UK's National Addiction Centre, that the modern concept defining alcoholism as a disease comes from the work of the director of the Yale Center for Alcohol Studies, Elvin M. Jellinek, in the 1940s [36]. Not all experts have been persuaded by the disease paradigm. Two types of challenges emerged: the first questioned the almost universal belief that alcoholics must abstain from drinking for their entire lives, and the second was aimed at the validity of the disease construct.

In 1962, the renowned British psychiatrist D. L. Davies published a report of seven alcohol-dependent individuals who returned to normal drinking without reverting to alcoholism [21, 25]. Edwards, who trained under Davies, followed these alcoholics and concluded that Davies' optimism was not sustained by their long-term behaviors ([25], pp. 159–161). In the 1970s, California psychologists Mark and Linda Sobell claimed that behavior modification could enable recovered alcoholics to return to what they called "controlled drinking" [70, 71]. The Sobells' research was the subject of a damning analysis published in *Science* in 1982, which concluded that "a review of the evidence, including official records and new interviews, reveals that most of the subjects in the controlled drinking experiment failed from the outset to drink safely. The majority were hospitalized for alcoholism treatment within a year after discharge from the research project." In fact, a 10-year follow-up revealed that only one of the original 20 subjects could be classified as having met the criteria of controlled drinking; four had died of alcohol-related causes ([25], pp. 148–164).

When a number of studies attacking the construction of alcoholism as a disease appeared in the late 1980s and 1990s, the response of the alcohol research community was hostile. These critiques, including highly publicized ones written by Herbert Fingarette [28] and Stanton Peele [60], have been the focus of sustained attacks from a wide range of alcohol researchers, and the authors have been marginalized and often stigmatized.

Although historians generally do not confront the controversy over controlled drinking, recent addiction histories can be read as providing support for the minority view questioning the robustness of the claims that alcohol addiction is a disease. Building on Levine, they have concluded that the separation and classification of alcohol addiction as substantially different from other drug addictions is a cultural construction.

Earlier histories of alcohol use have detailed the battles between pro- and anti-prohibitionists [47], but sociologist Ron Roizen believes that this focus has obscured the more important story of the depoliticization of alcohol [65]. The construction of alcoholism as a disease, according to Roizen, meshed with the values of both the "spiritual orientation" of Alcoholics Anonymous and the "disinterestedness, objectivity, and empiricism" of contemporary science. Ironically, the notion that alcoholism was a disease "also offered destigmatization to the alcoholic and a measure of new symbolic legitimacy for [the] beverage alcohol itself." From the disease perspective, alcohol "harbored little more

responsibility for alcoholism or alcohol related troubles than did sugar for the disease of diabetes" ([65], p. 64). The dominant belief remains that moderate drinking is safe for all but the potential and actual alcoholic. For Roizen, "the story of modern alcoholism" reveals "its strongly social-constructionist character and flimsy science base" and "invites our attention to the relationship between alcohol science and the wider society" ([65], p. 74). Roizen also has been particularly vocal in his opposition to what he sees as a new public health campaign to demonize alcohol [27].

One of the linchpins for the notion of alcoholism as a disease is the widespread popular belief that Native Americans are genetically vulnerable to alcoholism. This view has been challenged by a number of recent studies. In 2000, in the *American Journal of Public Health*, John W. Frank and his colleagues emphasize that beyond obvious "risk factors in contemporary life," there is the need to consider the historical sources of Native American drinking problems. "In contrast to other explanatory factors," they write, "the role of history seems to have been underemphasized in the voluminous literature attempting to explain the problem of drinking among Native Americans." For instance, one must acknowledge "the extraordinary barrage of inducements to drink heavily in the early years after European contact. The harmful drinking patterns established during those years have largely persisted." Thus they conclude that "the cultural dimensions of Native American drinking must be considered far more important than the notion that Native Americans' propensity for heavy and dependant drinking is primarily genetic" ([29], pp. 349–350).

Although historian Peter C. Mancall does not cite Frank et al., he endorses their findings [50]. Mancall agrees that some individuals "seem to possess an inherited predisposition toward alcohol abuse," but he insists that "there is no convincing evidence suggesting that Indians as a group are more inclined to possess these traits than the general American population" ([50], pp. 99–100). Historical research, according to Mancall, reveals that "there has been no single Native American response to liquor. Consumption patterns have differed over time by region and even in specific communities." They also have varied by age and gender. "Patterns of alcohol-related illness, disease … and trauma are not uniform within the Native American population today, and were not in past centuries either" ([50], p. 93). Europeans, Mancall reminds us, who had been exposed to alcohol for centuries, "had developed rules for its consumption." Nevertheless, they too experienced "periods of wide-spread alcohol-related problems," including the so-called gin craze in the mid-eighteenth century, which "occurred in part because of wider availability of more potent alcohol during the early phases of the industrial revolution when the English and other Europeans drank more alcohol" in an attempt to "escape from the disorienting social changes of their everyday lives" ([50], p. 100). For Mancall then, like Frank et al., "history, not biology, holds the key to understanding Native American drinking patterns, just as history, not biology holds the key to understanding alcohol consumption in other American populations" ([50], p. 101).

Mancall's thesis is built on a number of studies [41], including Craig MacAndrew and Robert B. Edgerton's 1969 cultural anthropology classic, *Drunken Comportment: A Social Explanation*, which explored variations in behaviors observed in different populations when they are drunk [49]. In relatively simple societies, people learn how they are supposed to behave when intoxicated; in more complex societies, the cultural expectations may vary, but the same principle holds. Edwards supports MacAndrew and Edgerton's anthropology. Acknowledging that "alcohol is a drug which has the inherent capacity to interfere with brain function and produce a state of intoxication," Edwards, nevertheless, argues that "intoxication is not, however, a fixed and monolithic state." Rather, based on narratives of South African and Bolivian drinking behaviors, Edwards explains behavioral reactions to alcohol intoxication as "plastic." By this he means that "drunkenness behavior can be molded by influences which

include the immediate context, the way people react to drunkenness, the drinker's personality, and the expectations given by culture and society." From this perspective, "drunkenness is more like clay than concrete" ([25], p. 56).

The history of attempts to treat drunkenness suggests that clay was often mistaken for concrete. This response can be seen in historian Katherine A. Chavigny's discussion of nineteenth century drinking reform [15]. She focuses on the emergence—from the antebellum period to the 1880s—of a consensus among a group whom she labels as "inebriety physicians" that drunkards were suffering from an inherited disease. If the cause of drunkenness was a degenerative inheritance, "those persons who had inherited a constitutional weakness for alcohol had little chance of becoming sober without long-term quarantine from temptation." These physicians urged the construction and maintenance of facilities to house and treat the afflicted, many of whom were poor, homeless, and criminal. Legislatures were not persuaded, and other more traditional reformers rejected "hereditarian interpretations of inebriety" because they "believed that such views discouraged drunkards from trying to reform and provided them with a ready excuse for backsliding" ([15], p. 118). Nevertheless, the failure of inebriety physicians to persuade legislatures and other reformers that drunkenness was a disease was a temporary setback.

In contrast, historian Sarah Tracy's "Building a Boozatorium" examines a successful attempt to medicalize habitual drunkenness in turn-of-the-century Iowa [76]. Similar to the physicians discussed by Chavigny, Tracy's reformers relied on degeneration theory and its eugenic offspring. Unlike the experts in Chavigny's narrative, this cohort of clinicians, clergy, and social reformers persuaded the Iowa legislature to designate a facility for confinement and treatment of the disease of intemperance. Tracy connects this success to its context in wider Progressive social reform. "As much as any reform passed in turn-of-the-century Iowa," writes Tracy, "the creation of inebriate hospitals embodied a diversity of elements that characterized Progressivism in America: the search for order." These include "the rise of 'issue-focused coalitions,' the secular institution of Protestant moral values; the growth of an increasingly regulatory state with a well-articulated, efficiently organized, social reform mission; the maturation of the professions; and the expansion of scientific and medical authority" ([76], p. 149).

While Chavigny uncovers the roots of the contemporary triumph of the medicalization of alcoholism in earlier reformers' ideology, Tracy finds a disconnect. A number of factors, writes Tracy, "worked against the wholesale adoption of the medical perspective" on alcohol abuse. Foremost was the failure of these institutions to demonstrate a robust cure rate. Moreover, these institutions "addressed a small percentage of the alcoholic population," and, as a result, medical care never was able to supplant the criminal justice system. "Prohibition and World War I cut short the medical efforts of physicians, drying up much of the political concern for the drunks" ([76], p. 153). Thus, "Iowa's efforts to medicalize habitual drunkenness were unsuccessful for as wide a range of reasons as they were initiated" ([76], p. 153).

Tracy's 2005 volume, *Alcoholism in America: from Reconstruction to Prohibition*, finds no medical consensus that alcoholism was a disease. However, like Chavigny, Tracy uncovers a persistent attempt by practitioners and social reformers to attach drunkenness to forces beyond individual choice [77]. Thus, reformers located the etiology of alcoholism in social forces, biological destiny, or some combination. Therefore, the current dominant discourse, in which alcoholism is considered a disease, has deep, if contested, historical roots.

Although today alcoholism is widely assumed to be organic, mid-twentieth century psychiatry focused on psychogenic etiologies, often tied to gender role confusion. Alcoholic males, writes Michelle McClellan, were characterized as effeminate with homosexual tendencies manifested by employment difficulties. In contrast, psychiatrists portrayed female alcoholics as displaying "masculine traits such as aggressiveness," and they "were often promiscuous or

frigid" women and inadequate mothers ([52], p. 274). Given the psychoanalytic paradigm that underpinned these views, gender identity and behavior issues were tied to childhood conflicts resulting from poor parenting. "Experts," according to McClellan, found that "many alcoholic women had displayed masculine and therefore deviant behavior as children—some had acted like tomboys, for example, while others exhibited unfeminine temper tantrums" ([52], p. 279). When later life stressors and emotional difficulties arose, particularly those tied to sexual and reproductive issues, these vulnerable women turned to alcohol.

Gendered assumptions, according to historian Lori E. Rotskoff, also informed psychiatric views about the role that sober wives played in their husbands' alcoholism [66, 67]. Underlying many of these observations was the tension of post-war readjustment of gender role expectations, with returning males displacing working women. The task, seen by many psychiatrists and social workers in the 1940s and 1950s, was to reestablish traditional gender roles within the American family. A number of psychiatrists suggested that "wives had a vested interest in maintaining their husbands' incompetence" ([67], p. 302). Some practitioners suggested that a husband's alcohol abuse was triggered by his wife's neuroses, manifested in dominating their emasculated husbands. Others saw the domination as resulting from the stress of their husband's addiction. Nevertheless, both of these perspectives suggested that alcoholism was a "family illness" and that "the whole family would need to convalesce" ([67], p. 307). Thus, by the 1950s, psychiatrists and social workers advocated group therapy for alcoholics' wives. "Given the nation's deep psychological investment in marriage," Rotskoff concludes, "it is apt that alcoholism's deleterious effects would increasingly be measured in marital terms. In large part, the cultural construction of the 'recovering' alcoholic marriage—comprised of sober husbands and supportive wives—gained public acceptance because it reflected and reshaped familial values in American society at large" ([67], p. 321).

What these historians have shown is that the theories that informed these arguments, interventions, and policies—degeneration, psychoanalysis, and eugenics—reflected dominant social values in the guise of science. One might argue that current scientific claims about alcoholism as a disease rely on a completely different science, informed by neurobiology, biochemistry, and genetics [9, 59]. However, having shown the culture-bound nature of earlier scientific theories supporting the idea that drunkenness is a disease, historians are skeptical of current scientific assertions that alcoholism is a disease.

Opiates and Other Illicit Drugs

The same science and psychiatry that have consistently viewed host predisposition as the trigger for alcohol addiction have, just as consistently, viewed opiates as posing an addictive risk for all who use them. According to Edwards, this is because alcohol intoxication "is remarkably susceptible to cultural prescriptions and proscriptions" and alcohol is "a widely accepted recreational drug," whereas, "in contrast, intoxication with crack cocaine, or injected amphetamines, or with a heavy dose of lysergic acid diethylamide (known more commonly as LSD), is not so easily shaped, and these are not drugs which society is ever likely to accord a licit recreational status" ([25], p. 57).

Alcohol prohibition was attempted, and, despite some revisionist arguments that it reduced drunkenness and alcohol addiction substantially [11], Prohibition was a social and political failure [46]. The contrast between the rejection of alcohol prohibition and the expansion of opiate prohibition is underlined by the triumph of the belief that alcohol use had a wide range of possible individual effects from benign to deadly. Where these effects fell on the spectrum was a consequence of host differences and excessive drinking. The refusal to accept a similar range of possibilities for opiates and other mind-altering substances, including marijuana, stimulants, and amphetamines, framed both the

official response and individual behavior of users [55]. Nevertheless, there remains a deeply held belief that there is such a thing as an addictive personality that leads one to drugs. This concept, as we will see, has deep historical roots, often attached to an array of negative character traits. In contrast to the alcoholic, predisposition toward narcotic use became evidence that drug addicts were sociopaths. As a result, prohibition of drugs and punishment for dependence were framed by a combination of claims about the nature of the substances and that of the addicts.

In *Creating the American Junkie* (2002) and her subsequent publications, Caroline Acker traces this history of opiate prohibition through an examination of the experience of users as they negotiated a world in which opiate use increasingly became criminalized [1]. Acker's work reinforces David Courtwright's study, *Dark Paradise* (2001), which, using similar narratives, demonstrates that "what we think about addiction very much depends on who is addicted" ([16], p. 4). In the early twentieth century, addicts could seek medical treatment that included prescriptions of maintenance doses. Beginning with the Harrison Narcotics Act in 1914, however, non-medical use or purchase of cocaine and opiates was restricted and all narcotics sold or prescribed were required to be registered. As a result, physicians were no longer able to treat addicts through maintenance, and ceased treating them altogether. This shift, writes Acker, transformed the context of opiate use and "as the context for the use of opiates changed, so did the meanings for those who used them" ([1], p. 166). Thus, "addicts developed their own strategies for maintaining their addiction," which resulted in "a new form of addict identity as the behaviors to maintain addiction were criminalized" ([1], p. 167).

Courtwright has a slightly different take. With the decline of medical (iatrogenic) addiction in the late nineteenth century, "opiate addiction . . . began to assume a new form: it ceased to be concentrated in upper-class and middle-class white females and began to appear more frequently in lower-class urban males, often neophyte members of the underworld. By 1914 the trend was unmistakable." For Courtwright, "the trend toward criminalization . . . was well underway before the basic narcotic statutes were enacted" ([16], p. 3).

Part of that identity, according to historian Timothy Hickman, was the emergence of "a double meaning of addiction," in which some of the addiction was attributed to disease and some to hedonism and antisocial behavior ([34], pp. 185–186). "The addiction concept of habitual narcotic use was embedded in the early twentieth century paradigm of professionalizing medical authority" ([34], p. 185) because it placed juridical addicts under medical authority and criminal addicts under criminal jurisdiction. Anti-narcotic legislation, argues Hickman, reflected this dichotomy, and, by the early 1920s, "volitional addicts came to be defined as *criminals*" while "juridical addicts . . . were defined as innocent *patients*" because of their willingness to seek medical treatment ([34], p. 188, italics in original). Hickman does not distinguish between alcohol and narcotic use, but his evidence and the wider historical record indicate that the division between those who were considered diseased and those who were classified as criminal mirrored the division between alcoholics and drug addicts.

Although Hickman does not make the connection, his essay provides a context for the emergence of the psychoanalytic construct of the "addicted personality," which first appeared in Lawrence Kolb's 1925 article, "Types and Characteristics of Drug Addicts" [38], and in his subsequent works [39]. Despite Kolb's insistence that addiction was a medical issue, federal officials adopted Kolb's construct as evidence of the general character defects of addicts and as justification to extend the criminalization of drug use [16, 78].

Speaker explains such results as almost inevitable given the rhetoric that informed drug addiction from the 1920s to the 1940s [72]. Acknowledging that "drug abuse is a significant and difficult public health problem," Speaker, nevertheless, points to accumulated evidence that suggests "that at least some persons can use drugs moderately without becoming abusers,

that even heavy abuse may not be a lifelong pattern, and that many 'outbreaks' of drug abuse are self-limiting and fairly short-lived" ([72], p. 203). Illicit drugs and nicotine were demonized with similar, if not the same, adjectives and hyperbole that once framed alcohol prohibition campaigns: "The drugs in question are powerful, seductive, and rapidly addictive; that everyone is at risk for addiction; that drugs *by themselves* are sufficient to cause any imaginable deviant behavior and are directly responsible for most crime and violence" ([72], p. 204, italics in original). Although, as Speaker asserts, with the end of Prohibition alcohol consumption was destigmatized, the use of other psychoactive drugs has not been. Indeed, made illicit, their use is not only illegal, but also immoral ([72], p. 205).

As medical treatment for alcohol addiction became the norm in the mid-twentieth century, maintenance clinics for the treatment of narcotics addiction became illegal. From 1923 to the opening of the first methadone treatment center in 1965 in New York City, writes Jim Baumohl, "addicts were demonized, hounded, subjected to draconian criminal penalties, and never treated except in the confines of a hospital or jail." Aside from a very few wealthy private clients, "abstinence was the only legitimate goal of treatment" [5]. By the 1930s, even the supporters of maintenance programs "believed most addicts to be incurable" ([5], p. 228).

It was in this context that in 1935 the U.S. Public Health Service established the Center for Drug Addiction at the federal prison hospital in Lexington, Kentucky [12]. Informally labeled as "Narco," the facility, which continued its addiction research until 1979, was designed to be a treatment hospital for incarcerated addicts. In 1948, the research unit became the first basic research laboratory of the newly formed National Institute of Mental Health, the Addiction Research Center. Inmates became voluntary participants in Addiction Research Center experiments that tested reactions to a wide variety of substances including alcohol, barbiturates, heroin, methadone, major and minor tranquilizers, and psychedelics. Campbell's *Discovering Addiction* examines the Center for Drug Addiction and Addiction Research Center in detail. She found that inmates often were re-addicted and some of the information obtained "was used by pharmaceutical companies seeking to bring drugs to market" ([12], p. 76). Nevertheless, Campbell concludes that "the research program yielded broadly distributed benefits to persons from the addicted class" ([12], p. 142).

The Center for Drug Addiction's benign approach to addicts was an exception, but the venue for its research, a federal prison, reflected the policies of Henry Anslinger, the influential director of the Federal Bureau of Narcotics (1930–1962). With bipartisan support, Anslinger advocated incarceration as the only deterrent. It didn't matter to Anslinger, writes Baumohl, whether addicts were confined to a jail or a hospital, but "the more like a jail, the better he liked the hospital" ([5], p. 254).

Anslinger's role in shaping and extending the criminalization of drug use policy, writes Rebecca Carroll, cannot be overestimated [13, 14]. Anslinger "influenced Americans' attitudes toward narcotic drugs and drug users and sellers, depicting both users and sellers as criminals." This is evident in Anslinger's 1937 Congressional testimony in which he claimed that marijuana "is dangerous to the mind and body, and particularly dangerous to the criminal type, because it releases all of the inhibitions." It causes some individuals to "have an increased feeling of physical strength and power," which is dangerous because they "fly into a delirious rage, and they are temporarily irresponsible and may commit violent crimes" [4].

Although a number of influential experts, including leaders of the American Medical Association and the American Bar Association, argued for the medicalization and clinical treatment of addicts, Anslinger stifled their voices [75]. In 1944, at the urging of New York City Mayor Fiorella La Guardia, the New York Academy of Medicine conducted a study on the effects of marijuana, the findings of which contradicted Anslinger's claims. The commission found that cannabis did not cause violence and, despite Anslinger's insistence otherwise,

concluded that marijuana could be medically beneficial. Anslinger denounced the report and instructed the Bureau of Narcotics agents to investigate the commission members' own drug use. Further, he threatened prison sentences for anyone carrying out independent research on cannabis.

In the post-war era, Anslinger altered his views of marijuana's effect on its users but not his policy toward its use. Testifying in Congress in 1948, Anslinger claimed that cannabis caused the user to become peaceful and pacifistic; thus, the Communists were recruiting Americans into cannabis use as part of a plot to weaken their will to fight [75].

Like Anslinger, those who continue criminalizing marijuana use in the United States today claim to base their views on scientific research, but, also like Anslinger, their antipathy toward marijuana use reflects deeper cultural values rather than robust science. A similar claim can probably be made about those who support unrestricted availability of marijuana. The point here, as much of recent addiction history reveals, is that the classification of substances as licit or illicit has less to do with science than with politics.

This political influence can be seen in attempts to control demand. Historian William B. McAllister's examination of international drug control shows that increasing regulation and criminalization of drugs has ended up pretty much as it began, with incarceration of drug users and a failure to stem the activities of suppliers [51]. What has changed, according to McAllister, is the "nature and scope" of anti-drug efforts. "Governments and international agencies constructed massive bureaucracies, engaged in considerable legislative activity, and attempted to implement policies intended to change the behaviors of millions of individuals, with varying degrees of success" ([51], p. 175). Although McAllister finds that "since the late nineteenth century, the American drug experience has largely mirrored that of other Western industrialized nations," he notes that the United States "has acted as the center of demand" for all types of drugs and has been the greatest force of "regulatory activism." As a result, McAllister concludes, "policy-makers, legislators, and citizens of the United States, much like addicts, cannot escape their relationship to the global drug scene" ([51], pp. 201–202). If, as a number of historians have indicated, the century-long activism failed to stem the drug addiction that it was aimed at curing [73], the rhetoric surrounding drug use, combined with the increasing classification of substances as addictive, has exacerbated the problem.

In a recent book, Richard Davenport-Hines argues that the criminalization and prohibition of drugs have resulted in an epidemic of use and an exacerbation of fatal encounters. The almost paranoid response of puritanical American policy-makers has, according to Davenport-Hines, led to a black market and growth in all types of criminal activity [20]. David Courtwright finds this argument unpersuasive: "What is unique about [Davenport-Hines'] *The Pursuit of Oblivion* is that it combines the simplification inherent to world history with the simplification peculiar to polemical exertion. The result is a book that, for all its length and erudition, is almost startlingly reductive: the story of a bad idea imposed upon a doubtful world by aggressive fools" ([18], p. 445).

Licit Mind-Altering Drugs

Neuroscientists typically attribute the heightened anti-drug rhetoric to a more sophisticated understanding of how these substances work on the human brain, a view shared by historian turned bio-ethicist Steven Novak [57]. He finds that when it came to lysergic acid diethylamide (i.e., LSD), despite the desires and pressures from researchers, their pharmaceutical sponsors, and influential lay persons, clinical and neurobiological research determined its ultimate classification. LSD became suspect because research data revealed suicide risks, prolonged psychotic sequelae, and anti-social behaviors. Meanwhile, LSD was being used

illegally for recreational purposes with many of the same dangerous effects. Although for some—Timothy Leary and his followers—it was LSD's mind-altering, liberating effect that spelled its doom, Novak's history suggests otherwise. The ongoing thalidomide revelations and resultant increased Congressional oversight led to legislation requiring prior Food and Drug Administration approval for all investigational drug trials, as well as a finding that a substance was safe and efficacious before it could be marketed. LSD met neither test and was eliminated from medical investigation, albeit with some resistance [57]. The importance of this history is that it was the biochemical action of LSD that determined its marginalization and eventual criminalization [79].

In contrast to LSD is the history of antidepressants—often addictive, mind-altering, but licit, drugs. With the introduction of a new class of antidepressants in the late 1980s called selective serotonin reuptake inhibitors (fluoxetine hydrochloride [Prozac®], paroxetine hydrochloride [Paxil®], and sertraline hydrochloride [Zoloft®]), antidepressant use has grown exponentially. Spurred on by massive advertising efforts in the late 1990s and Peter Kramer's best-selling book, *Listening to Prozac* [40], selective serotonin reuptake inhibitors, according to psychiatrist Nicholas Weiss, have become "consumer products appropriate for wide usage or general lifestyle enhancement." Selective serotonin reuptake inhibitors' predecessors, monoamine oxidase inhibitors and tricyclic antidepressants, were viewed as "disease therapies to be kept strictly in the medical domain" [83]. Why, asks Weiss, had "no one listened to [the tricyclic antidepressant] imipramine?" ([83], p. 329). His answer, like so much else connected to addiction, lies in the history of alcoholism.

The definition of "alcoholism" as a distinct disease affecting only a minority of drinkers, writes Weiss, has removed the blame for alcohol-related social problems from the substance to a subgroup of susceptible individuals. Thus, alcohol use, though not abuse (drunkenness), is socially acceptable. "This enabled the alcohol beverage industry to sell its product, despite widespread concerns about the dangers and evils of alcohol, as long as drinking was officially proscribed for that susceptible population" ([83], p. 349). The diagnosis of depression, according to Weiss, "functioned in an analogous, though inverse manner." A diagnosis of depression identified a susceptible group "who *should* become users, those with a current or potential medical depression" ([83], p. 349, italics added). Therefore, dependence on selective serotonin reuptake inhibitors is authorized, even though they are mind-altering (and often addictive) substances, because depression has been constructed as a disease. The risks of selective serotonin reuptake inhibitor use are downplayed because the condition that they treat is defined as illness, despite a spate of warnings about the hazards associated with selective serotonin reuptake inhibitors [10, 30, 33].

Similarly, although Weiss does not make this connection, a diagnosis of attention deficit hyperactivity disorder authorizes placing individuals (mainly children) on addictive stimulant medications such as Ritalin® (methylphenidate) [22]. According to historian Nicholas Rasmussen, the current amphetamine epidemic should be viewed in the context of the medical use of stimulants to treat depressive disorders and how this resulted in a wider epidemic of stimulant use by the mid-twentieth century. Building on this history, Rasmussen connects the present methamphetamine epidemic to the earlier iatrogenic epidemic [62, 63]. This history appears to be repeating itself as Ritalin® and other stimulants prescribed for the treatment of attention deficit hyperactivity disorder become widely used as recreational drugs on American college campuses and beyond.

Recognizing how prescription medication use once again has morphed into recreational and self-medicating substance use and abuse has important implications for those who wish to understand and treat the current wave of addiction and substance abuse. For Rasmussen, these evolutions have resulted as much from changing populations who use stimulants as from the biological actions of these drugs. A similar

argument has recently been made by psychologist Richard DeGrandpre in *The Cult of Pharmacology* (2006) [23].

In fact, for most illicit addictive substances, there is a companion licit substance, such as methylphenidate, the action of which mirrors that of the proscribed drug. As DeGrandpre points out, although Ritalin® and cocaine act similarly on the brain, the former is widely prescribed for children while the use of cocaine is a felony. Similarly, the street drug ecstasy acts on the same serotonin receptors as selective serotonin reuptake inhibitors. Although far from controversial, the risk of addiction to mind-altering pharmaceuticals has been justified because of the putative benefit conferred by their consumption. This returns us to the tensions that exist regarding alcohol and nicotine use. Each has been sanctioned because of their alleged benefits and vilified because of their harms.

Smoking and Nicotine

As Alan Brandt points out, although the addictive potential of nicotine in tobacco was often noted long before the 1988 Surgeon General's report on nicotine and addiction [82], attitudes toward cigarette smoking have a complex history. The prohibition of alcohol in 1919, writes Brandt, "had the effect of further legitimating the use of cigarettes. Cigarettes now assumed many of the positive cultural and social attributes previously associated with drinking—leisure, pleasure, and sociability—without the risks of intoxication with its consequent social and familial pathologies" ([7], p. 386). For the next several decades, moderate smoking was portrayed in the media, including in medical journals, as risk free and possibly beneficial to overall health. Smoking, Brandt argues, was contrasted with drug addiction and characterized as "a habit that could be broken without much trouble" ([7], p. 387). In fact, "often cigarettes were seen as a vehicle for assisting in breaking addictions to more dangerous substances like alcohol or opiates" ([7], p. 388). As late as 1964, the Surgeon General's advisory committee on the health consequences of smoking concluded that "the evidence indicates this dependence to be psychogenic in origin" and "the biological effects of tobacco, like coffee . . . are not comparable to those produced by morphine, alcohol, barbiturates, and many other potent addicting drugs" [80]. As a result of the dramatic decline of smoking because of its associated health risks, its recategorization as addictive in the 1980s was, according to Brandt, "far less problematic than would have been the case a decade earlier." This was particularly so because smoking increasingly had become "associated with certain social groups—generally those less educated and of lower socioeconomic status," and, notes Brandt, "in a culture prone to stigmatize its poor and disfavored, changing perceptions about the 'average smoker' eased the growing attribution of addiction" ([7], p. 391).

In his recent book, *The Cigarette Century*, Brandt focuses more on the dangers associated with smoking, and, consonant with his role as an expert witness for the Justice Department in its prosecution of the tobacco industry, he focuses on the health risks associated with smoking [8]. Although Brandt remains sympathetic to those who continue to smoke, others have been less scrupulous in translating the justified demonization of the tobacco industry to smokers themselves.

In sequential media conferences hosted by the American Cancer Society in 1985 and the National Cancer Institute in 1988, strategies were adopted that were aimed at portraying the tobacco industry as illegitimate, deceptive, and criminal. The American Cancer Society's *Media Handbook*, *Smoke Signals*, suggested delegitimizing the industry by referring to them as "drug pushers," "profiteers from human misery," environmental polluters, and "death and disease merchants" [3]. At the American Cancer Society meeting and its follow-up 1988 Media Advocacy Consensus Conference in Washington, DC, attendees were urged to shame the industry's allies and dependent community arts organizations into severing their ties with the tobacco industry [3, 81]. Although both conferences

warned "to be careful about blaming the victim" ([81], p. 36), inevitably these attitudes spilled over to the smokers as well. The American Cancer Society's *Media Handbook* suggested that one response to claims of smokers' rights was: "your right to smoke stops where my nose begins and my lungs are exposed." Smokers were to be confronted with the dangers that they posed to children who are "more prone to bronchitis, pneumonia, and other respiratory problems." Children, smokers were to be reminded, deserved "fresh, clean, smoke-free air" ([3], p. 23). In the last two decades, the rhetoric has ratcheted up as accusations claiming deception and criminal activity by the tobacco industry have become the subject of seemingly endless lawsuits. Those who continue to smoke often find themselves collateral victims, increasingly ostracized and demonized. "There are," writes Brandt, "powerful currents in our culture that define smokers as weak-willed and ignorant, who abuse their own health and others', while polluting the common environment" ([7], p. 398).

Despite these powerful forces and the health risks associated with smoking, many persist in the habit. Part of the reason for this persistence, according to Keane, is evident if one contrasts the immediate rewards of smoking with its long-term consequences [37]. For instance, Keane cites studies that suggest that smoking enables working-class women to cope with boring working conditions. However, as she points out, from a rhetorical perspective, smoking "is reduced to its potentially most undesirable outcomes, namely, various premature, painful, and protracted forms of death," while any potential benefits are dismissed as "illusory and excluded from the calculation of risk" ([37], pp. 102–103). Given that those who smoke are, as Brandt points out, already socially marginalized, the benefits of smoking, like those who smoke, have become increasingly unattractive.

Speaker [72] argues that the prohibition of a substance is almost always preceded by a demonization of its producers and users. If this observation is correct, we may be well along the road to prohibiting smoking in North America.

Rhetoric and Reality

In combination, these new histories make a persuasive case for the cultural construction of drug classification and addiction. They illuminate the role of rhetoric in influencing legal statutes, court decisions, and the criminal justice system. The ambiguous attitude toward smoking and nicotine addiction provides an ongoing case study of how cultural values and legal structures evolve and interact, determining where on the spectrum of legitimacy a mind-altering substance and its users are located.

Despite the growth of restrictions, heightened rhetoric, and ratcheting up of penalties for many mind-altering drugs, the use of those drugs is either persistent or increasing. However, Courtwright warns against conflating drug policy with drug use. "When doing drug *policy* history, it pays to zoom in on details: What was the mix of regulations, taxes, and penalties governing access to this drug in this society at this time? When doing drug *use* history, it pays to zoom out, looking for broader connections among drugs and across cultures." Thus, writes Courtwright, "Opium smoking would not have taken root in China had it not been for the introduction and spread of tobacco, with which opium was first smoked. Marijuana smoking would not have taken such hold among Western youth had it not been for the antecedent cigarette revolution. Fewer alcoholics would have meant fewer narcotic addicts, the relief of hangover often inspiring the use of opiates. 'Licit' and 'illicit' categories obscure the indivisibility of drug history" [18].

If substances such as caffeine, chocolate, and carbohydrates are included, not to mention addictive behaviors including gambling, sex, and shopping, we either inhabit the most addictive society that ever existed or have failed to notice retrospectively how addictive human behaviors are. Alternatively, as the logic of the histories that are reviewed here suggests, a wide range of human consumption and behaviors have been (re)constructed as addictions.

Speaker asks to what extent the "characteristic rhetoric" toward addictive substances is a

"reflection of genuine drug problems . . . and to what extent it is an expression of various social tensions—class struggles, demographic changes, racial and ethnic conflicts, etc.—or an expression of particular values and ideologies?" She also wonders "what accounts for the persistent use of these themes and images," and "to what extent . . . this popular rhetoric not only reflected but shaped public perceptions and drug policy itself during this century" ([72], p. 219). To these questions we may add what the histories of addiction reveal about the biological effects on the human brain and what these biological mechanisms reveal about the histories of addiction.

The skepticism of many addiction historians toward current scientific claims is rooted in the evidence that each successive psychiatric addiction paradigm has revealed more about the culture that enabled it than about the robustness of scientific findings. For many historians, portraying biology and the past sciences of addictions as culturally constructed appears to authorize ignoring current science altogether. However, the fact that science, like everything else, is socially constructed in no way diminishes its explanatory power any more than it limits the value of historical interpretations, such as those examined in this chapter, which—like all historical research and writing—are socially constructed and contingent [42]. In any case, an increasing number of historians of addiction have begun to engage rather than ignore current addiction science. Those historians have much to say that addiction scientists should consider.

Taking History Seriously

What does addiction history reveal about addictive behaviors? Can all this evidence be interpreted as culturally framed? According to Edwards, the answer is both yes and no. He suggests that histories of alcohol use lead to a deeper engagement with the putative organic mechanisms that have been attached to alcoholism. Such an approach opens up an alternative interpretation that brings together seemingly contradictory social constructionist and biologically reductionist claims. Alcoholism, according to Edwards, is "best approached through a framework of the dependence-syndrome concept," where "the dependent state is not a matter of all or nothing (addict or not addict), but something which can be experienced in varied and measurable degrees (more or less dependent)" ([25], p. 162). Edwards' insistence on the distinction between syndrome and disease is not trivial. Measles, polio, and Huntington's are diseases because a tentative diagnosis based on signs and symptoms is confirmed or rejected through a laboratory test indicating infection by a pathogen or the presence of a genetic mutation. In contrast, the cause of a syndrome, such as schizophrenia, Tourette's syndrome, or affective disorders (depressions), remains unknown [45, 74]. The diagnosis of syndromes depends on the identification of a list of possible combinations of signs and symptoms displayed by an individual within a certain time period. This list of signs and symptoms is tentative, and disagreement often surfaces over which signs and symptoms are crucial to authorize a diagnosis [31, 43]. As a result, identification of a syndrome often varies over time and by geographic location [86].

As with pneumonia, a variety of routes can lead to alcohol dependence. Unlike pneumonia, but like most psychiatric syndromes, these include both cultural and/or biological factors in the enabling spectrum. Those who meet the criteria (in terms of signs and symptoms) for alcohol dependence experience real illness, even if the etiology and level of distress and particular path to dependence are not the same for every alcohol-dependent person. Recognition of the many routes to an alcohol dependence syndrome sanctions researchers and clinicians to craft a variety of interventions and policies that consider a spectrum of cultural and biological triggers. Such recognition must include, no matter what the trigger, the biological and social effects on the individual. This requires engagement with the accumulating evidence from recent research that substance dependence, including alcohol

dependence, alters brain reward mechanisms, such as brain architecture and neurochemistry, sometimes permanently [9, 85]. This seems true even when the addiction, such as gambling, is not attached to a substance. The question remains whether labeling non-substance behaviors as addictions is justified because they impact and alter the same brain reward systems (i.e., the ventral tegmental area) as do cocaine and heroin [6, 56, 85]. Since most behaviors have an impact on brain chemistry, how do we decide which of these are addictions and which are not? Many of the histories of addiction discussed in this chapter agree that what is considered and not considered an addiction reflects social and cultural values as much as it tells us a truth about the mechanisms of the brain.

Saying that does not, however, excuse trivializing the importance of biology to addiction. As Edwards writes in his discussion of the history of the failed controlled drinking experiments, the "belief that the troubled drinker can recover only through abstinence" was based on "accumulated personal testimony and front-line clinical experience." Dismissing these observations and experiences "as no more than repressive moralism" is "mistaken and ungenerous" ([25], pp. 163–164). Effective treatment requires acceptance by uncontrolled drinkers and those around them that the alcoholism involves organic mechanisms. Such an admission in no way diminishes the reality that alcohol dependence includes both cultural causes and social consequences. Any understanding of the history of alcoholism requires such an integrative approach. The same claims may be made for all addictions—they are syndromes of dependence, informed and "enabled" by an interaction of culture and biology.

As with alcohol, nicotine acts differently on different hosts. It may be extremely addictive, but 50 percent of smokers have managed to cease smoking since the late 1960s. All smokers probably fit into some definition of addiction, but if we were to apply Edwards' notion of syndrome of dependence, we might develop better insights into who smokes, why some persist despite overwhelming evidence of negative health consequences, and why others are able to stop smoking.

As Tracy and Acker write, earlier scientific explanations for the mechanisms of addiction seem retrospectively quaint ([78], pp. 15–18), but there have been persistent observations of addictive predispositions, or what psychoanalysts used to label "addictive personalities." If previous theories of the mechanisms of addiction appear retrospectively tenuous, the existence of addictive personality types seems less so.

This returns us to Edwards' view that what we call addictions are actually syndromes of dependence that have multiple triggers and pathways, ranging from the cultural to organic, but are probably informed by a combination that we might label as "cultural biology." This cultural biology of substance dependence is based on centuries of observations. The science of each era has attempted to identify the mechanisms that underlay the observed behaviors. The fact that, in retrospect, these attempts reflect the dominant scientific paradigm of each era is not surprising; nor does it undercut the evidence that there are organic triggers for and biological effects from substance dependence. That these interact with cultural and social forces would not surprise any serious neuroscientist. Like Edwards, they would concede that current neurobiological hypotheses are by definition tentative, precisely because for a scientific claim to be robust, it must be testable (falsifiable) and replicable.

This interdisciplinary perspective allows us to consider the multiple meanings of the Tracy and Acker title, *Altering American Consciousness*. As Courtwright has shown in *Forces of Habit*, humans have attempted to alter their consciousness since time immemorial [17]. Evolutionary biologist Tammy Saah finds that "drug use and addiction seem to have been a part of mammalian society since ancient times." For Saah, "looking at drug addiction from an evolutionary perspective" is the best way to "understand its underlying significance and evaluate its threefold nature: biology, psychology, and social influences" [68]. Any persuasive interpretation of the history of addiction, insists Courtwright,

must consider the impact of the biological action of drugs on human hosts. However, if it ignores history and culture, the impact of that biology will be missed [17].

Western economies and culture, writes Courtwright, are built on the production, sale, and use of mind-altering drugs, including alcohol, tobacco, coffee, cocoa, tea, sugar, carbohydrates, and an array of prescription medications. This could not have happened without biological as well as cultural mechanisms. In *Dark Paradise*, Courtwright shows how addiction is exacerbated and enabled by the availability of and exposure to mind-altering substances [16]. Considering the neurobiological mechanisms of addiction, says Courtwright, can offer powerful clues for comprehending this drive to alter consciousness.

As Edwards reminds us, for much of human history, including our own era, most mind-altering substances have been initially consumed as a means of self-medication for a variety of ills, not least of all for disorders of consciousness, including major and minor psychiatric disorders [25]. That self-medication plays an important role in persistent substance use and abuse, despite awareness of potential harm, provides fertile ground for further historical research [2, 26, 54]. Self-medication, like the conditions it aims to treat, is rooted in culture and biology and cannot be understood apart from that interaction. Like all culturally mediated biological phenomena, each society responds to these human behaviors within the context and confines of larger social, political, and cultural constraints. From this perspective, addiction is one possible outcome of humans' drive to alter consciousness; what we label "addiction" might be understood as a *possible* consequence of the human desire to alter consciousness.

Taking history seriously would force addiction scientists to confront the reasons for failure of the abstinence policy. First and foremost, abstinence is a failed policy because it denies the historical evidence that humans in all societies and cultures have relied and continue to rely on substances to alter their consciousness. Addictive behaviors, rather than diminishing, have increased, spurred on in part by industries that manufacture and market consciousness-altering commodities. In the face of persistent human drives to alter consciousness and markets that cater to them, abstinence appears unattainable. Moreover, the pursuit of abstinence has led to a number of counterproductive policies. Among them is the assumption, writes Campbell, that restricting knowledge about the safe use of illicit drugs or about ways to reduce the harms associated with their use "is good because condoning drug use is bad." Yet, by denying illegal drug users information that could reduce risks, we ensure even worse outcomes. The histories of addiction indicate that abstinence is also a failed policy because, as both historians and brain researchers recognize, addiction is a chronic relapsing/remitting syndrome. From that perspective as well, any successful policy or intervention must include harm reduction. Historians of addiction, Campbell insists, "have a crucial role to play in shifting drug policy toward public health and harm reduction" ([12], p. 237). The history discussed in these pages supports that claim.

Acknowledgments The research and writing of this article were partially supported by a grant from National Institutes of Health, National Institute on Drug Abuse, entitled "Current Smokers: A Phenomenological Inquiry" (R01 DA015707–01A2) and a grant from the Engelhard Foundation, "Sophomore Year at Emory Living and Learning Experience: An Interdisciplinary Seminar Course/Internship in Addiction and Depression." Some of the material in this chapter appeared previously in Howard I. Kushner, "Taking Biology Seriously: The Next Task for Historians of Addiction?" *Bulletin of the History of Medicine* 80 (Spring 2006): 115–143. I thank Carol R. Kushner and Robert Cormier for editorial assistance.

Introduction

Diagnosis and classification are ways in which we make sense of our clinical and epidemiological observations and help communicate our findings to others. Thus, they provide an important basis for the prevention of human disorders and for the management of people who develop them. This applies as much to substance use and other addictive disorders as to other afflictions. Indeed, careful diagnosis and categorization are particularly important in the addictions given the great variety of psychoactive substances (of different pharmacological and chemical classes), the wide spectrum of use and misuse of these substances, and the innumerable complications that arise from such use. (The term "misuse" is employed in this chapter as a shorthand term to encompass a variety of types of excessive substance use; it is not used as a diagnostic term.) Precision in diagnosis is clearly vital for clinical purposes, and epidemiological researchers and health statisticians need valid and cross-culturally applicable diagnoses.

This chapter explores three distinct but overlapping areas. In the first section, there is a review of the nature of psychoactive substance use, misuse, and dependence. The alternative, indeed competing, conceptualizations are discussed, and there follows an account of how the present diagnostic and classification systems have been developed. The next section describes the main substance use diagnoses, focusing on the dependence syndrome, but also including

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_5,

non-dependent repetitive substance use and the main substance-induced mental and physical disorders. In the final part of this chapter, we examine the approach to diagnosis in research but particularly in clinical practice. This includes an account of clinical techniques, questionnaires, interview schedules, and laboratory tests.

The Nature of Substance Use Disorders

Given the many professional disciplines that have contributed to an understanding of psychoactive substances and their effects, it is not surprising that scientists and practitioners have drawn upon different traditions to explain their essential nature. There also have been many lay interpretations. In the nineteenth century, a popular conceptualization of excessive alcohol and drug use was that it represented a failure of morals or character [30]. This notion, although superseded in the professional literature of the later twentieth century, continues to influence community and political views as to the nature of substance use disorders and that of people with them.

Personality Disorder

In the first edition of the *Diagnostic and Statistical Manual of Mental Disorders*, published in 1952, substance misuse was included in the personality disorders [1]. Drug addiction was not specifically defined, but there was a statement that "Addiction is usually symptomatic of a personality disorder. The proper personality classification is to be made as an additional diagnosis." The second edition, published in 1968 [2], still had substance use disorders classified within the personality disorders. No specific definitions or criteria were provided, and there was little description of the conditions, although the text included a statement that "the best direct evidence for alcoholism is the appearance of withdrawal symptoms" and that the diagnosis of drug dependence required "evidence of habitual use or a clear sense of a need for the drug" [2].

The Disease Concept

A different tradition saw substance misuse as reflecting a disease process, which was biologically determined, resulted in the individual having some type of idiosyncratic reaction to alcohol or a drug, and had a relatively predictable natural history. This conceptualization influenced and was subsequently embraced by the self-help movements, such as Alcoholic Anonymous. Jellinek developed the concept of the disease of alcoholism in the 1940s and 1950s [25], although in his later work he increasingly recognized the role of environmental influences. During the 1960s and 1970s, the concept that substance misuse might represent a disease process was dismissed by most scientists and professionals. Likewise, the role of genetic predisposition was thought to be inconsequential, with the familial aggregation of substance misuse explained by cultural influences, role-modeling, or malfunction within families.

Epidemiological and Sociological Formulations

A third tradition may be described as the epidemiological and sociological one. Put simply, substance misuse and problems arise fundamentally because of the overall level of use of that particular substance in society. In the 1950s, Ledermann [32] proposed a relationship between the level of alcohol consumption in a community and the prevalence of alcoholism. The level of use is, in turn, influenced by the availability of alcohol, its manufacture and distribution, its price (importantly), and cultural traditions and sanctions. Inherent in these conceptualizations is that individual pathology is considered of secondary importance. The social constructionist school views substance use problems as disaggregated, with no special relationship

among them. This school of thought was concerned about the stigma attributable to diagnostic labels and the potential of treatment as a form of social control [46].

Learned Behavior

The 1970s saw the rise of social-cognitive theory [7] as an influential paradigm to explain the development and resolution of alcohol and drug problems. This school of thought teaches that the (many) influences that determined behavior in general apply to the uptake of substance use and the development of disordered use. Positive consequences encourage repeated use, negative ones the opposite. Patterns of substance use behavior could become established in this way, but, equally, repetitive substance use could be "unlearned". This led to the development of a range of cognitive behavioral therapies, some of which were aimed at moderated or "controlled" substance use [57].

Clinical Syndrome

The need for an understanding of substance misuse that spanned these various discipline-bound conceptualizations and terms was largely met by the formulation of the concept of a "substance dependence syndrome" originally proposed with regard to alcohol dependence by Edwards and Gross in 1976 [18]. The basis of the dependence syndrome was a clinical description of key clinical features in a way that was essentially atheoretical and was not based on any particular etiological understanding of the disorder, be it biological, behavioral, or sociological. Rather, certain experiences, behaviors, and symptoms related to repetitive alcohol use were identified as tending to cluster in time and to occur repeatedly. The advantage of a descriptive account of dependence is that it can accommodate etiological models but not be beholden to them.

The concept of the dependence syndrome has been very influential. It has been shown to apply to many other psychoactive substances that have the potential for reinforcement of use, including benzodiazepines, illicit and prescribed opioids, cannabis, inhalants, psychostimulants such as cocaine and the amphetamines, nicotine, caffeine, and anabolic steroids [21, 34, 40, 58]. It also may apply to repetitive behaviors that do not involve self-administration of a psychoactive substance. These include pathological gambling and compulsive shopping and exercise [33, 41].

The dependence syndrome is at the heart of the present classification systems of psychoactive substance use disorders [30, 53]. It takes center stage in the latest version of the International Classification of Diseases, published in 1992 [62], and in the most recent revisions of the *Diagnostic and Statistical Manual of Mental Disorders*, namely the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition, Revised and the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, which was published in 1994 [3] and underwent text revisions in 2000 [4].

Neurobiological Disorder

Arguably the most important development in our understanding of the nature of substance misuse in recent years has been in neurobiological processes, complemented by findings from genetic research. There is now compelling evidence that repeated use of psychoactive substances leads to powerful and enduring changes in cortico-mesolimbic reward, stress, and control systems [28]. In turn, these result in reinforcement and perpetuation of such use.

There are three key neurobiological changes that underpin dependence.

(1) Activation and then inhibition of brain reward systems, particularly involving dopaminergic transmission and opioidergic transmission. These have the effect of resetting the reward systems such that larger amounts of the substance are needed to produce the desired effect and natural rewards are not as reinforced because of the

relatively low response from these systems [60].
(2) Recruitment of brain stress systems, including those subserved by glutamate neurotransmission and corticotrophin-releasing factor [27] and suppression or uncoupling of anti-stress systems [47].
(3) Impairment of inhibitory control pathways from the prefrontal cortex to the mesolimbic systems, resulting in impaired decision-making capacity [65].

Dopamine release leads to neuronal plasticity [29], which underpins associative learning and memories that result in repetitive substance use even though the original personal triggers and environmental influences have changed [53]. Thus, dependence may be construed as an "internal driving force" [53] that results from repeated exposure to a psychoactive substance and that in turn leads to further repetitive substance use, which is now self-perpetuating and typically occurs even in the face of harmful consequences. A recent publication on the neuroscience of addiction by the World Health Organization summarizes the key developments in biomedical research over this period [63].

Investigations into possible genetic influences have accompanied this research on neural circuitry. Biometric genetic studies have shown that children born of parents with substance dependence are more likely to have substance dependence themselves [52] and that this is largely explained by genetic transmission rather than environmental factors [6, 52]. Genomic analysis in human and laboratory animals has identified several areas of the genome where mutations are associated with increased risk of substance use disorders [6].

Achieving a Synthesis

It is clear that psychoactive substance use exists as a continuum in society but equally clear that within this spectrum it is possible—and important—to define syndromes that have a distinct set of physiological and behavioral features. Substance dependence is a syndrome that occurs in response to repeated and typically high-level alcohol or other drug use, is driven by a profound resetting of key neurobiological systems, is compounded by impaired executive control, and leads to continuing and damaging substance use.

Other forms of repetitive substance use seem not to have these neurobiological changes—at least not to the extent of dependence. They appear to be influenced primarily by factors that affect many types of repetitive human behavior [7]. These include expectations of a substance's effect, responding to learned associations with substance use, the many and varied environmental influences, including peer group pressure, ethnic and workplace culture, and the influences of availability and accessibility of alcohol and various drugs.

Separate from the dependence syndrome and non-dependent forms of substance misuse are the multiple consequences of substance misuse. These may be physical, neurocognitive, mental, and social. They typically reflect the adverse effects of the substance, the mode and means of administration of the substance, and/or the implications of the dependence processes. They include disorders of the heart, lungs, gastrointestinal tract, liver, muscles, brain, and peripheral nerves. Mental health complications include mood and anxiety disorders and various psychoses. Social complications encompass interpersonal, financial, occupational, and legal difficulties.

Substance Use Diagnoses in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition and the International Statistical Classification of Diseases and Related Health Problems, 10th Revision

Although many different systems of diagnosis and classification have been proposed for substance use disorders over the years, two

have international recognition. They are the *Diagnostic and Statistical Manual of Mental Disorders*, currently in its fourth edition [3, 4], which covers mental and behavioral disorders, and the International Classification of Diseases, which is now in its tenth revision [62] and published by the World Health Organization. The International Statistical Classification of Diseases and Related Health Problems, 10th Revision is a classification of all diseases, injuries, and causes of death.

Substance Dependence

The dependence syndrome is defined in both the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition and the International Statistical Classification of Diseases and Related Health Problems, 10th Revision as a cluster of behavioral, cognitive, and physiological phenomena that develop after repeated drinking or substance use, and which tends to be self-perpetuating. Typically it occurs in people who use large amounts of psychoactive substances repeatedly—for example, consuming alcohol in excess of 120 g/day (men) or 80 g/day (women). However, the diagnosis of substance dependence is made primarily not on the level of consumption but on criteria based largely on the original Edwards and Gross formulation [18]. The criteria in the two systems (in summary format with comments) are listed in Table 1.

As can be seen, substance dependence in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition is defined very similarly to the International Statistical Classification of Diseases and Related Health Problems, 10th Revision. As with all diagnostic systems, to be of optimal use in the clinic or for the needs of epidemiology and public health planning, the criteria must be both valid and straightforward, and this was foremost in the minds of those who fashioned them. The dependence syndrome applies to most psychoactive substances that have the potential for reinforcement of use (such as benzodiazepines, opioids, cannabis, psychostimulants, nicotine, caffeine, and anabolic steroids, as described earlier). However, elements of the syndrome are not necessarily applicable to all substances. For example, cannabis withdrawal is not recognized in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, although this may change in the next revision. Dependence also may apply to repetitive behaviors that do not involve self-administration of psychoactive substances, such as gambling, compulsive shopping, and compulsive exercise [33, 41], not just to impulse control disorders.

Substance Withdrawal Syndrome

The substance withdrawal syndrome refers to a state seen in individuals with the dependence syndrome when use is curtailed. It is an important manifestation of the neurobiological changes that underpin dependence. In general, the features of the withdrawal syndrome are opposite to those of the acute pharmacological effects of the substance. In contrast to dependence, the substance withdrawal syndrome varies appreciably according to the substance used. Psychostimulant withdrawal is very different from withdrawal from, say, sedative-hypnotics.

The withdrawal syndrome is defined as a group of symptoms of variable clustering and severity that occur on the absolute or relative withdrawal of a substance after repeated—and usually prolonged and/or high-dose—use of that substance. The specific criteria in the International Statistical Classification of Diseases and Related Health Problems, 10th Revision and the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition are listed in Table 2. The onset and course of the withdrawal state are time limited and are related to the type of substance and the dose being used immediately before abstinence. Three types of withdrawal are recognized in the International Statistical Classification of Diseases and Related Health Problems, 10th Revision and the *Diagnostic and Statistical Manual of Mental Disorders*,

Table 1 Diagnostic guidelines for dependence and sample questions [3, 4, 62]

International statistical classification of diseases and related health problems, 10th revision	Diagnostic and statistical manual of mental disorders, 4th edition	Sample questions
A strong desire or sense of compulsion to take the psychoactive substance (*craving or compulsion*).	No equivalent criterion—mentioned in text.	Have you felt a strong desire or urge to use that you could not resist?
No equivalent criterion, but text states that the subjective awareness of compulsion is most commonly seen during attempts to stop or control substance use.	There is persistent desire or unsuccessful attempts to cut down or control substance use.	Have you wanted to stop or cut down on your use but could not? Have you more than once tried unsuccessfully to stop or cut down on your use?
Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use (*loss of control*).	The substance is often taken in larger amounts or over a longer period of time than was intended.	Have you started using and found it difficult to stop (before you became intoxicated)? Have you used much more than you expected to when you began, or for a longer period of time than you intended to?
Progressive neglect of alternative pleasures because of psychoactive substance use, or increased amount of time necessary to obtain or take the substance or to recover from its effects.	Important social, occupational, or recreational activities are given up or reduced because of drinking or psychoactive substance use.	Have you given up or greatly reduced important activities in order to use, such as sports, work, or associating with friends and relatives?
Subsumed in above criterion.	A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects.	Is a great/er deal of time spent using a substance or getting over the effects of the substance?
Tolerance, such that increased doses of the psychoactive substances are required in order to achieve effects originally produced by lower doses.	Tolerance, as defined by either (1) a need for markedly increased amounts of the substance to achieve the desired effects or (2) markedly diminished effect with continued use of the same amount of the substance.	Have you found that you need to use much more than before to get the same effect, or that using the usual amount has less effect than before?
A physiological withdrawal state when substance use has ceased or been reduced, as evidenced by the characteristic withdrawal syndrome for the substance; or use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms.	Withdrawal as manifested by either (1) the characteristic withdrawal syndrome for the substance or (2) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms.	Did stopping or cutting down use ever cause you problems such as (list expected withdrawal symptoms)? Have you ever used to keep from having problems or make any of these problems go away?
Persisting with substance use despite clear evidence of overtly harmful consequences.	The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.	Has substance use ever caused you any physical or psychological problems? (If yes, list the problem/s.) Did you continue to use after you realized that it caused you problems? (State the problem/s.)

Table 2 Diagnostic guidelines for substance withdrawal syndrome [3, 4, 62]

International statistical classification of diseases and related health problems, 10th revision	Diagnostic and statistical manual of mental disorders, 4th edition
Clear evidence of recent cessation or reduction of substance use after repeated and usually prolonged and/or high-dose use of that substance; one of the main indicators of the dependence syndrome.	(A) The development of a substance-specific syndrome due to cessation of, or reduction in, substance use that has been heavy and prolonged.
Symptoms and signs compatible with the known features of a withdrawal state from the particular substance or substances. Physical symptoms vary according to the substance being used. Psychological disturbances (e.g., anxiety, depression, sleep disorders) also are common features of withdrawal. Typically, the client reports that withdrawal symptoms are relieved by further substance use.	(B) The substance-specific syndrome causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
The features are not accounted for by a medical disorder unrelated to the substance use, and not better accounted for by another mental or behavioral disorder.	(C) The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.
Differential diagnosis: Many symptoms present in drug withdrawal state may also be caused by other psychiatric conditions—e.g., anxiety, depressive disorders.	

4th Edition criteria: simple uncomplicated withdrawal, withdrawal with convulsions, and withdrawal with delirium [3, 4, 62].

Non-Dependent Repetitive Substance Use

Repetitive substance use that does not fulfill the criteria for the dependence syndrome is still of clinical significance. It is handled differently in the two systems. In the International Statistical Classification of Diseases and Related Health Problems, 10th Revision, the term "harmful use" applies to repetitive use of a psychoactive substance that has caused physical or mental harm to the person. In the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, the term "substance abuse" refers to repetitive use of a psychoactive substance that essentially is causing social harm or problems. There is no equivalent term in the International Statistical Classification of Diseases and Related Health Problems, 10th Revision; indeed, the International Statistical Classification of Diseases and Related Health Problems, 10th Revision eschews the notion of a disorder that is defined by social criteria. Other non-dependence conditions have been proposed and tentatively defined; they are covered later.

Diagnostic and Statistical Manual of Mental Disorders, 4th Edition Substance Abuse

Substance abuse is defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition as repeated substance use that leads to one or more social or occupational problems (Table 3). It is understood as a less severe condition than dependence. The two diagnoses cannot coexist in the same time period, as substance abuse is pre-empted by a diagnosis of dependence. Substance abuse can be envisaged as one axis of a biaxial conceptualization of substance use disorders, which separates the core syndrome of dependence from the consequences. However, there is blurring of this conceptualization because of its hierarchical relationship with dependence, i.e., as a less severe disorder. The extent to which the biaxial relationship applies—and indeed whether abuse is properly separated from dependence—remains controversial, with some studies finding that a one-factor solution that covers the spectrum of abuse and dependence criteria is optimal [19, 39, 58].

Table 3 Diagnostic guidelines for substance abuse in the *Diagnostic and Statistical Manual of Mental Disorders, 4th editio n* [4]

(A) Pattern of recurrent substance use leading to significant impairment or distress, as evidenced by one (or more) of the following criteria within a 12-month period:
1. Recurrent substance use that results in failure to fulfill major obligations at work, school, or home
2. Recurrent substance use in situations in which it is typically hazardous (e.g., drunk driving)
3. Recurrent substance-related legal problems (e.g., driving an automobile or operating a machine when impaired by substance use)
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)

(B) The symptoms have never met the criteria for substance dependence for this class of substance.

International Statistical Classification of Diseases and Related Health Problems, 10th Revision Harmful Use

Harmful substance use is a repetitive pattern of substance use, at levels that result in actual physical or mental harm, but it does not fulfill the criteria for the dependence syndrome [62]. The harmful effects may be acute or chronic. Examples of acute complications include fractures and other forms of trauma, acute gastritis, and acute psychotic symptoms following substance use. Chronic medical complications encompass liver disease (e.g., alcoholic liver disease or hepatitis C-induced liver disease following injecting drug use), cardiovascular diseases, respiratory diseases, various neurological sequelae, and many others. Examples of mental complications are depressive episodes secondary to heavy alcohol intake, and substance-induced psychosis. In clear distinction from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, social complications *per se* are insufficient to justify a diagnosis of harmful use under the World Health Organization nomenclature [53, 62].

Other Diagnostic Entities

The three disorders—substance dependence, substance abuse, and harmful use—do not encompass the whole spectrum of repetitive, damaging (or potentially so) substance use and, therefore, pose limitations, especially for epidemiological purposes. In the work of a World Health Organization Expert Committee in the 1970s, several other conditions characterized by repetitive substance use were proposed to complement the dependence syndrome [19]. However, only one, "harmful use", survived to appear in the International Statistical Classification of Diseases and Related Health Problems, 10th Revision. Perhaps because of the breadth of the task, there have been few attempts to develop a classification system that encompasses the broad spectrum of substance use and misuse. The terms proposed by the World Health Organization committee were "unsanctioned use", "dysfunction use", and "hazardous use".

Unsanctioned Use

This was defined as the use of a substance that is not approved by a society or by a group within that society. This term implies that this disapproval is accepted as a fact in its own right, without the need to determine or justify the basis of the disapproval.

Dysfunctional Use

This is substance use that leads to impaired psychological or social functioning—for example, loss of employment or marital problems.

Hazardous Use

This is repetitive substance use that places the person at risk of harmful consequences. In the World Health Organization formulation, this was defined as physical and mental harm, but in other definitions, harm has been taken to incorporate social and legal consequences too. Hazardous substance use is sometimes referred to as "at-risk", "risky", "medium-risk", or "high-risk" substance use.

The Need for the Term "Hazardous Use"

Hazardous ("risky") use has been operationalized for alcohol consumption in several countries. For example, in the United States, men who drink five or more standard drinks (65 g of alcohol) in a day or more than 15 standard drinks (195 g) per week, and women who drink four or more standard drinks (50 g) in a day or eight standard drinks (105 g) per week, are considered to be drinking excessively [38, 49]. Repeatedly consuming 5+ (men) or 4+ (women) United States standard drinks (65 g and 50 g of alcohol, respectively) confers a risk of alcohol use disorders, acute and chronic illnesses, and injuries [16, 48]. In Australia, hazardous or risky consumption is defined presently as repeated daily consumption of more than four Australian standard drinks (40 g of alcohol) for a man and more than two standard drinks (20 g) for a woman [10]. In other countries, it is variably defined as regular drinking of more than 29 drinks (290 g of alcohol) per week for men or more than 15 standard drinks (150 g of alcohol) per week for women, with two alcohol-free days per week recommended for both men and women. In some Asian countries, hazardous or risky drinking indicates consumption at levels that lead to intoxication twice a month or more.

The application of hazardous or "risky" use to other substances has been slower. For nicotine (tobacco), it can be argued that there is no non-hazardous level of use. Likewise, because of uncertainties as to whether there is truly a safe or low-risk level of use for other substances, the concept has not been applied widely to illicit drugs such as cannabis, the amphetamines, cocaine, or heroin, although research on quantifying and establishing the risk of low-level cannabis use is emerging.

Hazardous substance use appeared in early drafts of the International Statistical Classification of Diseases and Related Health Problems, 10th Revision but was omitted from the published version following the results of field trials that revealed an inter-rater reliability (kappa) coefficient of only 0.4 [51]. Because of the difficulty in operationalizing it, the diagnosis was considered to be open to misuse. The decision to omit hazardous substance use from the International Statistical Classification of Diseases and Related Health Problems, 10th Revision also was influenced by doubts as to whether it represented a disease process, which in many people's minds was a prerequisite for inclusion in a classification system of diseases. In the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, one of the four criteria of substance abuse [3, 4] is recurrent substance use in situations in which it is typically hazardous. This is known by many as the "hazardous use" criterion. It is most commonly fulfilled when a person has been convicted of a drunk-driving offense. However, it differs from other definitions in that there is not a clear statement of what is being risked—namely, physical and mental consequences.

For epidemiological and public health purposes, having a term that defines various levels or patterns of substance use as conferring risk is advantageous. Indeed, recent data from the National Epidemiologic Survey of Alcohol and Related Conditions indicate that hazardous alcohol consumption (defined as the United States 5+/4+ standard drink criterion) exists within the continuum of abuse and dependence criteria [50]. As the frequency of this level of consumption increases, this experience moves along the severity continuum to overlap with abuse and dependence criteria [50].

At the same time, to examine relationships between use patterns and consequences without considering whether a diagnosable substance use disorder is present, as is usual in epidemiological studies, is limiting. The reduction in all-causes mortality among people with moderate levels of alcohol consumption is not seen in those who have had a previous diagnosis of alcohol dependence [15]. In support of including hazardous use in a diagnostic system is the evidence that it can be defined and it responds to therapy, the evidence base for the effectiveness of interventions for hazardous alcohol consumption being particularly strong [8, 26]. Thus, in a comprehensive diagnostic system, there are grounds for having a dependence category, a non-dependence disorder that is of clinical consequence, and a "sub-threshold" disorder that indicates risk to individuals and populations.

Diagnostic Orphans

Diagnostic orphans are substance users who report some symptoms of dependence but do not meet the diagnostic criteria for either *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition dependence or substance abuse. In young people, it is a common category, as common (with respect to alcohol) as dependence or abuse [20]. Alcohol diagnostic orphans have a natural history that is closest to that of alcohol abuse, though they have fewer alcohol-related problems over time. Cannabis diagnostic orphans also are similar in use patterns to those with cannabis abuse, but they do not have higher rates of mental complications than non-cannabis users [17].

Substance-Related Problems

Substance-related problems (or disabilities) were conceptualized by the World Health Organization Committee as the *consequences* of repetitive substance use [19, 53]. They include both acute (short-term) effects and chronic (long-term) ones [31]. Harmful alcohol consumption (or alcohol dependence) can affect virtually every organ system in the body, while cannabis and tobacco commonly induce respiratory complications [5]. Repetitive psychostimulant use can lead to a range of psychiatric syndromes, including mood disorder and psychotic disorder. Complications arising from repetitive substance use stem not only from the pharmacological properties of a particular substance but from unknown potency, purity, and sterility due to contaminants and adulterants with which the substance is prepared, unsafe injecting practices, and the associated lifestyle of the user. The spread of bacterial infections and viral infections, such as hepatitis C and HIV, and to a lesser extent hepatitis B, is important in this regard [5]. The disinhibiting effect of alcohol and substance use also places users at risk of sexually transmitted diseases.

Substance-Induced Mental Disorders

In the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition and the International Statistical Classification of Diseases and Related Health Problems, 10th Revision, there are several substance-related psychiatric syndromes. Here we shall discuss just three of them: delirium, psychotic disorder, and amnesic syndrome.

Delirium

Delirium (Table 4) is an uncommon feature of substance misuse, although sometimes the diagnosis is made in persons with acute intoxication. Substance intoxication with delirium is an accepted diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition [3, 4] but not in the International Statistical Classification of Diseases and Related Health Problems, 10th Revision [62]. Most commonly it is seen in those with a severe withdrawal syndrome from alcohol or

Table 4 Diagnostic criteria for delirium tremens [62]

Withdrawal state with delirium—delirium tremens
Prodromal symptoms:
• Insomnia
• Tremulousness
• Fear
Clinical features
• Clouding of consciousness and confusion
• Vivid hallucinations and illusions affecting any sensory modality
• Marked tremor
• Delusions
• Agitation
• Insomnia or sleep reversal cycle
• Autonomic overactivity

sedative-hypnotic drugs. The classical disorder is delirium tremens [56], which is a short-lived but occasionally life-threatening toxic-confusional state with accompanying somatic disturbances (Table 4). It usually is a consequence of absolute or relative cessation of alcohol in severely dependent drinkers with a long history of use. Its onset may be preceded by features of simple withdrawal and/or by withdrawal convulsions. A similar withdrawal delirium is seen after cessation of benzodiazepines and other sedative-hypnotics although with less tremor.

Psychotic Disorder

Psychosis and/or psychotic symptoms occur in many people with substance use disorders. In some, this reflects an underlying independent disorder such as schizophrenia. In others, the psychosis is a consequence of drug use. Sometimes the precise mechanism remains unclear. The International Statistical Classification of Diseases and Related Health Problems, 10th Revision defines substance-induced psychotic disorder as a phenomenon that occurs during or immediately after psychoactive substance use (usually within 48 h) and is characterized by vivid hallucinations (typically auditory but often in more than one sensory modality), misidentifications, delusions, and/or ideas of reference (often of a paranoid or persecutory nature), psychomotor disturbances (excitement or stupor), and an abnormal affect, which may range from intense fear to ecstasy [62]. The sensorium is usually clear, but some degree of clouding of consciousness, though not severe confusion, may be present. The disorder typically resolves at least partially within 1 month and fully within 6 months. The diagnosis is excluded if the psychotic state is a manifestation of substance withdrawal syndrome. According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, a substance-induced psychotic disorder is defined by: (i) prominent hallucinations or delusions developing during, or within a month of, substance intoxication or withdrawal, (ii) the phenomenon is etiologically related to the disturbance, and (iii) the disturbance is not accounted for by a psychotic disorder that is not substance induced [4].

For psychostimulants such as amphetamines and cocaine, there is a dose-response relationship, with psychosis occurring especially in those who have been using high doses and/or using the drug over a lengthy period. According to the International Statistical Classification of Diseases and Related Health Problems, 10th Revision, a diagnosis of psychotic disorder should not be made merely on the basis of perceptual distortions or hallucinatory experiences when substances having primary hallucinogenic effects (e.g., lysergic acid, mescaline, and cannabis in high doses) have been taken. In such cases, and also for confusional states, a possible diagnosis of acute intoxication should be considered. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition has no such exclusion.

Amnesic Syndrome

Amnesic (or amnestic) syndrome (Table 5) is an example of a substance-related disorder where, typically, neuronal loss has occurred. The most common form is characterized by impairment of recent memory, with relative preservation of remote memory and with normal immediate recall [3, 4, 62]. Disturbances of time sense and ordering of events are usually evident, as are

Table 5 Diagnostic criteria for the amnesic syndrome/amnestic disorder

International statistical classification of diseases and related health problems, 10th revision amnesic syndrome [62]	Diagnostic and statistical manual of mental disorders, 4th edition criteria for amnestic disorder [4]
1. Memory impairment as shown in impairment of recent memory and learning of new material; disturbance of time sense (e.g., rearrangement of chronological sequence, telescoping of repeated events into one, etc.) 2. Absence of defect in immediate recall, impairment of consciousness, and of generalized cognitive impairment 3. History of objective evidence of chronic (and particularly high-dose) use of alcohol or drugs Includes Korsakoff's psychosis or syndrome, induced by alcohol or other psychoactive substance	(A) The development of memory impairment as manifested by impairment in ability to learn new information or the inability to recall previously learned information (B) The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning. (C) The memory disturbance does not occur exclusively during the course of a delirium or dementia and persists beyond the usual duration of substance intoxication or withdrawal. (D) There is evidence from history, physical examination, or laboratory finding that the memory disturbance is etiologically related to the persisting effects of substance use.

difficulties in learning new material. Confabulation may be marked but is not invariably present and should not be regarded as a prerequisite for diagnosis. Importantly, other cognitive functions are usually relatively well preserved; the amnesic defects are, therefore, out of proportion to other disturbances. Personality changes, often with apparent apathy and loss of initiative, and tendency toward self-neglect may be present but are not regarded as necessary for diagnosis.

Practical Approaches to Diagnosis

The Distinction Between Research and Practice

The way diagnoses are made varies considerably. For the research scientist, there are several well-validated diagnostic interview schedules, which allow diagnoses to be made from a systematic structured interview of the respondent. They include the Diagnostic Interview Schedule [43, 44], the Composite International Diagnostic Interview [45], the Schedules for Clinical Assessment in Neuropsychiatry [61], and the Alcohol Use Disorder and Associated Disabilities Interview Schedule [9, 22, 23]. The constituent questions represent the individual diagnostic criteria of the particular condition. Algorithms are employed to establish whether the combination of responses fulfills these criteria and then to determine the number and combination of criteria that are required to fulfill the diagnosis. These questionnaires have sound psychometric properties; they have been subjected to rigorous testing of their reliability and validity [14, 42], and there is much information available on their cross-cultural applicability [59]. In addition to their use in research studies, the structured interview schedules have an important role in the training of psychiatrists, psychologists, and other health practitioners.

Making a diagnosis in clinical practice is usually much less systematic than this. It requires that the practitioner has a clinical qualification, typically in medicine or psychology, and has had a lengthy period of specific supervised experience. In most cases, the clinician will take a narrative history and there will be an assessment of the person's mental state and, in the case of medical practitioners, his/her physical state. The information amassed is set against the known features and diagnostic criteria of the various disorders, and a decision is made as to whether the individual has a particular condition or not. Following completion of training, clinicians tend not to employ diagnostic schedules. However, some clinical services

require completion of such a schedule or an alternative, such as the Addiction Severity Index [36, 37], to ensure consistency in the assessment of clients. Shorter screening and brief assessment questionnaires, such as the Alcohol Use Disorders Identification Test [55] and the Alcohol, Smoking and Substance Involvement Screening Test [64], also are employed in many services to facilitate assessment.

Much of the information obtained in clinical work is designed to identify experiences and problems that the person has had and that lead not only to a diagnosis but to a comprehensive understanding of the person's background, symptoms, problems, and difficulties [43]. Thus, the information obtained in a clinical assessment is broad-ranging and has multiple purposes, of which only one, albeit a crucial one, is to make the diagnosis. In this final part of the chapter, we shall summarize the information that is relevant to collect in clinical practice and the extent to which this points to a diagnosis or is important ancillary information.

Approaches to the History

The great majority of diagnostic information relevant to substance use disorders is obtained from a careful history. The accuracy of the information is highly dependent on the setting and context of the interview and the interactional style of the clinician. With an empathic approach and in a clinical (as opposed to a custodial) setting, a high level of accuracy can be obtained. Inter-rater and test-retest assessment indicates reliability coefficients of 0.8–0.9 for average daily alcohol consumption and the experience of dependence symptoms and problems [13, 54]. Validity, as assessed by comparison with information provided and by a collateral source or from official statistical data, also is high, with intraclass coefficients of approximately 0.65–0.85 [35, 54].

Among the approaches that enhance the quality and accuracy of the history are to:

(1) show empathy and understanding;
(2) establish a good therapeutic rapport with the client;
(3) be non-judgmental, and
(4) be sensitive to the client's cultural background.

Experienced practitioners sometimes employ what are termed "enhancement techniques", such as:

(1) placing the onus of denial of substance use on the client;
(2) suggesting high levels of intake, the "top high technique" [54], and
(3) being aware of diversionary tactics and not being diverted from the line of questioning.

These techniques should be employed only by experienced clinicians as their use may rebound on the practitioner and lead to termination of the interview.

In addition, collaborative information should be sought from family members, the family physician, and the client's medical records, with due care paid to ethical and privacy issues.

Quantification

Quantification of the amount of a substance used is a key aspect of the history. This is relatively easy with legal substances such as alcohol, tobacco, and prescribed medication but still is feasible with illicit drugs (Table 6).

Amongst the information that should be obtained is the following:

- quantity
- frequency
- cost
- duration
- pattern or variability
- mode of administration
- time of last use
- periods of abstinence.

The reliability and validity of such information obtained on illicit drug use is generally good, provided that there are no negative implications of supplying the information [24, 35].

Table 6 Quantification of substance use

Alcohol	Grams Standard drinks Standard units
Tobacco	Number of cigarettes Ounces of tobacco
Sedative-hypnotics	Dose (per tablet) Number of tablets per day
Cannabis	Number of joints Number of cones Number of bongs
Heroin	Weights "Street" grams Cost (e.g., dollars)
Amphetamines/ methamphetamine	Points (0.1 g) Grams Cost (e.g., dollars)
3,4-Methylenedioxy-methamphetamine	Number of tablets
Cocaine	Grams Cost (e.g., dollars)

Experiences Indicating Dependence

Establishing whether an individual has a dependence syndrome is the next step. Although this is typically suggested by the quantity and frequency of substance use, these measures are not diagnostic criteria in and of themselves. The experienced practitioner will, however, assess whether the history of substance use points to dependence from information provided about the circumstances and intensity of use, whether this has continued despite harm, and the extent to which the person's life is shaped around the substance. Questions reflecting the individual diagnostic criteria for dependence then are asked. Sample questions and the criteria from which they derive are presented in Table 1.

Problems or Consequences

The adverse consequences of a substance use disorder are legion. At this stage in the interview, the practitioner will have identified several that are uppermost in the client's (or relative's) mind. Enquiry should continue on problems typically associated with the substance in question. These can be grouped conveniently with the following domains:

- relationships
- interpersonal difficulties
- financial
- work related/unemployment/prostitution
- legal/forensic—drunk driving, assault, criminal charges.

Key Factors on Physical Examination

Physical examination is an integral part of a comprehensive medical assessment, but it often is omitted, in which case important diagnostic information can be missed. Signs on physical examination can on occasion point almost instantaneously to diagnoses, and a wealth of corroborative information is potentially available. In general, physical examination abnormalities are more apparent in individuals with alcohol use disorders, particularly in those with alcohol dependence. Specific physical abnormalities also are evident in many individuals who are injecting drugs; these may reflect local complications at the site of injection or systemic infections. Significant respiratory abnormalities also may be apparent in people who are tobacco or cannabis smokers.

Physical examination is undertaken routinely by internal medicine physicians and most addiction physicians. A focused examination is undertaken typically by family physicians and some psychiatrists. Physical examination is considered by many psychiatrists to interfere with the development of a therapeutic relationship, and there are readily apparent requirements for chaperoning, particularly when examining individuals of the opposite sex. These compose significant hurdles in a busy practice. Psychiatrists often refer patients to their general medical practitioner for physical examination. Attempts have been made to establish a minimum physical examination that is appropriate for psychiatric practice [54], but there is no

consistency nationally or internationally as to what is an accepted minimum.

Table 7 depicts some of the findings on physical examination that are commonly seen in substance use disorders in relation to the primary substance used. There are many more that stem from alcohol use disorders than any other substance class, reflecting the widespread tissue toxicity caused by alcohol misuse [16, 31].

Neurological and Mental State Examination

Emphasis should be placed on identifying the common mental comorbidities and neurocognitive impairments. The mental state examination is a vital component of the overall assessment when undertaken by a medical practitioner or psychologist. Key components are the client's general appearance, his/her reaction to the interview, speech, mood, affect, thought form, thought content, perception, presence of hallucinations, cognitive function, attention, concentration, orientation, memory (immediate recall, short-term memory, and long-term memory), intelligence, insight, and judgment [31].

The degree of rapport between the client and clinician provides clues about the client's relationships with others. The clinician's reaction to the client also may provide clues on the disorder from which the client is suffering. Suicide risk assessment is particularly important.

Laboratory Tests

The assessment of the client is complemented by undertaking relevant laboratory tests. These can include blood tests, urine assays (typically for drugs or metabolites), saliva analysis, breath analysis, and, less commonly, analysis of hair. Such samples can be examined for the presence of alcohol, nicotine, prescribed and illicit drugs, and their metabolites. In addition, for alcohol there are numerous tests that reflect its pathophysiological effects on blood, the liver, and other organs.

Considerable effort has been devoted to the development of laboratory tests of substance use disorders. There are several reasons for this. There remains a lingering concern by many researchers and clinicians about the validity of self-report despite the evidence for its accuracy in most circumstances. There is a desire for corroboration of self-report information, particularly in forensic settings or where there are significant implications for the individual for being diagnosed with a substance use problem. In addition, there is a desire for tests to simplify or speed the diagnostic process. More substantively, a test that reflects the biological processes of dependence or other pathology would be a valuable addition to diagnostic capability.

At present, no diagnostic test or procedures such as imaging directly point to specific substance use disorders. The nearest example perhaps is the finding of a high blood alcohol or drug level in a person who shows no signs of intoxication (or any substance effect). This is presumptive evidence of tolerance and points to the likely presence of a substance dependence syndrome. The biological markers of alcohol reflect a range of physiological processes [11], including liver enzyme induction and liver cell damage, suppression of hematopoiesis, and metabolic disturbances, such as hyperuricemia. None of these abnormalities is specific to alcohol. However, abnormalities can be used to support a diagnosis in conjunction with primary evidence of the substance use disorder. The most specific test reflecting the biological effects of alcohol is the presence of abnormal isoforms of transferrin, collectively known as carbohydrate-deficient transferrin [11]. An elevated blood carbohydrate-deficient transferrin is found in 40–70% of persons with alcohol dependence or harmful alcohol consumption. It is highly specific for these diagnoses (a specificity of 98% has been reported), with only a few uncommon inherited metabolic disorders and occasionally primary biliary cirrhosis and pregnancy resulting in abnormal levels. Table 8

Table 7 Findings on physical examination

Alcohol	Alcohol on breath Features of intoxication or of withdrawal Facial/periorbital puffiness Facial flushing/telangiectasia Old scars Conjunctival injection Scleral jaundice Signs of: • trauma • chronic liver disease • gastritis/duodenitis/gastric bleeding • pancreatitis • hypertension • atrial fibrillation • rib fractures • nystagmus • peripheral neuropathy • head injury • cognitive impairment
Tobacco	Nicotine-stained fingers Chronic airways disease Cardiovascular disease
Cannabis	Smell of marijuana Conjunctival injection Features of intoxication
Sedative-hypnotics	Drowsy, slurred speech (overdose) Anxious agitated (withdrawal)
Injecting drug users in general (unsafe injecting practices, associated lifestyle)	Malnutrition Poor self-care Needle track marks (fresh or old) Tattoos Jaundice (viral hepatitis C and B) Thrombophlebitis Cellulitis Lymphedema Skin abscesses Indurated skin Caries Mouth ulcers Pneumonia Septic arthritis HIV/AIDS and sexually transmitted infections
Heroin	Overdose or withdrawal Pupillary size: • pinpoint (overdose) • dilated (withdrawal) Low blood pressure Low respiratory rate Non-cardiogenic pulmonary edema
Psychostimulants	Underweight and emaciated Pupil size—dilated Excoriations (formication) Clenched jaws (bruxism) Caries/broken teeth Repetitive stereotypic movements Nasal septal necrosis (cocaine)

Table 8 Biological markers of alcohol misuse

Laboratory tests	Indicates excess alcohol intake
Urine or blood alcohol concentration >0.05%	Does not distinguish between acute and chronic consumption of excess alcohol
Full blood count: • Macrocytosis	Detects heavy drinkers: 20–30% in the community and 50–70% in hospital inpatients
Liver function tests • Elevated gamma-glutamyl transferase	Detects heavy drinkers: 30–50% in the community and 50–80% in hospital inpatients
Carbohydrate-deficient transferrin $t^1/_2$	Carbohydrate-deficient transferrin >2.6% reflects heavy alcohol use in the past 2 weeks
Newer biological markers not yet in common use	
Ratio of urinary 5-hydroxytryptophol/5-hydroxyindoleacetic acid	Increased ratio of 5-hydroxytryptophol/5-hydroxyindoleacetic acid
Ethanol metabolites in the urine: • ethyl glucuronide • ethyl sulfate	Helps to detect excess alcohol use when blood alcohol concentration is zero in the emergency department
Ethanol metabolites in hair samples • ethyl glucuronide • fatty acid ethyl esters	Evidence of excessive drinking when: • >25 pg/mg • >1 ng/mg

summarizes some of the most commonly employed laboratory markers of alcohol (see also [12]).

Neuroimaging techniques such as functional magnetic resonance imaging, positron emission tomography, and single photon emission computerized tomography scanning currently are illuminating some of the central neurobiological mechanisms of dependence. As yet, they are not part of routine clinical assessment, but this may well change with greater experience using these techniques over the next decade.

Part II
Behavioral Theories for Addiction

Drug Reinforcement in Animals

Wendy J. Lynch and Scott E. Hemby

Contents

Introduction

Early demonstrations that drugs could serve as reinforcers maintaining operant behavior in laboratory animals led to the development of a model of human drug abuse (see Box 1). The traditional self-administration model was developed within a behavior analysis conceptual framework that views drugs as reinforcers similar to other "natural" reinforcers such as food and sex. The fundamental principle underlying behavioral analysis is that certain aspects of behavior are controlled by their consequences [54]. A drug is said to be functioning as a reinforcer if responding for it is maintained above responding for saline or other control conditions. The traditional model entails training an animal to self-administer a drug during a short daily session, typically 1–3 h. A low ratio requirement is typically used, such as a fixed ratio 1 where each response produces a drug delivery. Under these conditions, intake is incredibly stable, which allows for the determination of the effects of pharmacological and environmental manipulations on the stable baseline level of intake.

Although the rat is most often used in these studies, this model has been implemented with a variety of species including non-human primates, mice, dogs, cats, and baboons. A variety of operant responses have also been used, and typically they depend on the species studied. For example, a lever press or a nose poke response is typically used for rats, whereas a panel press response is typically used for non-human primates. The most common routes of administration are intravenous and oral, but intracerebroventricular, intracranial, inhalation, intragastric, and intramuscular routes have also been used. Generally, these studies use the route of administration that is most similar to the route used in humans for that particular drug, so, for example, animal studies with alcohol typically use an oral route of administration, whereas an intravenous route is used for drugs that have a rapid onset in humans, such as cocaine, heroin, and nicotine.

Box 1 Definitions and terms

This glossary of some of the terms used in studying drug reinforcement, drawn primarily from Iversen and Lattal [46], is provided to aid in the reading of this chapter.

Addiction – a disease that is characterized by impaired control over use of the substance, preoccupation with the substance, use of the substance despite adverse consequences, and distortions in thinking [66].

Acquisition – the process by which a new behavior, such as lever pressing for drug deliveries, is added to the organism's behavioral repertoire.

Choice procedure – the allocation of one of two or more alternative, usually incompatible, responses.

Fixed-ratio schedule – a schedule in which a response is reinforced only after the animal has responded a specified number of times. For example, with a fixed-ratio 5 schedule of reinforcement, responding is reinforced after every 5 responses.

Progressive-ratio schedule – a higher-order schedule that requires the animal to emit an increasing number of responses for each successive reinforcer. For example, at the start of the session, the animal may be required to lever press once to receive a drug delivery, twice for the second drug delivery, four times for the third, eight times for the fourth, etc.

Operant behavior – emitted behavior that can be modified by its consequences (also termed instrumental behavior). This class of behavior is often referred to as purposeful or voluntary.

Reinforcer – a stimulus event that strengthens the behavior that follows it.

Reinforcement – the *process* whereby a behavior is strengthened by the event that follows the behavior, and a *procedure* by which the contingencies between the reinforcers and behavior are arranged within a paradigm.

Reinforcing efficacy – the likelihood that a drug will serve as a reinforcer under various experimental conditions (also termed reinforcing strength). For example, a drug that is only self-administered when the work requirement to obtain a delivery is low (i.e., fixed-ratio 1) would be considered a weak reinforcer, whereas a drug that is self-administered under a variety of different experimental conditions and when the work requirement is high would be considered a strong reinforcer.

Reinstatement paradigm – a model of relapse whereby the animal is tested on responding on a lever that was formerly associated with the drug following re-exposure to a small priming dose of the drug or the environmental stimuli associated with the drug. Stress also is often used as a trigger for drug-seeking behavior during reinstatement testing.

Self-administration – operant responding that directly produces administration of the drug.

Second-order schedule (higher-order schedule) – a schedule requiring the completion of an individual component of the schedule that produces availability to the terminal event. A second schedule of reinforcement must then be completed to produce the terminal event. For example, under a second-order fixed-ratio 10 (i.e., fixed interval of 10 s) schedule of reinforcement, 10 successive fixed-interval schedules would have to be completed before a response is reinforced.

Results from animal drug self-administration studies have revealed good correspondence between humans and animals; drugs abused by humans generally maintain responding in animals, whereas drugs that do not maintain responding in animals are typically not abused by humans, indicating this paradigm's utility for determining abuse liability [22, 42, 47]. Additionally, similar patterns of drug intake have been reported in humans and animals for ethanol, opioids, nicotine, and cocaine self-administration (for a review, see [43]). These parallel results between the human and animal drug literature validate the animal model of drug abuse and suggest that the use of this model may lead to a better understanding of human drug-taking behavior.

In addition to screening drugs for abuse liability, the traditional self-administration procedure has been used to study, through biochemical and pharmacological manipulation, the neurobiological processes underlying the drug reinforcement process. For example, by demonstrating that lesions in some areas of the brain decrease or abolish self-administration behavior, we have developed an understanding of the neuroanatomical substrates for drug reinforcement (e.g., [88]).

Assessing Reinforcing Efficacy

Despite the advances in our understanding of drug reinforcement in animals, reinforcing efficacy, or a drug's reinforcing strength, has been more difficult to measure. The ability of a drug to support self-administration in laboratory animals under different experimental conditions is a measure of the drug's strength as a reinforcer. Thus, a highly efficacious drug will be self-administered under a variety of experimental conditions such as low dose conditions, conditions that require a large work effort, or enriched environmental conditions where other reinforcers are available as choices. In contrast, a weakly efficacious drug will be self-administered only under limited conditions such as food-restricted conditions, moderate-to-high dose conditions, conditions that require a low work effort, or impoverished environmental conditions where there are few or no other reinforcers available as choices.

Although it is generally believed that the reinforcing strength of a drug is related to its abuse liability, actually measuring reinforcing strength is not as straightforward because factors other than the drug's reinforcing effects can directly and indirectly influence responding (i.e., satiating effects, direct effects on responding, and aversive effects). As mentioned above, the fixed-ratio schedule is typically used in studies investigating drug reinforcement in animals (e.g., 1- to 3-h sessions), and under these conditions, an inverted U-shaped relationship has been described between drug dose and rate of responding [16, 39, 72, 73]. That is, as dose increases, responding initially increases (ascending limb) and then decreases (descending limb). At low doses, responding decreases and these doses may not maintain responding. However, doses on the descending limb, which would be presumed to be more efficacious than doses on the ascending limb, maintain quantitatively similar levels or even lower levels of responding than those maintained by doses on the ascending limb. This issue is particularly problematic for the interpretation of changes in reinforcing efficacy in that it is difficult to determine the direction of the change. A number of approaches have been taken to address this issue, including the use of rate-independent approaches such as the progressive-ratio schedule, second-order schedules, and the choice paradigm.

Progressive-Ratio Schedule

The progressive-ratio schedule has been used to evaluate the reinforcing strength of self-administered drugs. With this schedule, the ratio requirement to obtain a delivery progressively increases within a session, and the final ratio completed, or breakpoint, is believed to be a sensitive measure of motivation to obtain the

drug (for a review, see [5]). In contrast to the fixed-ratio schedule, the dose-effect curve under the progressive-ratio schedule is linear, whereby responding is directly related to reinforcer magnitude; an increase in the unit dose of the self-administered drug corresponds to an increase in breakpoint. This linear relationship allows for a more straightforward determination of direction of change in reinforcing efficacy than is allowed by more traditional self-administration procedures. Other strengths are that responding for a particular dose of drug can be incredibly stable from day to day within subjects and that there are considerable individual differences in levels of responding between subjects. Sensitivity to individual differences is thus a strength of the progressive-ratio schedule. Sex differences and hormonal influences on drug self-administration behavior are good examples of this strength in that under simple fixed-ratio schedules, sex differences and hormonal influences are generally not revealed, whereas, under the progressive-ratio schedule, these factors influence breakpoints robustly (for a review, see [56]). Another advantage with this schedule is that it can be used reliably across different pharmacological classes of drugs. However, as with the more traditional self-administration paradigms, the satiating and behavioral disruptive effects of drugs can also impact responding under a progressive-ratio schedule, particularly during earlier parts of the sessions and under low or slowly increasing progressive-ratio schedules.

Second-Order Schedules

Second-order schedules have been developed and have been useful for minimizing issues of satiety and other rate-limiting effects of drugs on responding. Much of the early work using second-order schedules was conducted with non-human primates and focused on conditioned or secondary reinforcement (for a review, see [77]). With this type of schedule, a non-drug stimulus, usually a light or a tone, takes on the characteristics of a reinforcer by its association with the drug delivery. Second-order schedules of drug delivery allow the study of more complex behavioral sequences than do traditional self-administration procedures. The use of second-order schedules has recently been extended to self-administration in rats, and these studies have been useful for the investigation of drug-seeking behavior (i.e., responding for drug that occurs prior to drug availability or when the drug is no longer available) and its neurobiological mechanisms (e.g., [31]).

Like the progressive-ratio schedule, second-order schedules minimize the descending limb of the dose-effect curve, allowing for determination of changes in reinforcing efficacy as a result of a pharmacological or environmental manipulation. Another advantage is that high rates of behavior can be maintained by the conditioned reinforcer with relatively few actual primary reinforcers delivered. Nicotine is a good example of a drug that is robustly self-administered under second-order schedules, whereas, under simple fixed-ratio schedules, it has been historically difficult to establish that it functions as a reinforcer [40]. In fact, even under more traditional self-administration paradigms, nicotine maintains more robust levels of responding when the drug deliveries are paired with a stimulus cue, such as a light [13]. However, one disadvantage of this approach is that it is often difficult to separate the reinforcing strength of the secondary reinforcer from that of the primary reinforcer.

Choice Procedures

Choice procedures are an increasingly popular tool for examining the reinforcing efficacy of drugs of abuse (for a review, see [8]). Early studies employing choice procedures showed that laboratory monkeys chose to self-administer a reinforcing drug over its vehicle [48]. The procedures used in choice experiments typically involve one of three types of experimental schedules: discrete trial schedules,

concurrent schedules, and concurrent chain schedules. With each of these schedules, animals choose among two or more options by responding on one of two or more levers. With choice procedures, the session typically begins with a sampling period during which the subject can respond to obtain each of the available reinforcer options (i.e., a low versus high dose of drug, drug versus saline, or drug versus some other reinforcer, such as food). The sampling period is then followed by a series of discrete trials or concurrent schedules during which the animals must complete the schedule requirement in order to obtain a drug delivery. Response allocation, rather than response frequency, provides a measure of the drug's reinforcing strength. This feature allows for the determination of reinforcing strength relative to behavior allocated toward an alternative reinforcer. As such, choice procedures are believed to mirror more directly the real-world situation where drug users allocate resources to obtain drugs rather than other non-drug reinforcers such as food and extracurricular activities. Indeed, most self-administration studies using drug-dependent humans have used choice procedures where subjects choose between drug deliveries and a non-drug alternative such as money (for a review, see [24]).

Studies have shown that laboratory animals not only choose drug over saline deliveries, but also prefer higher doses of drugs. For example, Carroll [17] conducted a study in which monkeys chose between a standard dose of phencyclidine (0.25 mg/kg) or one of several other doses that were concurrently available (0.06, 0.12, 0.50, or 1.00 mg/kg). Carroll found that subjects chose the large concentrations more often than the smaller ones. Similar results have been shown for a variety of other drugs including cocaine, remifentanil, methylphenidate, and pentobarbital [4, 45, 48, 52, 64]. Importantly, larger doses have been shown to be preferred over lower doses even under conditions where the behavioral disruptive effects of the drug are apparent (i.e., conditions that allow for access to the moderate-to-high drug doses with relatively short inter-dose intervals; [45]). One disadvantage with the choice procedure is that preference for high doses over lower ones has been more difficult to show in rats [58, 59].

Modeling Aspects of Addiction

The majority of the preclinical studies on addiction have used the traditional self-administration paradigm or other conditions that limit drug intake—that is, maintenance conditions that produce stable and relatively low levels of self-administration. As such, the behavioral and neurobiological principles defined by these studies may be restricted to drug reinforcement and not necessarily be characteristic of "addiction". Specifically, while the positive reinforcing effects of drugs are involved in addiction, particularly during initiation of drug use, other characteristics, such as loss of control over drug use and the resulting excessive use of the drug, as well as the negative reinforcing effects of drugs (i.e., use to alleviate withdrawal or craving), also appear to be critically involved. Newer methods have attempted to incorporate features of human drug addiction that are not represented in more traditional procedures. These methods have focused on addressing critical questions regarding addiction, such as: "Why do some individuals become addicted but not others?"; "What are the factors that influence the transition from controlled or causal use to compulsive use or addiction?", and "What are the factors that influence relapse or reinstatement to drug use?" The models that have been developed to address these questions are discussed below.

Individual Differences in Vulnerability to Addiction

The majority of people in the United States have used drugs, and if alcohol is included, users comprise over 90% of the population [82]. Although a substantial number of people do become addicted, addicts make up only a small

percentage of the total number of users. Thus, mere drug use does not inevitably lead to addiction. The reinforcing effects of a drug appear to be a primary determinant during initiation of drug self-administration. Clinical data suggest that a strong predictor of the development of drug addiction is the individual's "vulnerability" to the reinforcing effects of drugs. Retrospective reports from drug users reveal that the response to initial drug exposure varies from highly positive to negative [35], and some evidence suggests that individual differences in sensitivity to drug reinforcement are predictive of later use [25].

Consistent with the clinical findings, there is considerable variability in laboratory animals in their propensity to self-administer drugs. Animal models of the initiation or acquisition phase have been developed to identify biological and behavioral factors underlying individual differences in vulnerability to the reinforcing effects of drugs of abuse that may apply to prevention efforts in humans (for a review, see [15]). However, the acquisition phase is difficult to study because it is typically brief and is characterized by a sudden shift from low to high levels of intake. Thus, methods that slow the acquisition process and decrease intersubject variability are necessary to observe this transitory period. For example, acquisition of drug self-administration is optimally investigated in drug-naive and experimentally naive animals that are maintained under food-satiated conditions (e.g., food restriction serves as a stressor that can greatly accelerate the acquisition process and obscure individual differences) and tested under low dose conditions (e.g., high doses are associated with not only reinforcing effects but also direct effects and aversive effects that may interfere with responding). Under these conditions, individual differences are maximized, and some rats will acquire self-administration whereas others will not; the question that is addressed is: "Which animals can detect the reinforcing effects of this low drug dose?"

A simple method of evaluating acquisition is to give an animal access to a drug during a daily experimental session, with deliveries available contingent upon an operant response (i.e., lever press; e.g., [26]). Another method that has been used to investigate individual differences in acquisition of drug self-administration is an autoshaping procedure. This procedure was adapted to the study of the acquisition of drug self-administration [18] from methods used to study the acquisition of food-reinforced responding [12]. Daily sessions consist of six 1-h autoshaping components followed by a 6-h self-administration component. During each 1-h autoshaping component, rats receive computer-automated, response-noncontingent infusions delivered on a random interval schedule that are paired with light cues and lever retraction. During each 6-h self-administration component, the lever remains extended and each response will result in a drug infusion. With both procedures, acquisition of drug self-administration is measured as the number of sessions needed to reach a criterion level of intake, which can be standardized and adjusted for dose and drug availability. The ratio of active to inactive lever-press responses is often used in conjunction with the intake criteria. All of the animals are included in the analyses, whether or not they acquire self-administration, and the focus is on how rapidly this process takes place and what percentage of each group of animals acquires drug-reinforced responding.

These acquisition methods have revealed a number of organismic and physiological factors that predict vulnerability to drug self-administration, such as genetic strain [81, 86], impulsivity [70], exploratory behavior in a novel environment [26, 67], corticosterone levels [71], innate saccharin preference [41, 68], dopamine release in brain regions associated with drug reward [37, 38, 44], behavioral reactivity to stressors and to acute injections of drugs [27, 61], age [79], and sex [56]. For example, we used an autoshaping procedure to train male and female rats to lever press for either cocaine infusions (0.2 mg/kg) or heroin infusion (0.015 mg/kg) under a fixed-ratio 1 schedule (i.e., one response per infusion). Under these conditions, female rats acquired cocaine and

heroin self-administration at a faster rate than male rats, and a greater percentage of female rats acquired cocaine self-administration than did male rats [57].

Environmental factors, such as feeding condition, the presence of an alternative non-drug reinforcer, and drug history, can also greatly impact acquisition [20, 21]. For example, Childs et al. [21] examined the effects of chronic cocaine exposure on subsequent rates of acquisition of cocaine, using rats with a history of cocaine discrimination. They found that rates of acquisition of cocaine self-administration were more rapid in cocaine-exposed rats compared with non-cocaine-exposed rats. Rates of acquisition also vary widely as a function of drug dose, type of drug, and route of administration. Under high dose conditions with a drug such as cocaine that rapidly enters the brain after an intravenous infusion, most if not all animals will acquire self-administration rapidly. However, when lower doses of cocaine are used, or an oral route of administration is used, fewer animals will acquire and the rates of acquisition become much slower. Similarly, when drugs such as caffeine or alcohol that are considered to have a less intense or less rapid onset of action are used, the acquisition process is slowed. With oral administration, the taste of the drug can also influence the probability and rates of acquisition (e.g., the acquisition of oral alcohol self-administration is relatively slow because animals typically have an aversion to the taste of unsweetened alcohol).

Animal Models of "Addiction"

Two of the defining features of addiction in humans, loss of control over drug use and the resulting excessive use of the drug, have been modeled in animals using several different methods (for a review, see [75]). Early studies with monkeys and rats used unlimited access conditions (e.g., each response is reinforced under a fixed-ratio 1 schedule of reinforcement during 24-h sessions) and showed that, as in humans, patterns of self-administration in laboratory animals were characterized by dysregulated and binge patterns of use. For example, animals self-administering psychomotor stimulants such as cocaine, d-amphetamine, and methamphetamine demonstrated periods of erratic and rapid drug intake interspersed with periods of self-imposed abstinence [9, 28]. Excessive drug self-administration develops rapidly under these conditions, leading to severe toxicity and, in some cases, death. Toxicity appears to be particularly problematic for psychostimulant drugs and opiates, thus necessitating the use of procedures that limit access to these drugs in some way.

Recent studies have attempted to capture these features, excessive and dysregulated patterns of consumption, but without the serious signs of toxicity. For example, excessive drug intake with limited signs of toxicity has been observed under 24-h access conditions with low unit doses of drug [19] under continuous-access fixed-ratio self-administration conditions that limit the number of hours of access each day (i.e., 6–12 h daily; [1]) or each period of continuous access (i.e., 72 h; [85]). Another method that allows for extended access to cocaine with limited toxicity is a discrete trial procedure wherein animals are given 24-h access to cocaine infusions that are available in discrete 10-min trials [34]. With this method, excessive cocaine use is observed as access conditions increase. For example, under short-access conditions (1–2 discrete trials/h, 1.5 mg/kg/infusion), rats consumed low levels of cocaine and intake was relatively stable over time [74]. However, under extended access conditions (i.e., 4 discrete trials/h, 1.5 mg/kg/infusion), rats self-administered high levels of cocaine in "binge/abstinent" patterns, taking nearly every infusion available for the first 1–2 days, followed by periods of self-imposed drug abstinence that were interspersed with periods of active drug use. Importantly, increased motivation for cocaine [65], as well as increased cocaine-primed and cue-induced cocaine-seeking [50, 63, 76], other critical

features of cocaine addiction (as discussed below), are observed following extended-access self-administration when examined after an abstinence period. For example, in our previous work with rats, we found that 10 days of access to cocaine under the discrete trial procedure (4 trials/h) produced a sustained increase from baseline levels of progressive-ratio responding for cocaine when assessed following a 7-day abstinence period [65]. Similar results have recently been reported following extended access to self-administered heroin and methamphetamine using similar procedures [2, 76, 87].

Other drugs, such as nicotine and ethanol, typically can be available under unlimited-access conditions with limited toxicity, and results from studies with these types of drugs have also revealed "addiction-like" behavioral profiles. For example, Wolffgramm and Heyne [89] developed an animal model of this transitional phase for oral alcohol self-administration in rats. Their procedure entails long-term ad libitum self-administration (1–2 months) followed by an extended drug abstinence period (4–9 months). Subsequently, rats were retested on self-administration behavior, and those animals that developed escalating patterns of intake prior to abstinence self-administered higher levels of intake compared with rats that did not show escalation.

As discussed above, access conditions, drug dose, and the drug being self-administered are crucial factors for the observation of excessive and dysregulated patterns of consumption [1, 51, 58, 75]. Individual differences during this transition phase also have been reported. For example, females appear to require less drug exposure than males to display increased motivation for cocaine, due to levels of circulating ovarian hormones [53, 56]. Sweet preference and level of reactivity to novelty also appear to influence the appearance of drug escalation/dysregulation as well as motivational changes following extended-access self-administration [62, 69]. Notably, the underlying neurobiology associated with extended-access drug self-administration appears to be different from the neurobiology associated with short-access drug self-administration (e.g., [6, 7, 11, 33, 36, 84]).

Animal Models of Relapse

Relapse, or recurrent resumption of drug use after detoxification and abstinence, is one of the most challenging problems in the treatment of addiction [3]. Various types of stimuli can precipitate relapse, including internal cues such as re-exposure to small "priming" doses of the drug and external cues such as specific people and places that were associated with drug use. Often, external stimuli lead to drug use, and then the internal stimuli associated with drug use sustain relapse [10]. Animal models of relapse have been developed and have provided critical information on the neurobiological mechanisms underlying the vulnerability to relapse to drug abuse [55, 80].

One model that has been used to investigate mechanisms underlying relapse is the reinstatement paradigm [49]. With this procedure, animals are trained to self-administer a drug and, once stable, responding is extinguished by discontinuing drug delivery. After responding reaches come criterion of unresponsiveness, the ability of various stimuli to reinstate drug seeking is determined under conditions of non-reinforcement (i.e., responses are no longer reinforced by the drug). A stimulus is said to reinstate responding if it causes an increase in responding that was formerly reinforced by the drug. This sequence of events can occur once a day (e.g., [29, 30]) or several times per day [78]. The results from preclinical studies have revealed that the conditions that reinstate drug seeking in laboratory animals are similar to those that trigger relapse in humans, including small doses of the drug itself, cues associated with the drug, and exposure to stressors (for a review, see [49]), thereby demonstrating the predictive validity of this model. As such, the reinstatement paradigm can be useful for screening potential medications for relapse prevention in humans as

well as for studying factors influencing relapse to drug use.

In general, reinstatement studies have shown that drugs from the same pharmacological class as the self-administered drug, or drugs that share discriminative stimulus effects with the self-administered drug, act as effective priming agents to reinstate extinguished responding [29, 30]. Examination of environmental manipulations under conditions of maintenance and reinstatement in the same animals reveals a dissociation between these two states of behavior. For example, Comer et al. [23] examined the effect of food restriction on the maintenance and reinstatement of extinguished cocaine-reinforced responding using the relapse model in rats. They found that food restriction potentiated the effects of priming injections of cocaine. One interpretation of these results is that food restriction produces an increased motivational state that generalizes to drug-seeking behavior (reinforcer-interaction hypothesis; [23]). In contrast, food restriction did not affect responding for cocaine during the 2-h self-administration session. A dissociation of treatment effectiveness in the maintenance versus reinstatement phases also has been reported (e.g., [14]).

Results from reinstatement studies also have revealed a number of factors that predict a vulnerability during this phase, including responsiveness to the acute and chronic locomotor activating effects of psychostimulants (e.g., [32]), locomotor responses to novelty [83], pattern of drug intake prior to reinstatement testing [83], and sex [56]. Notably, there appear to be important interactions of cues used to trigger reinstatement responding and vulnerability factors. For example, while females show enhanced reinstatement responding compared with males following exposure to priming injections of a drug, males have been reported to respond at similar or higher levels following exposure to drug-associated cues [56]. Similar results have been reported in laboratory studies with drug-dependent men and women (for a review, see [60]), suggesting that vulnerability to relapse may be due to a complex interplay of environmental and biological factors.

Conclusions

Traditional self-administration procedures have firmly established that drugs of abuse function as reinforcers in animals. While the reinforcing effects of drugs are certainly important in the acquisition and maintenance of the addiction process, it is becoming increasingly apparent that other factors are involved. The shift to focusing on vulnerability factors for addiction and the use of models that mimic more closely characteristics of addiction in humans is likely to advance our ability to understand the key factors involved in addiction and, ultimately, identify potential pharmacological and environmental treatments.

Introduction

According to the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition—Text Revision* [7], drug dependence involves "…a pattern of repeated self-administration that can result in tolerance, withdrawal, and compulsive drug-taking behavior". The development of medications useful for the treatment of alcohol or drug dependence requires the clinical and preclinical testing of existing and novel compounds in various experimental models useful to evaluate the mechanism, safety, and possible efficacy of the putative treatment [113, 132, 178, 233]. Medication development research

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_7,

has sought to evaluate both existing medications already on the market for other indications as well as new, novel compounds never yet tested in humans. Regardless of the stage of development for any particular medication, experimental studies of human subjects in controlled laboratory environments (i.e., "human laboratory" studies) will be required at some step of the process for one of three possible reasons.

a) *Phase I Safety Testing of Novel Compounds*: For novel compounds not yet approved by the United States Food and Drug Administration, Phase I clinical trials will be required to evaluate the safety and abuse liability of the new medications. Basic safety testing in healthy subjects is normally required for first-in-man studies but basic Phase I safety testing approaches will be required in the drug-using target population as well before the Food and Drug Administration will allow Phase II and III treatment trials to proceed.
b) *Phase I, II Safety Testing in the Target Population*: If the medication is already approved by the Food and Drug Administration for another indication, development of that medication for addictions treatment still will require testing its safety in drug-using or addicted populations. Safety evaluation includes both the biomedical safety of treatment in a drug-using population but also an assessment of the abuse liability of the medication in a population likely to misuse substances. Additionally, the Food and Drug Administration likely will require these studies to address the safety of the drug interaction between the treatment medication and the drug of abuse.
c) *Evaluation of Pharmacokinetic and Pharmacodynamic Mechanisms*: Though Phase III treatment trials will be required to demonstrate efficacy, human laboratory studies also can be helpful to evaluate the clinical pharmacology (both kinetics and dynamics) of the medication. These studies can evaluate the possible behavioral or neurochemical mechanism(s) of action or use human laboratory models to estimate the possible efficacy of new medications.

For many human laboratory studies, subjects are research volunteers not engaged in treatment. However, individuals who are "in treatment" also may be tested under controlled human laboratory conditions. The purpose of this review is to identify and highlight the role of and contributions made by human laboratory studies in the development of new medication treatments for alcohol and drug dependence.

Pioneering studies conducted in the 1950s, 1960s, and 1970s at the Addiction Research Center of the Public Health Service Hospital in Lexington, Kentucky developed the basic experimental approaches useful to understand the clinical pharmacology of alcohol and drug dependence, and their treatment [59–61, 153]. Because studies of addiction require an understanding of the clinical effects of drugs of abuse and how these drugs promote or maintain drug-taking behaviors, even the earliest of studies involved the administration of drugs of abuse to subjects with histories of drug abuse and dependence. The National Advisory Council on Drug Abuse has recommended guidelines for the ethical and safe study of drugs given to human subjects (http://www.drugabuse.gov/Funding/HSGuide.html) [50, 51, 161] and human laboratory methods and approaches for these studies have been well established. Broadly speaking, pharmacological approaches to the study of the behavioral effects of drug abuse and its treatment are characterized under the umbrella of abuse liability assessment [10, 11, 69]. Abuse liability assessment involves estimation of the *likelihood* that a substance will be used or self-administered and/or the *liability or harmfulness* of that use [193, 198]. Thus, abuse liability assessment approaches to human laboratory studies encompass all aspects necessary to evaluate both the safety (i.e., *abuse liability* of the treatment agent and the *harmfulness* of the drug interaction) and possible efficacy (i.e., does it reduce the *likelihood* of using the drug of abuse) of medications useful to treat alcohol and drug dependence. The current chapter

is designed to highlight how human laboratory studies have or have not contributed towards understanding and developing medication treatments for addiction. We will focus on studies done with opiate, alcohol, and stimulant dependence where the bulk of this work has been done.

Role of the Human Laboratory to Evaluate the Abuse Liability of New Medications

When medications are developed for human use, the Food and Drug Administration or Drug Enforcement Administration may require an assessment of the abuse potential of the new agent and this generally will require human laboratory studies [10, 69, 149]. Typically, abuse liability assessment will be required when the medication under development shares pharmacological characteristics or planned indications with other drugs of known abuse potential. Broadly speaking, the abuse liability of a potential medication can be characterized in the human laboratory using one or more of three different behavioral approaches as described below.

To Characterize Adverse or Harmful Effects

Characterizing the effects of a new drug on various dimensions of physiological function and performance or other behavioral impairment, can be valuable to understand how the drug might alter or impair important biobehavioral functions [193]. For example, drugs could be examined for how they alter cognitive, psychomotor, or other behavioral performance [33, 34, 96] or physiological functioning [104, 105, 153]. Characterization of drug effects on each of these dimensions provides valuable information to assess the potential *liability* or *harm* that can occur with drug use. For the development of any new medication, awareness of these potential effects is important to assess the safety of the medication. In the context of drug abuse, it also is important to know about the safety of the drug interaction should the new medication be combined with the drug of abuse. For this reason, many studies have been devoted to assessing the potential interactions between the new medication and alcohol—the most common drug for which potentially dangerous interactions might occur [4, 5]. The safety of drug interactions also is very important for Food and Drug Administration approval of potential treatments for alcohol or drug addiction since it is very likely that drug-dependent populations undergoing treatment with a medication will at some point at least sample their primary drug of dependence. In many National Institute on Drug Abuse-sponsored Phase I clinical trials for stimulant dependence, the safety of the drug interaction on cardiovascular toxicity has been a primary concern to be addressed in these studies. Furthermore, the characterization of the drug interaction in the experimental laboratory may provide insight into the mechanism and possible effectiveness of that medication.

To Characterize Its Comparative Pharmacological Profile

The most common approach of abuse liability assessment is the pharmacological bioassay, which is a standard evaluation of the clinical and pharmacological profile of the new drug in comparison with another known drug from the same or similar pharmacological class [10, 69, 198, 209]. Necessarily, pharmacological profiling means evaluating the pharmacodynamic effects of the drug on a variety of dimensions which could include assessment of performance or physiological effects, but for abuse liability also includes assessment of subjective effects or euphoria. An adequate evaluation of pharmacological profile requires the testing of a range of doses to construct a dose-response curve because the testing of a single dose loses an understanding of the dose-responsiveness of observed effects and is fraught with the potential for

false negative findings. Because drug abusers are likely to consume supra-therapeutic doses of a marketed medication, its true potential for abuse cannot be known without testing doses that are at the higher end of the dose-response curve. Comparison of the new drug with a standard drug of known abuse potential is an essential element in the pharmacological comparison approach for at least three reasons. First, use of the standard drug establishes the positive control level of response to drugs of abuse under the standard conditions employed by the experiment. This is particularly important given that false positive or negative results may occur due to variations in the assessments, population, or other study conditions. Second, relative potency or relative effect size comparisons between the novel drug and the standard drug of abuse provide the basis for the most meaningful interpretation of data. Thus, the new drug may differ in the dose-response slope, the maximum effect size, or the relative potency on different dimensions of effect. Each of these variables has a different implication for abuse liability. Third, for clinical advantage estimation purposes, the Food and Drug Administration and medical prescribers would like to know about the differential efficacy contrast of the new drug in comparison with a known drug, which may be a standard drug of abuse or a scheduled prescription medication that has known abuse potential.

To Evaluate Its Reinforcing Effects or Potential for Self-Administration

Numerous animal models of addiction, studied across a wide variety of drugs and species have shown that drug taking is a drug-reinforced behavior controlled by operant contingencies and schedules of reinforcement [70, 201]. The same also has been shown in humans where several human laboratory models of drug reinforcement and self-administration have been established [28, 70, 91, 92, 219]. Ultimately, the behavior we are interested to understand, predict, and treat, is the likelihood that a drug/substance will be used or consumed in a pattern consistent with abuse or dependence. For a medication to be used in a substance-abusing population, we need to identify whether or not the medication has any potential for abuse in and of itself. A yes/no decision whether or not the drug is self-administered by the subject population may not be sufficient here because the environment and the availability of alternatives influence choice behavior. For example, the likelihood that a sedative or stimulant drug will be self-administered is influenced by how stimulating the experimental environment is [213, 221]. This phenomenon likely explains how even the sedating atypical antipsychotic quetiapine, with little apparent abuse liability, may become a highly preferred drug of abuse in a prison or psychiatric hospital environment where access to other drugs is limited [131, 227]. Therefore, an all-or-none conclusion of whether or not a drug is self-administered under one set of conditions doesn't indicate much about its potential for self-administration under a different set of circumstances. Thus, studies of the potential for reinforcement or self-administration are limited by the range of conditions (dose, circumstance, population, etc.) under which they are tested [69, 198, 209].

Issues in Human Laboratory Studies of Abuse Liability

There are several issues which need to be considered by any human laboratory study of abuse liability. Information below summarizes the issues that generally exist in the field and potentially limit any conclusions coming from human laboratory studies of medication effects on drugs of abuse.

Role of Subjective Effects

Ever since the earliest studies at the addiction research unit at the United States Public Health Service Hospital at Lexington, Kentucky,

it has been observed that drugs of abuse as diverse as alcohol, barbiturates, opiates, and psychomotor stimulants all share a profile of psychoactive effects characterized as euphoria [49, 188, 191]. It is generally accepted that euphoria is at least a partial explanation of why these drugs are abused. Because of the subjective and unobservable nature of this psychoactivity, self-report questionnaires are used to assess these subjective effects. One of the early questionnaires developed to measure the subjective effects of drugs of abuse was the Addiction Research Center Inventory. The Addiction Research Center Inventory is a multi-item questionnaire completed by human subjects during drug intoxication [76]. Factor analysis was used to empirically derive subscales of items responsive to characteristic drugs of abuse including amphetamine, benzedrine, morphine, pentobarbital, alcohol, chlorpromazine, and lysergic acid diethylamide. Subsequently [59], the morphine-benzedrine groups were combined to represent an opiate or stimulant-type of "euphoria" scale, the pentobarbital-chlorpromazine-alcohol group a distinctly "sedative" scale, and the lysergic acid diethylamide scale as a "dysphoria" or unpleasantness scale. It is important to recognize that these scales actually were derived to measure subjective mood changes induced by pharmacologically distinct drugs of intoxication and not euphoria *per se*. Therefore, while the morphine-benzedrine scale is called a "euphoria" scale, it really measures morphine and benzedrine intoxication, and is not sensitive to sedative euphoria [59, 69, 198]. The Profile of Mood States [158] is a multi-item questionnaire derived in the measurement of mood in normal healthy college students. Nonetheless, it has been used commonly to measure changes in depression-dejection, tension-anxiety, vigor, arousal, and other mood states by various populations under the influence of drugs [35, 48, 49, 247]. Generalized mood measures are valuable to assess the pharmacological profile of a drug and are sometimes presumed to predict abuse potential under the assumption that positive mood states could reflect an increased potential while negative mood states could reflect a decreased potential. In alcoholism research, the biphasic alcohol effects scale [151] was derived to measure the positive and disinhibiting arousal that may occur during the ascending limb of the blood-alcohol curve and the sedative-inhibition that occurs on the descending limb of the curve. Actually, there are many other factor-analyzed and single item rating scales that have been used to evaluate the subjective effects of psychoactive drugs and enumerating them is beyond the scope of this review.

The psychoactive effects of psychotropic drugs are studied in animal subjects using discriminative stimulus procedures where subjects are trained to discriminate the differences between drugs. Discriminative stimulus procedures also have been developed to train human subjects to discriminate the interoceptive stimulus effects of drugs [43, 107, 187, 191, 222]. While subjective rating scales take advantage of the verbal capacity of human subjects to quantitatively report the qualitative characteristics of their subjective experience, the discriminative stimulus approach uses a qualitative analysis of same/different comparisons between drugs. There is reasonable correspondence between conclusions drawn from subjective effects and those from discriminative stimulus studies in humans [43, 191, 222]. Because of differential reinforcement of behavior during discriminative training, it is likely possible to gain a tighter level of discriminative control with this paradigm than with standard subjective questionnaires. However, the specificity and sensitivity of this procedure very much depends upon the discrimination training conditions [108] and are achieved only through lengthy training procedures. Nonetheless, the ability to compare the human study results with the preclinical data using discriminative stimulus analyses is a distinct advantage of this procedure [43, 107].

Clearly, a description of subjective mood states induced by drugs is part of a thorough characterization of pharmacological effects in humans [10, 69, 198]. The question of some debate is whether or not treatment-related changes in discriminative or subjective effects predict a change in the likelihood of

drug taking [28, 52, 53]. Although there is a good correspondence been "positive" subjective effects and the likelihood of drug self-administration, it is certainly not true that either positive or negative subjective effects alone explain the cause or the reason why drugs are or are not self-administered.

Role of Subjective Euphoria

The cardinal subjective effect commonly assumed to be important to abuse potential is the experience of psychoactive drug effects which are pleasant, preferred, or "euphoric". A number of reviews of human abuse liability have discussed issues of drug-induced subjective euphoria and its measurement [49, 52, 53, 69, 188, 191, 198]. Actually, most drug users do not refer to "euphoria" but rather describe the drug intoxication as a "high". Though cocaine intoxication has been described as "intensely stimulating and pleasurable", or "orgasmic", it is clear that not all drugs of abuse produce such intense pleasurable sensations. For many drugs including alcohol, the intoxication is more often described as a "buzz", or "drunk", or "high" that has "good" features and that people report "liking". Consequently, most studies employ individual item rating scales for subjects to rate the extent of "high" and "good" subjective effects and the extent to which subjects "like" the effect. There is no standard euphoria scale used by a majority of studies. Though the Addiction Research Center Inventory-morphine-benzedrine scale has been described as a general euphoria scale it really is only validated for opiate and stimulant drugs and usually is not responsive to sedative drugs of abuse. Likewise, the Profile of Mood States "elation" scale has been used as a general euphoric mood scale, but its sensitivity as a general measure of drug-induced euphoria has not been established. In fact, it is likely that the soporific and disinhibited state of sedative euphoria is inherently different than the exhilarated and aroused state of stimulant-induced euphoria.

Importance of Measuring Self-Administration Behavior

There have been controversies over the definitions and value of terms such as use, misuse, abuse, addiction, tolerance, withdrawal, craving, etc., and their importance as "explanations" of alcoholism or drug dependence. Current conceptions of the disease condition recognize that the core feature of substance abuse or dependence is the pattern of drug self-administration that is considered by society as harmful or compulsive [7, 178]. Consequently, most studies of abuse liability seek primarily to predict the *likelihood* of drug self-use for non-medical purposes. Though studies of subjective euphoria may have some predictive correlation with drug-taking behavior, it is important to directly study the self-administration of drugs as the cardinal symptom of substance abuse or dependence. Ample previous research clearly has demonstrated that drugs of abuse maintain the self-administration behavior of both humans and animals through the process of operant reinforcement. Ever since the earliest studies at the Addiction Research Center observing heroin self-administration in a heroin addict [248], a variety of different procedures have been developed to study self-administration behavior in human laboratory environments and these have been described in previous reviews [28, 70, 83, 90, 92, 201, 219]. These reviews describe the effects of variations in self-administration procedures such as:

a) the specific drug reinforcer, its route of administration, and whether or not dose was varied (higher doses and more rapid increases in blood level are more reinforcing);
b) whether the drug reinforcer was administered immediately or after a time delay (immediate drug delivery is more reinforcing);
c) whether the self-administered dose was a high bolus dose or multiple smaller doses (multiple smaller doses result in more sensitive measures of reinforcement);
d) whether or not the drug reinforcer was "blinded" and placebo controls were

employed (blinded procedures have greater validity);
e) whether the self-administration behavior was a verbal request or responses on a response instrument (responses on a manipulanda provide quantitative measures of behavior);
f) the extent to which behavioral "cost" was varied in the operant contingency (increasing "cost" decreases the probability of self-administration);
g) whether the self-administration procedure included choices among alternative reinforcers (choice between alternatives provides a better quantitative assessment of relative reinforcement); and
h) whether drug taking was quantified by measuring amount consumed vs. the proportion of subjects responding (amount measures are more sensitive measures).

Thus validated operant models of drug reinforcement have been established for human laboratory studies, and these have become increasingly used over the last two decades. Although pleasant subjective effects generally are correlated with the tendency of subjects to self-administer drugs in the human laboratory [25, 35, 70, 109, 110, 191, 198] drug-taking behavior does occur in the absence of measurable subjective effects [141, 197]. At times, the needs to examine complete dose-response functions in making between-drug pharmacological comparisons [69] may preclude self-administration studies [198]. Nonetheless, direct observations of drug-taking behavior generally are preferred over measures of subjective effects alone [28].

Role of Environment and Cost in Controlling Self-Administration

Although this review will not discuss specific advantages and disadvantages of different self-administration procedures, variations in the procedure are likely to alter the sensitivity to change of the drug-taking measure [219]. In fact these procedural variables are likely to be important both in determining whether or not the drug is self-administered, as well as the sensitivity to change to show increases or decreases in drug-taking behavior. One of the variables that importantly influences drug-taking behavior is the role of the internal or external stimulus environment and how that can increase or decrease the likelihood of self-use. For example, diazepam is not normally preferred by healthy controls [109] but preference increases under environmental conditions which increase anxiety [90]. Also, sedative drugs are preferred over stimulants in sedentary environments while stimulants are preferred over sedatives when task performance contingencies require alertness [213, 221]. The reason that a stimulating environment may decrease the reinforcing effects of a sedative but enhance the reinforcing effects of a stimulant probably is related to behavioral cost and alternative reinforcement [201, 219]. Understanding this phenomenon involves recognition of the behavioral economics of drug taking [14, 15]. In behavioral economics, choice of the drug involves a behavioral cost and may occur at the expense of access to alternative reinforcers. In human laboratory studies, it is common to make monetary choices available as an alternative to drug taking [30, 94, 160, 219] wherein choices between increasing amounts of money vs. drug result in reductions of drug self-administration. Griffiths and colleagues [72, 73] exploited this phenomenon in creating the "Multiple Choice Procedure", which is a questionnaire wherein across a series of single-item questions, subjects choose between receiving the drug or a gradually increasing amount of money. In order to establish the questionnaire responses as a true measure of choice/preference for drug, one of the many item questions is selected at random and the subjects actually receive as a consequence, the drug or the money amount they selected for that item.

Role of Subject Population Variables

One of the issues associated with subjective effects assessment, is that the extent to which

subjective psychoactivity is considered pleasurable or "euphoric" varies across different populations and is shaped and influenced by experience. For example, early studies by Beecher [12] showed that normal healthy volunteers reported unpleasant experiences when given opiates or barbiturates while drug-experienced users reported those drug effects to be pleasant or euphoric. Balanced placebo research designs controlling subject expectations with 2 × 2 factorial experiments where subjects were either told or not told they are receiving drug under conditions where they actually did or did not receive drug have shown that the subjective reports of drug effects in normal populations are substantially influenced by expectation [157]. Of course expectations occur in drug-dependent populations as well. Compared with normal drinkers, heavy alcohol drinkers report greater expectations of euphoric responses and other positive or beneficial effects of alcohol [21, 31]. It is likely that some of the differences between drug-experienced and naive populations are due to learned or acquired factors altering attribution or expectation. For example, the itching, flushing, and nauseating effects of opiate analgesics is unpleasant to most people, but narcotic addicts call these signs a "pleasant sickness" associated with "good stuff". Thus, associative experience may condition drug users to "like" the effects of drugs of abuse and report euphoric "highs" in response. Generally, normal subject populations, who do not abuse drugs, do not report higher levels of liking drug effects or do not experience euphoric mood changes, or self-administer most drugs of abuse [69, 109, 110, 198, 209]. Strong evidence for the importance of drug abuse history and experience is seen in patient-controlled analgesia studies where opiate analgesics with known addiction potential can be given for medically ill populations to self-administer and yet those without a substance abuse history do not become drug abusers or addicts [95, 246]. Therefore, valid assessment of abuse liability must employ drug-experienced abuser populations in order to gauge what drug abusers will do with a drug of abuse [69, 198, 209]. This is not to say that certain drugs may not have some abuse liability even for normal healthy populations. In fact, studies of stimulant abuse liability [52, 53] among normal college populations observe that amphetamines tend to be preferred over placebo while sedative benzodiazepines are not preferred [35, 109, 110]. Of course, caffeine clearly has reinforcing properties in healthy human populations worldwide [71]. For these reasons, valid inferences about relative changes in abuse liability have to include experimental controls showing base response rates of the study population and study procedures as a point of comparison [69, 198, 209]. For pharmacological studies comparing across drugs, the comparison drug may show greater or less abuse liability than a standard reference drug in the designated population under standard study conditions.

Population-related differences in drug response could be due in part, to genetically controlled individual differences in innate sensitivity [154]. An example of this is found in Asians populations who commonly have the ALDH2*2 allele for aldehyde dehydrogenase which increases levels of the ethanol metabolite acetylaldehyde, resulting in an unpleasant flushing response which reduces the risks of experiencing alcohol-induced euphoria [236, 238]. Another example of this may be found in studies of the children of alcoholic parents where young adult children of alcoholic parents may report greater euphoric response and lesser negative, sedative effects of alcohol than do children without a family history of alcoholism [212].

Role of Craving

Many addicted individuals report that stimulus cues in the environment elicit powerful "cravings" and impulses to use drugs [40, 176, 177]. However, there has been much debate about the meaning of the term "craving" and what role it plays in the risk of drug use [186, 229]. Early pioneering work in the human

laboratory considered craving as a conditioned-withdrawal-like motivational state [249, 250]. With the operant model of drug dependence, it has been argued that "craving" primarily refers to the urge or impulse to use [137]. Still others suggest that craving involves at least three dimensions: (1) withdrawal and negative affect-related escape motivation, (2) reward-related conditioned impulses/urges, and (3) obsessive thoughts and/or cognitive-control mechanisms [41, 229]. Many human laboratory studies have studied cue-induced craving in addicted populations (cf. [24, 41, 176, 177]). These studies provide visual, olfactory, auditory, and/or tactile stimuli historically associated with drug use; though tactile cue procedures of handling drug paraphernalia have been among the most effective stimulus cues [8, 203]. Idiosyncratic script-driven mental imagery techniques also can be used to guide the cue exposure session [215, 216]. Cue responses can be physiological (of which heart rate is the most reliable) or subjective (of which craving is the most reliable) though there often is not a good correlation between the physiological and subjective craving measures [202]. A meta-analysis of the literature [24] concluded that subject ratings of craving were the most reliable and selective reaction to drug cues and showed the largest effect size across studies. Multi-item factor scales have been used in the human laboratory to measure craving for alcohol [17, 210], marijuana [89], or cocaine [78] but many studies commonly use only graded analog scales of single item ratings such as "crave" [103], "desire" [37], "urge", or "want" [52, 53, 244]. Craving ratings sometimes have been correlated with drug use in outpatient studies [88]. However, dissociation between craving ratings and drug-taking behavior have been demonstrated clearly in laboratory studies [42, 81, 142, 186] and the extent of cue-craving observed in the laboratory has not correlated with relapse to alcohol drinking among alcoholics [205]. Thus, craving is neither a necessary nor sufficient precursor to drug use or relapse. Rather, it appears to reflect a parallel cognitive process as proposed by Tiffany [228, 229] or a subjective state experienced as urge or impulse that is associated with drug-related environmental stimuli as suggested by a consensus panel [186]. In either case, "craving" is not a proxy for drug self-administration and may not always predict or be correlated with drug-taking behavior.

Human Laboratory Studies of Pharmacological Agonists and Antagonist Treatments

Human laboratory studies have been useful to help us understand the potential value of various pharmacological approaches to treatment. The potential of using pharmacological agonists or antagonists in the treatment of substance abuse is best illustrated through studies of opiate dependence as described below.

Utility to Evaluate Pharmacological Antagonist Treatments

Early studies of opiate antagonists at the Addiction Research Center showed that they could completely block the subjective and physiological effects of morphine [60, 105, 152] and precipitate withdrawal in dependent individuals [104, 105]. Subsequent studies showed that oral naltrexone [2, 160] blocked heroin self-administration and subjective effects in human laboratory models of drug taking. The robustness of the observed pharmacological antagonism and the nearly complete blockade of any behavioral effects or abuse liability of heroin observed in these studies strongly suggested efficacy for the antagonist approach. However, as we now know, outpatient treatment effectiveness with antagonists like naltrexone is poor [134] because of poor medication compliance among heroin addicts who find it too easy to discontinue antagonist therapy so as to recover the heroin effect they seek. These findings suggest a significant weakness of human laboratory procedures to predict efficacy with antagonist approaches.

Specifically, even perfect blockade of abuse potential does not predict treatment efficacy because medication non-compliance will nullify even complete pharmacological blockade. More recently, human laboratory studies again have evaluated the depot formulation of naltrexone [29, 224] and shown that it will block heroin self-administration and subjective effects. Although there is reason to hope that depot formulations of naltrexone could improve the effectiveness of antagonist treatments, especially in conjunction with court-ordered treatment [183], the outcome data do not yet exist to support it [145]. Notably, because of the diffuse mechanisms of action for alcohol, cocaine, and methamphetamine, direct, receptor-medicated pharmacological antagonists are unlikely to exist for those drugs. For nicotine dependence, human laboratory studies of the nicotinic antagonist mecamylamine have shown increased smoking [169] or increased intravenous nicotine self-administration [207] which is consistent with a surmountable pharmacological blockade. However, another human laboratory study found no effect of mecamylamine [245], and clinically, there is no evidence for treatment efficacy with nicotinic antagonists [22] in outpatient treatment. No efficacy trial has examined the use of the cannabinoid-1 antagonist, anandimide (rimonabant), for cannabis dependence, but early human laboratory studies have shown only partial or inconsistent blockade of the effects of smoked cannabis [98].

Utility to Evaluate Pharmacological Agonist Replacement Approaches

A study at the Addiction Research Center [128] was the first human laboratory study showing that oral methadone produced dose-related decreases in the subjective effects, liking, and self-administration of hydromorphone. Thirty years later, a human laboratory study showed that short-term treatment with methadone doses of 50, 100, and 150 mg showed dose-related blockade of the subjective effects and self-administration of heroin [38]. The authors of this later study used their human laboratory data to argue that clinical tendencies to use lower methadone doses for maintenance are counterproductive. Importantly, these findings exactly parallel the dose equivalence and clinical experience with methadone maintenance treatment [223]. Previous reviews [16, 104, 188] have described human abuse liability testing with a variety of opiate agonists, partial agonists, and mixed agonists/antagonists which demonstrated unequivocally that agonist effects at the mu opiate receptor are responsible for the abuse potential of opiates. In the course of this work, human laboratory studies were critical to the ultimate development of buprenorphine as a partial agonist pharmacotherapy, with a reduced abuse potential [28, 106, 240]. Human laboratory studies were particularly important to demonstrate buprenorphine reduced the reinforcing effects heroin [159] and to demonstrate that small doses of naloxone could be added to buprenorphine to further reduce its abuse potential without precipitating withdrawal in morphine-dependent subjects [162]. These studies illustrate very clearly, a strong concordance between the human laboratory studies and clinical experience with buprenorphine. Furthermore, when compared with the studies and clinical experience with antagonist medications, they suggest that human laboratory studies seeking to antagonize the reinforcing effects of a drug of abuse might look for medications that have at least a partial agonist-like activity. Of course, nicotine replacement strategies for tobacco dependence have been very successful [22] to reduce smoking behavior. Human laboratory studies have shown that smoking [185] and nicotine gum [170] pretreatments each decreased cigarette smoking. Also, transdermal nicotine patches decreased cue-induced craving [230], the discriminative stimulus and reinforcing effects of nicotine spray [184], and reinforcing effects of intravenous nicotine [217]. The partial nicotinic agonist, varenicline, is the first non-nicotine treatment for tobacco dependence approved by the Food and Drug Administration [232], though human laboratory studies evaluating its ability to decrease nicotine reinforcement have not been conducted.

Role of Human Laboratory Studies in Developing Medications for Alcohol Dependence

A brief review of medications which have been or are being developed for alcoholism treatment will be used to illustrate how pharmacological mechanisms other than agonist replacement or direct pharmacological antagonism of the drug of abuse can be exploited in medications development. Currently, there are three medications approved by the Food and Drug Administration for the treatment of alcohol dependence. Additionally, we will discuss human laboratory studies conducted with three other medications which have shown promise in clinical treatment trials.

Disulfiram

Disulfiram (Antabuse®) was the first medication approved by the United States Food and Drug Administration for the treatment of addiction. Human laboratory studies as well as preclinical studies of biochemistry and toxicology were included in the first report of the disulfiram-ethanol reaction which ensues upon alcohol exposure [77]. Over a period of more than 40 years, human laboratory studies have been important to characterize the nature, the safety, and the mechanism of the Antabuse®-alcohol reaction [26, 111, 192, 208]. These studies were instrumental in showing that inhibition of aldehyde dehydrogenase and the subsequent accumulation of the acetylaldehyde metabolite is responsible for the unpleasant effects of the Antabuse® reaction and that a hypotensive crisis is a serious medical risk. Either because of the way the disulfiram makes alcohol effects so unpleasant or because of the direct side effects of disulfiram itself, compliance with this medication is a serious problem limiting its utility and effectiveness for the treatment of alcohol dependence [20, 140]. Consequently, there is little ongoing research in further development of disulfiram as a treatment for alcohol dependence.

Naltrexone

The opiate antagonist, naltrexone was the second medication approved by the Food and Drug Administration for the treatment of alcohol dependence. Based largely upon preclinical studies showing that naltrexone reduced alcohol drinking in rodents, the first clinical trials [180, 235] were Phase III outpatient efficacy trials of a medication that had already been approved for narcotic addiction. Subsequently, human laboratory studies have been useful to demonstrate that naltrexone can reduce alcohol self-administration in some paradigms [40, 181] but not others [39] and has a mixed profile to reduce some of alcohol's positive subjective effects [133, 226] and cue-reactive craving [33, 164, 181, 204]. Naltrexone also has been shown to reduce the behavioral activating effects of alcohol as measured by heart rate increases, subjective liking, and ACTH/Cortisol elevations [156]. This latter finding is interesting given that other studies have shown that parental family histories of alcoholism are associated with greater activation of the hypothalamic-pituitary-adrenal axis at baseline and in response to mu-opioid receptor blockade by naloxone [93] and that these differences may predict naltrexone response [133, 181]. Recently, a study administered naltrexone vs. placebo to 92 non-treatment-seeking, alcohol-dependent subjects for 6 outpatient days before bringing them into the human laboratory for a drink self-administration session [139]. Study findings showed that naltrexone reduced alcohol self-administration in subjects with a positive family history of alcoholism and may actually have increased drinking in subjects without a family history. Though the genes associated with family history are not known, an earlier laboratory study identified a single nucleotide polymorphism of the mu-receptor conferring naloxone-reactive hypothalamic-pituitary-adrenal activation [243] and this same polymorphism recently was shown to predict naltrexone treatment response in Project COMBINE [6]. Overall, these human laboratory studies have shown results consistent

with the outpatient treatment trials concluding that naltrexone is modestly effective to reduce some of the reinforcing but not the subjective effects of alcohol and that this action may block the alcohol-seeking or craving that is primed or cued by the initial doses of alcohol consumed during a binge. Intriguingly, human laboratory studies of the functioning of the hypothalamic-pituitary-adrenal axis may lead to a better understanding of the inherited biologic risk of alcohol dependence and treatment responsiveness with medications such as naltrexone.

Acamprosate

Based largely upon three European treatment trials [138], the Food and Drug Administration approved the glutamate antagonist acamprosate, as the third medication for the treatment of alcohol dependence. Prior to that approval, a human laboratory study examined the safety of the combination of acamprosate with naltrexone in alcohol-dependent subjects [119] as a prelude to the larger outpatient treatment trial known as Project COMBINE which tested the efficacy of acamprosate and naltrexone alone and in combination [6]. Although meta-analyses of several clinical trials have supported the efficacy of acamprosate at preventing relapse in alcohol-dependent individuals [138, 148], Project COMBINE did not demonstrate efficacy at reducing drinking in alcohol-dependent outpatients. Despite a large preclinical literature examining acamprosate's actions and mechanisms [36], only two human laboratory studies have been reported. One study found that acamprosate reduced the heart rate response, but not the subjective craving induced by alcohol cues [182]. Another study administered repeated doses of acamprosate to non-treatment-seeking heavy drinkers in an outpatient setting and brought the subjects into a human laboratory where acamprosate was without effect to alter the subjective or behavioral responses to challenge doses of alcohol [18].

Other Possible Medications for Alcohol Dependence

Two other medications have been reported to have efficacy in the outpatient treatment of alcohol dependence and to be examined in human laboratory studies evaluating possible mechanisms. The serotonin-3 antagonist ondansetron was initially reported to reduce the subjective effects of ethanol in social drinkers [117, 225]. Subsequently, a large clinical trial showed efficacy of ondansetron to reduce alcoholic drinking, at least in Early Onset Alcoholics, but not Late Onset Alcoholics [125]. Serotonergic abnormalities in "biologically predisposed" individuals have been suggested as the mechanism of this differential efficacy [112]. A subsequent human laboratory study reported that the alcohol cue-induced craving of early onset alcoholics may differ as a function of genetic polymorphisms in the serotonin transporter [1]. Topiramate, an anticonvulsant with gamma-aminobutyric acid agonist and glutamate antagonist activity, has been shown to have efficacy to reduce drinking in alcohol-dependent outpatients in two randomized controlled trials [114, 126]. After the initial treatment study evidenced efficacy, a large sample ($n = 61$) human laboratory study was designed to evaluate whether or not these effects of topiramate were due to reductions in craving induced by alcohol cues [163]. In order to reduce some of the adverse cognitive side effects of topiramate, the study included a gradual dose-escalation period of more than 5 weeks where of subjects received placebo, 200, or 300 mg per day during outpatient treatment before they were brought into the laboratory. Interestingly, there was no evidence for topiramate to reduce cue-induced craving in the laboratory. However, investigators did observe that these non-treatment seeking heavy drinkers reported topiramate-related reductions in their drinking during the outpatient dose-run up phase. Though it may be true that topiramate does not block craving in response to alcohol cues, the findings of drinking reductions during the outpatient dose loading procedure are

consistent with the treatment trials. This finding further supports the idea that cue-reactive craving is not well correlated with self-administration behavior.

Hutchinson and colleagues have been studying olanzapine in the human laboratory and in the clinic as a medication having a mixed profile of actions as an antagonist at the D_2, D_4, and serotonin-2 receptors. An initial laboratory study of heavy social drinkers reported that 5 mg olanzapine reduced the urge to drink after exposure to alcohol cues and a priming dose of alcohol [100]. However, a treatment trial in alcohol-dependent outpatients failed to show efficacy of 10–15 mg olanzapine [74]. Subsequently, another laboratory study [99] showed that a functional polymorphism in the dopamine D_4 receptor (DRD4) gene mediates the cue-reactive effects of alcohol and that olanzapine really was only effective to reduce cue-reactivity [102] in the subgroup of subjects having the long (L) form of the variable number tandem repeat for the DRD4 gene. Finally, this investigative group studied a group of alcohol-dependent subjects given 2.5–5 mg olanzapine vs. placebo during a 12-week treatment trial [101]. These subjects were brought into the human laboratory before and after 2 weeks of double-blind treatment and were tested in the cue-reactivity paradigm. The study showed that olanzapine was effective only in the L-carriers where it reduced cue-reactive craving observed in the laboratory and also was effective to reduce alcohol drinking in the outpatient treatment component of the study.

Role of the Human Laboratory to Evaluate Medications for Cocaine Dependence

At least partly because of lack of interest from major pharmaceutical manufacturers, the National Institute on Drug Abuse has maintained an active Medications Development Program [45, 233, 234] which has included Phase I, II, and III clinical trials directed to evaluate and possibly develop medications to treat cocaine and methamphetamine dependence. Through research funded mostly by the National Institute on Drug Abuse, many different potential medications with a variety of different pharmacological mechanisms have been tested in Phase II and III efficacy trials looking for a medication to treatment cocaine dependence. Several recent reviews have described the different medications that have been evaluated for the treatment of cocaine dependence and so the reader is referred to those articles for further information [62, 65, 218, 234]. Although there have been some promising developments from these studies, no medications have yet been proven effective or approved by the Food and Drug Administration. Cocaine acts to inhibit monoamine transporters although the mechanism of action related to addiction is believed to be primarily through actions on the dopamine transporter to enhance dopamine activity in brain reward neurocircuitry. Consequently, many pharmacological studies have targeted dopamine synthesis, receptors, and the reuptake transporter. Additionally, other medications targeting other neurochemical modulators of the brain reward pathways also have been studied.

Evaluation of Dopamine Agonists and Antagonists for Cocaine Treatment

Several human laboratory studies have examined the ability of dopamine antagonists to reduce cocaine-induced subjective effects or self-administration. In cocaine-dependent individuals, haloperidol antagonized cue-elicited craving [13]. In subjects with cocaine abuse or dependence, risperidone [172] reduced the subjective effects of cocaine, but flupenthixol [47] had no effect on cocaine subjective effects or self-administration. Again, in subjects with cocaine abuse or dependence, the $D_{1/5}$ antagonist ecopipam reduced cocaine's subjective effects acutely [206]; however, these effects were not replicated in a study employing repeated ecopipam dosing [167] or in a study of smoked cocaine where ecopipam actually increased the subjective and reinforcing effects of cocaine [84]. These results suggest that at

best, dopamine antagonists produce variable and inconsistent reductions in positive subjective effects of cocaine. The overall conclusion from these and other studies do not support the utility of dopamine antagonist treatments [28, 65, 67, 234]. Furthermore, they suggest that direct and potentially unpleasant side effects of treatment with dopamine antagonists could actually enhance the reinforcing effects of cocaine which could explain the increase in cocaine use observed in an outpatient treatment study using olanzapine [130].

Human laboratory studies also have examined the effects of direct acting dopamine agonists. The D2 agonist, bromocriptine was shown to reduce the blood pressure elevations but enhance the heart rate effects of cocaine and it caused undesirable "fainting" without changing cocaine's subjective effects [190]. Another D2 agonist, pergolide [81] reduced the subjective effects but did not alter cocaine self-administration. The D1 agonist ABT-431 was reported also to reduce the subjective effects and blood pressure but enhance the heart rate effects of cocaine without altering cocaine self-administration [80]. Two dopamine partial agonists also have been examined. Amantidine had no effect on the cardiovascular or subjective effects of cocaine or on cocaine self-administration [27] and aripiprazole was actually reported to increase cocaine subjective effects [144] and self-administration [82]. Though not acting directly upon the dopamine receptor, but rather indirectly upon the dopamine transporter, bupropion was found only to produce slight alterations in cocaine-related subjective effects [179]. The general lack of positive results in these human laboratory studies is consistent with the lack of efficacy of dopamine agonists, partial agonists, and bupropion in the outpatient treatment of cocaine dependence [65, 237].

Evaluation of Stimulant Replacement Strategies for Cocaine

In contrast to the disappointment with dopamine agonists and antagonist approaches, studies examining the use of psychomotor stimulants in a stimulant "replacement"-type of reproach [65, 67, 200] have been more encouraging. The basis for stimulant use is related to the clinical experience with opiate and tobacco dependence where harm-reducing pharmacological-replacement treatments have demonstrated efficacy. An intriguing 5-week inpatient human laboratory study showed that gradually increasing oral doses of cocaine (25–100 mg/kg 4 times daily) produced modest reductions in the subjective effects of intravenous challenge doses of cocaine without potentiating the cardiovascular effects of cocaine [241]. Previous human laboratory studies have shown that cocaine binges are associated with substantial "acute" tolerance where most of the subjective and cardiovascular effects of cocaine are seen with the initial dose and subsequent doses only serve to maintain the initial effect without adding additional effect [3, 54, 57, 58]. When combined with data that speed of onset is an important determinant of euphoria [168], the efficacy of the oral cocaine pretreatment is likely due to the lesser euphoria resulting from the oral pretreatment dose of cocaine coupled with cross-tolerance to the acute effects of the additional cocaine challenge doses. This is exactly analogous to what is believed to occur with methadone maintenance and is similar to that observed in a human laboratory study where experimenter-administered doses of heroin given on top of methadone pretreatment show diminished responses [38]. Nonetheless, concerns about the ethics or social acceptance of cocaine-replacement approaches for cocaine addiction are likely to limit consideration of this approach. Thus, most studies of the agonist-like replacement approach [65, 67, 200] have examined dopamine reuptake inhibitors and stimulant drugs other than cocaine. Although human laboratory studies with cocaine have reported substantial tolerance to the cardiovascular acceleration that occurs within a cocaine binge [54, 57, 58], there still are substantial cardiovascular safety concerns regarding the possible drug-drug interactions between cocaine and other stimulant drugs. Thus, human laboratory studies evaluating medications with possible

stimulant profiles must address the safety of this drug interaction. Actually, for any medication to be approved by the Food and Drug Administration for use in humans, Phase I and early Phase II safety testing including drug-drug interaction studies are required and human laboratory studies are required to achieve this end.

A double-blind, placebo-controlled efficacy trial examined the effects of placebo and two doses of oral dextroamphetamine as a treatment for cocaine-dependent outpatients [64]. That study included a human laboratory component which gave the outpatients their initial double-blind dose in a controlled environment as part of a safety assessment [200]. In the laboratory assessment component, dextroamphetamine showed characteristic stimulant effects including mild elevations of subjective effects and euphoria, and there were no limiting adverse events observed. Coupled with treatment findings showing dose-related increases in treatment retention and reduced cocaine use without evidence of abuse or diversion of dextroamphetamine, these data suggest stimulant therapy for cocaine dependence may be a reasonable approach. In another study taking the same approach with methylphenidate, the human laboratory component found that methylphenidate produced adverse stimulant effects but not subjective euphoria in the cocaine-dependent population [196]. Interestingly, methylphenidate also was not efficacious in the main outpatient treatment trial either [66]. Thus, these two studies, conducted in treatment-seeking individuals, show a good correspondence between the human laboratory findings and treatment outcome and further suggest that the positive subjective effects of dextroamphetamine may be an essential component of efficacy in the stimulant-replacement approach to treatment of cocaine dependence [65, 67, 200].

Still the question remains about the safety of the cocaine + stimulant drug interaction in cocaine-dependent populations. Several human laboratory studies have evaluated the cardiovascular safety and abuse liability of giving combinations of cocaine plus other stimulants. In one such study [189], acute dosing with mazindol did not substantially alter the acute subjective effects of cocaine, but it significantly enhanced the blood pressure and heart rate elevations produced by intravenous cocaine leading the authors to suggest that mazindol would not be a desirable treatment. A follow-up clinical treatment trial in cocaine-dependent methadone maintenance participants did not find mazindol vs. placebo differences in outcome [150] although, importantly, there was no evidence for harmful or counter-therapeutic effects of mazindol either. Another study gave up to 30 mg oral dextroamphetamine in combination with up to 96 mg intranasal cocaine to non-treatment seeking cocaine abusers and reported that there were no significant potentiating effects on cardiovascular measures [194, 195, 200]—a finding that generally was supported in the outpatient trial of dextroamphetamine for cocaine dependence [64]. In yet another study [32], modafinil blunted several subjective effects and even the systolic blood pressure increases produced by intravenous cocaine infusion. This human laboratory study was followed up by the National Institute on Drug Abuse in clinical treatment trial which found that modafinil was superior to placebo to reduce cocaine use among the subgroup of individuals without a comorbid alcohol use disorder, but it was not effective amongst the subgroup of individuals who had a comorbid alcohol use disorder [44]. Overall, these human laboratory data clearly predicted that stimulant medications with lesser abuse potential than cocaine could be given safely to cocaine-dependent populations with a reasonable expectation that individuals would benefit from a stimulant-replacement approach to treatment.

Evaluation of Cocaine Treatments Affecting Other Neurochemical Systems

A number of other pharmacological approaches to treatment for cocaine dependence also

have been evaluated in the human laboratory. Aside from dopamine, several studies have attempted to alter other monoamine neurotransmitter levels (i.e., norepineprine and serotonin). Catecholamine depletion by means of consuming a tyrosine-depleting amino acid beverage was shown to reduce cue and low dose cocaine-induced craving for more cocaine, but did not alter cocaine-induced euphoria or self-administration [142]. The monoamine oxidase-B inhibitor selegiline, which should increase catecholamine levels including dopamine, was reported to have no effect [75] or to reduce [97, 171] the subjective effects of cocaine. Two studies [50, 135] reported that the catecholamine reuptake inhibitor desipramine increased baseline blood pressures, decreased cocaine craving, and altered the positive subjective effects of cocaine without altering the high or self-administration of cocaine. Blockade of the serotonin transporter with fluoxetine was reported to reduce the subjective euphoria of cocaine in one study [242] but not another study [85]. These human laboratory studies indicate that at best, medications which alter serotonin or norepinephrine activity in general do not have robust effects to alter cocaine euphoria or reinforcement and so it is no surprise that outpatient treatment trials with these medications have not been positive either [65, 234]. In cocaine using research volunteers, the gamma-aminobutyric acid reuptake inhibitor tiagabine, had no effect on the subjective or reinforcing effects of oral cocaine [143] and the gamma-aminobutyric acid agonist gabapentin reduced the subjective effects but not self-administration in cocaine-dependent subjects [87]. Each of these pharmacological approaches has been evaluated in clinical trials and none have been found to efficacious [65, 234].

Several human laboratory studies have examined the effects of antihypertensive calcium channel blockers in cocaine dependence. As cerebrovascular vasodilators, they have been suggested as possible treatments of vascular stroke and cognitive impairment related to cocaine dependence [63, 118]. In this regard, isradipine was shown to reduce the ischemic effects of cocaine infusion [116]. In other laboratory studies in cocaine-dependent subjects, nifedipine [166], nimodipine [136], and isradipine [121] were shown to block the blood pressure elevating effects of cocaine in subjects but not the stimulant or euphoric subjective responses. Following both acute [121] and repeated dosing [127] with isradipine, the reduction in cocaine-related pressor effects was also associated with an exacerbation of cocaine-related heart rate increases. Additionally, repeated dosing with isradipine was shown to produce headaches and other unpleasant effects and to increase the positive and reinforcing effects of intravenous cocaine infusion [199]. Given these laboratory results as noted above, it is no wonder that a 12-week trial of amlodipine for the treatment of cocaine-dependent outpatients was plagued by high drop-out rates, and failed to reduce cocaine craving or cocaine use more than was seen with placebo treatment [146].

Two other medications have shown efficacy in human laboratory and outpatient treatment studies, but are not likely to be pursued as treatments for primary cocaine dependence for safety reasons. The mu-receptor partial agonist, buprenorphine, was shown in two studies to reduce cocaine self-administration. One study in intravenous heroin and cocaine users reported that buprenorphine decreased intravenous cocaine self-administration, but it also potentiated several subjective effects including euphoria and sedation [55]. Another study in cocaine-dependent methadone maintenance participants found that substitution to buprenorphine was superior to continued methadone maintenance to decrease desire ("I want") for cocaine and self-administration behavior without altering other subjective effects [56]. Despite these positive results, the abuse potential of buprenorphine coupled with its potential for physiological dependence, make its use for primary cocaine dependence unlikely. Nonetheless, it still may be useful to decrease cocaine use in buprenorphine-maintenance therapy for opioid dependence [165]. A second medication, shown

to have efficacy in the outpatient treatment of cocaine dependence [23], is the alcoholism treatment agent disulfiram. Several human laboratory studies have shown that disulfiram inhibits cocaine metabolism and increases cocaine blood levels and its cardiovascular effects [79, 155]. Although those initial studies reported no significant alteration of cocaine's subjective effects, a more recent study [9] reported that disulfiram decreased cocaine-induced subjective high. The putative mechanism for efficacy of disulfiram in the treatment of cocaine dependence is presumed to be due to its inhibition of dopamine beta-hydroxylase [218]. However, because of disulfiram's inhibition of cocaine metabolism and its side effect profile, there are concerns about its safety as a treatment for primary cocaine dependence. Because alcohol may be consumed by a cocaine-intoxicated individual treated with disulfiram, the safety of an Antabuse®-alcohol reaction was evaluated in subjects with cocaine abuse or dependence in a 3-way drug interaction study (Roache JD. An early initial report of this study was presented at CPDD [239], but now the study data are complete and being analyzed for final publication, "unpublished observations"). That study found that alcohol administration was associated with clinically significant hypotension and increased heart rate in subjects given 5–7 days of disulfiram (250–500 mg) pretreatment. Intravenous infusion of 30 mg cocaine under these conditions counteracted the hypotension but tended to potentiate the heart rate effects. However, safety stop-point criteria prevented the administration of cocaine in two of three subjects who were hypotensive due to an Antabuse®-alcohol reaction in subjects treated with 500 mg disulfiram. This human laboratory study illustrates the safety concerns of using disulfiram in the treatment of cocaine dependence. Nonetheless, a review of the safety data from a number of published studies administering disulfiram to cocaine-dependent outpatients and to patents with dual cocaine-alcohol dependence has concluded that it can be safely used for cocaine treatment [147].

Human Laboratory Studies of Medications for Amphetamine or Methamphetamine

Evaluation of Dopaminergic Treatments for Methamphetamine

In normal healthy volunteers, acute doses of pimozide failed to reduce the subjective effects of amphetamine [19] and neither haloperidol nor risperidone reduced the euphoric effects of methamphetamine [237]. In subjects with histories of amphetamine abuse or dependence, acute doses of haloperidol did reduce positive subjective effects of amphetamine [211], as did repeated doses of chlorpromazine and to a lesser extent pimozide [129]. However, these mixed findings focusing on subjective effects are similar to those seen using dopamine antagonists for cocaine dependence. There is no reason to believe that dopamine antagonists will be any more successful for amphetamine or methamphetamine dependence than they have been for cocaine [67]. The partial D2 receptor agonist, aripiprazole, has been evaluated in two human laboratory studies and in one outpatient treatment trial. In normal healthy subjects, acute doses of aripiprazole produced dose-related reductions in the discriminative stimulus, subjective effects, and cardiovascular increases produced by d-amphetamine [220]. In methamphetamine-dependent volunteers, two weeks of treatment with aripiprazole did not increase cue-induced craving for methamphetamine, but did increase methamphetamine-induced stimulant and euphoric subjective effects, and increased baseline levels of desire for methamphetamine [175]. These data in non-treatment seeking methamphetamine-dependent subjects clearly suggest that aripiprazole would be counter-therapeutic as a treatment for methamphetamine. In an clinical treatment trial of amphetamine-dependent outpatients, a three-arm comparison study was stopped early in the trial, because an interim analysis showed that aripiprazole increased amphetamine use

relative to placebo, while methylphenidate was significantly better than placebo [231]. These data clearly indicate that dopamine agonist treatments may be counter-therapeutic for the treatment of amphetamine/methamphetamine dependence. However, the one study with methylphenidate, and several with bupropion suggest that dopamine reuptake inhibitors may be beneficial for the treatment of amphetamine/methamphetamine dependence. In methamphetamine-dependent research volunteers, a Phase I safety study showed that repeated oral doses of bupropion reduced both the cardiovascular pressor effects of methamphetamine as well as the subjective high and liking produced by intravenous infusion of moderate doses of methamphetamine [173, 174]. Subsequent to this human laboratory study, a multisite treatment trial [46] found that bupropion was superior to placebo to reduce methamphetamine use in outpatients who used less frequently than daily, but not in frequent daily users (Elkashef A, "personal communication", reported that a reanalysis of these data showed that bupropion was superior to placebo in all subjects using methamphetamine less frequently than daily.

Evaluation of Methamphetamine Treatments Affecting Other Neurochemical Systems

In two human laboratory studies conducted in healthy volunteers, ondansetron, was reported to produce modest reductions of positive subjective effects of amphetamine [68] or to reduce the amphetamine-induced decrease in hunger [214]. However, a treatment trial using varying doses of ondansetron in methamphetamine-dependent outpatients did not show evidence of efficacy [115]. The *N*-methyl-*D*-aspartate antagonist memantine was reported to alter the discriminative stimulus effects of methamphetamine in healthy subjects with limited histories of cocaine or amphetamine use [86]. Importantly, memantine also produced positive stimulant-like subjective effects of its own and did not reduce those produced by methamphetamine. In methamphetamine-dependent volunteers given intravenous methamphetamine, acute doses of the anticonvulsant topiramate produced sedative and undesirable side effects by itself and enhanced the positive subjective effects [122] and reduced the perceptual-motor facilitating effects [123] of methamphetamine. These human laboratory studies are consistent with the findings of a pilot outpatient treatment study where topiramate was not helpful to reduce methamphetamine use (Johnson BA, A NIDA-sponsored, multisite trial using topiramate treatment for methamphetamine dependence failed to show evidence of efficacy vs. placebo "personal communication"). In healthy volunteers, acute doses of isradipine reduced some of the positive subjective effects produced by methamphetamine and increased ratings of "I could refuse" [124]. In subjects with methamphetamine dependence, a within-subject crossover design found that repeated doses of isradipine reduced euphoria and positive subjective effects of methamphetamine but only when placebo treatment occurred first and not when isradipine treatment occurred first [120]. Although isradipine did reduce blood pressure elevations produced methamphetamine, it also enhanced the heart rate effects [127]. Though no treatment study has been attempted to our knowledge, the potential for tachycardic interactions between isradipine and methamphetamine are considered a sufficient concern to preclude further development.

General Conclusions Regarding Human Laboratory Studies

Methods to assess the abuse liability of multiple classes of drugs of abuse in human subjects tested in experimental laboratory environments are well established and validated. Increasingly, over the past decade, the human abuse liability assessment model has been used to examine

the drug interaction of candidate medication treatments with opiates, alcohol, cocaine, and methamphetamine. This review illustrated the: (1) results with the agonist/antagonist approaches that have been the basis for the treatment of opiate and nicotine dependence; (2) mechanistic evaluation of approved and potential medications for alcohol dependence, and (3) numerous medications that have been evaluated as possible treatments for cocaine and methamphetamine dependence. Useful and important information from these studies has helped to advance our understanding of the safety, mechanism, and possible efficacy of different pharmacological approaches to treatment and has contributed to the development of specific agents for treatment. Several general conclusions are possible from this review.

Human laboratory studies of direct pharmacological agonist or antagonist therapy mostly have been possible only in the study of opiate and nicotine dependence where opiates and nicotine act directly and selectively upon specific neurotransmitter systems. Here it is notable, that human laboratory studies of the effects of agonist replacement therapy with nicotine replacement, methadone, and buprenorphine have played an important role to verify possible efficacy and understand the mechanism(s) involved in such drug-drug interactions. Conclusions from the human laboratory studies showing that agonist replacement produces cross-tolerance with commensurate reductions in euphoria and reinforcing effects are consistent with outpatient treatment trials showing efficacy with agonist replacement strategies for nicotine and opiate dependence. However, human laboratory studies with antagonist treatments generally have produced false positive results because, though a pharmacological antagonist shows perfect efficacy in the human laboratory, clinical experience reveals poor effectiveness of antagonist treatment due to poor medication compliance. Though behavioral/legal contingencies may be useful to enhance compliance and efficacy of antagonist therapy, this is not a strategy that is generally available in community practice.

Although human laboratories are increasingly being used in studies of medications for alcohol dependence, disulfiram, naltrexone, and acamprosate were developed without the benefit of those studies. Nonetheless, newer putative treatments are increasingly being studied in the human laboratory and even the existing treatments are being studied using human abuse liability methods to better understand the possible biobehavioral mechanism(s) for the actions of these medications. Notably, the laboratory study results showing that disulfiram and naltrexone can reduce the euphoric and reinforcing effects of alcohol are generally consistent with the outpatient treatment literature. Again, though human laboratory studies did reveal the aversive and unpleasant effects of the Antabuse®-alcohol reaction, it took clinical experience to recognize that this would be a limitation on effectiveness due to poor compliance.

Many different pharmaceutical approaches have been tried for cocaine and methamphetamine dependence treatment. Since none have proven generally useful or effective, it is difficult to gauge exactly the extent to which the human laboratory results have been helpful towards this objective. Nonetheless, this review has suggested that in general, the results from the human laboratory studies have been consistent in the following ways. First, direct acting dopamine agonists and antagonists generally have not been effective in either the human laboratory or in the outpatient clinical setting and there is some evidence from both the laboratory and clinic that dopamine agonists may actually be countertherapeutic. Second, human laboratory experiments with agonist-like replacement strategies using stimulant medications have been valuable to show possible efficacy and the safety of this approach. These findings are consistent with the results of outpatient treatment trials showing efficacy with D-amphetamine, modafinil, or bupropion. Third, though there are some false positive results from human laboratory studies showing treatment-related reductions in cocaine or methamphetamine effects, we conclude that many of these suffer from limitations related to studying healthy volunteers rather than

drug-dependent populations and/or because of a focus on craving/subjective effects rather than self-administration. Fourth, the human laboratory plays an indispensible role to enable Phase I, II safety evaluations of medication effects in the target population both with and without the addition of the drug interaction between the treatment and cocaine/methamphetamine.

Finally, this review shows that when one recognizes the strengths and limitations of human laboratory methods in the medication development process, it is clear that these kinds of studies are valuable and will play an increasingly important role in the evaluation of the mechanism, safety, and possible efficacy of putative treatment agents for alcohol, cocaine, and methamphetamine. Though it has not been discussed specifically, it is reasonable to suggest that human laboratory methodological approaches are useful to evaluate medication treatments for other drug dependencies as well.

Conditioning of Addiction

M. Foster Olive and Peter W. Kalivas

Contents

Introduction

It is widely held that drug use is initiated because of the ability of these substances to produce feelings of pleasure and well-being (i.e., euphoria). Over time, however, tolerance develops to the euphorigenic properties of many drugs of abuse, which perpetuates drug-seeking behavior by leading the user to increase the dose and/or frequency of drug use in order to obtain the euphoria that was previously experienced (so-called "chasing the dragon"). With repeated drug use, the user begins to form associations between the subjective effects of the drug and environmental stimuli that are associated with the drug. These associations are formed by classical (Pavlovian) conditioning processes, and the types of stimuli or "cues" that become paired with drug use can be spatial, visual, auditory, tactile, olfactory, temporal, or interoceptive in nature. Examples of such stimuli include drug paraphernalia, the location in which the drug is repeatedly taken, the smell of alcohol or tobacco smoke, or the time of day. Since drug addicts do not typically live under conditions in which they are isolated from drug-associated cues (a possible exception being an addict who has been incarcerated or placed in a residential treatment program), active drug addicts typically encounter these drug-associated environmental stimuli on a daily basis. This repeated exposure to drug-associated stimuli can elicit expectation of drug availability or memories of previous euphoric experiences under the influence of a particular drug, which may in turn result in drug craving and drug-seeking behavior, leading ultimately to the perpetuation of drug self-administration and the addiction cycle [21, 43, 48, 51, 99, 121, 137, 140].

Most drugs of abuse are ingested in cyclic patterns consisting of active drug self-administration followed by abstinence. During the abstinence phase, the repeated emergence

of withdrawal symptoms may result in conditioned associations between environmental stimuli and the negative affective state (i.e., depression, anxiety, irritability, etc.) that typically manifest during withdrawal. As a result, withdrawal-associated environmental stimuli may also trigger drug-seeking behavior to alleviate the evoked negative affect via negative reinforcement processes (i.e., removal of withdrawal-induced dysphoria).

The neurobiological basis of conditioning of drug addiction has been significantly advanced by 1) the development of various animal models of drug-environment conditioning and 2) human imaging studies in which brain activity is monitored during exposure of an addict to drug-associated stimuli. In this chapter, we will discuss four of the most widely used animal models of drug conditioning: the conditioned place preference paradigm, cue-induced enhancement of drug-self administration, second-order schedules of reinforcement, and cue-induced reinstatement of drug-seeking behavior. We will then summarize key findings from studies using these paradigms on the neural substrates of drug conditioning. Next, we will discuss the findings from human brain imaging studies that have revealed specific neuroanatomical loci that are involved in processing information regarding drug-associated stimuli. Finally, from a treatment perspective, we will discuss recent progress in using behavioral and pharmacological therapies to facilitate the extinction of drug-environment associations, as well as to attenuate cue-evoked drug craving and relapse.

Methods for Assessing the Conditioned Effects of Drugs of Abuse in Laboratory Animals

Like human beings, laboratory animals including rats, mice, dogs, and non-human primates are able to form associations between environmental stimuli and appetitive rewards such as food, sweetened substances such as sucrose, and euphorigenic drugs of abuse. These species are also able to form similar associations between environmental stimuli and aversive events such as the presentation of an electric shock or the experience of drug withdrawal symptoms. The most notable experimental studies on this type of "conditioning" were conducted in the late nineteenth and early twentieth centuries by noted Russian physiologist Ivan Pavlov [107]. Pavlov noted that experimental dogs began to salivate in anticipation of the presentation of food. Eventually, Pavlov was able to elicit salivation in these dogs by presentation of a discrete environmental stimulus (the sounding of a bell) immediately prior to the presentation of food. These landmark studies, for which Pavlov was awarded the Nobel Prize in Physiology and Medicine, were the first to describe the phenomenon of "classical" or "Pavlovian" conditioning, where a previous neutral stimulus (i.e., the sound of a bell, serving as the "conditioned" stimulus) becomes associated with a naturally appetitive stimulus (i.e., food, the "unconditioned" stimulus). Eventually, with repeated conditioning, the organism learns to predict the availability of the unconditioned stimulus upon presentation of the conditioned stimulus, and thus the conditioned stimulus becomes motivationally salient.

In the context of drug addiction, classical conditioning is a widely prevalent phenomenon, such that during the course of repeated drug-taking behavior, environmental stimuli associated with the drug (i.e., the conditioned stimulus, such as the smell of tobacco smoke or the sight of a hypodermic syringe) become associated with and eventually predict the availability of the drug (i.e., the unconditioned stimulus). The chronic nature of drug addiction allows for numerous pairings of the conditioned stimulus and unconditioned stimulus, to the point that the conditioned stimulus becomes motivationally salient to the addict. In the case of an addict attempting to abstain from drug use, encountering a conditioned stimulus can provoke intense drug craving, which leads to drug-seeking behavior and greatly increases the propensity for relapse.

The neural basis of classical conditioning has been studied for decades at the cellular and molecular levels from *in vitro* preparations to the behavioral analysis of animals and humans. Here, we will briefly summarize four of the most commonly used behavioral paradigms in laboratory rodents that are designed to investigate the phenomenon of conditioning factors in drug addiction. These include the conditioned place preference paradigm, cue-induced enhancement of drug-self administration, second-order schedules of reinforcement, and cue-induced reinstatement of drug-seeking behavior.

Conditioned Place Preference

In the *conditioned place preference paradigm*, an animal learns to associate the effects of a passively administered substance with the environment in which the drug was received. A typical conditioned place preference apparatus is shown in Fig. 1, and consists of two compartments with unique tactile and visual characteristics (i.e., striped walls and mesh flooring in one compartment vs. transparent or solid walls and metal bar flooring in the other). Occasionally, distinct

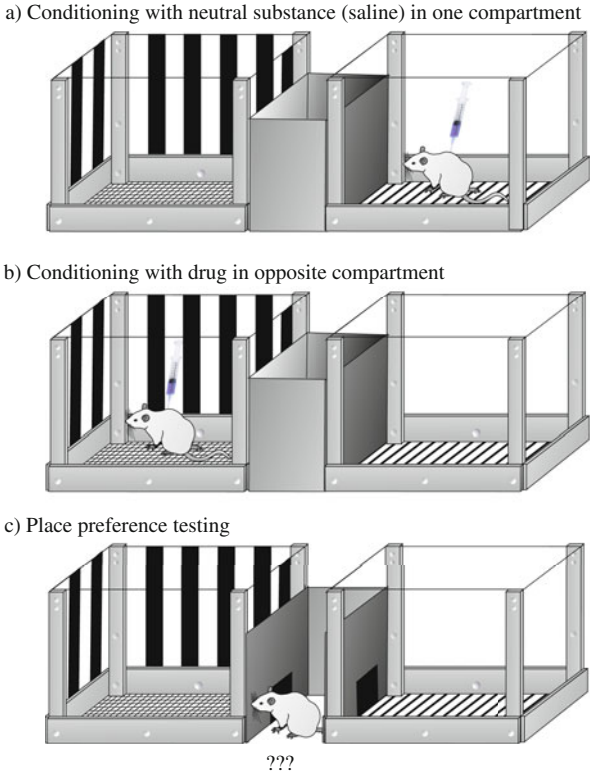

Fig. 1 The conditioned place preference paradigm. (**a**) Following a pre-conditioning test to habituate the animal to the conditioned place preference apparatus and to detect any innate bias toward one of the conditioning compartments, the animal is injected with a neutral substance, such as saline, and confined to one of the two contextually distinct conditioning compartments for a fixed amount of time. (**b**) After a period of several hours or on the following day, the animal is injected with a drug of abuse, such as cocaine, and confined to the other compartment for the same amount of time. (**c**) Following several days of conditioning, the animal is then placed in the center "start" compartment and is given the opportunity to enter either compartment at will (as indicated by *question marks* in the figure). Most abused drugs reliably produce a preference for the drug-paired environment over the saline-paired environment. The front wall of the start compartment in panel c is removed to show the location of the animal

olfactory cues are used in each compartment. These two "conditioning" compartments are connected by a neutral center "start" compartment. Each compartment is typically equipped with photobeams located just above the floor that can detect the presence of the animal and concurrent locomotor activity and record them via an interfaced computer.

In a typical conditioned place preference experiment, an animal undergoes baseline preference testing and habituation, whereby it is placed in the center start compartment and allowed free access to both conditioning chambers for a set amount of time (i.e., 30 min). This allows for the animal to habituate to the testing environment as well as for the experimenter to determine whether the animal exhibits any innate bias toward one of the two conditioning compartments. (An ideal conditioned place preference apparatus would produce no innate preferences for either compartment.) This first period of access to the conditioning compartment also serves as a preconditioning test, and the time spent in either compartment can later be compared against the same variable after conditioning with the drug. Following this habituation and preconditioning test, the animal is injected with a neutral substance (i.e., saline) and is then confined to one of the two conditioning compartments (using automated or manual guillotine-type doors) for a fixed period of time. On the following day, the animal is injected with the conditioning drug (e.g., morphine, cocaine, amphetamine, etc.) and confined to the other conditioning compartment for the same amount of time. These conditioning trials are repeated in an alternating fashion (i.e., saline-drug-saline-drug-. . .) a number of times so the animal learns to associate the unique physical characteristics of the drug-paired compartment with the subjective effects of the conditioning drug. Finally, on the test day, the animal is placed back in the center compartment in a drug-free state and is allowed free access to both conditioning compartments for the same amount of time as during the preconditioning test. If the animal spends significantly more time in the drug-paired compartment than in the saline-paired compartment, conditioned place preference has been established, reflecting the animal's association of the drug compartment with the subjective (presumably pleasurable or "rewarding") effects of the drug. Conditioned place preference has been demonstrated in rodents for all drugs of abuse [9, 115, 129, 130], although the experimental procedures may vary by the drug and its individual pharmacokinetic properties. Conditioned place aversion is observed if the animal spends significantly less time in the drug-paired compartment than in the saline-paired compartment. Withdrawal from chronic drug exposure reliably produces conditioned place aversion. In addition, some drugs such as ethanol can also produce conditioned place aversion if the peak positive subjective effects of the drug are not timed and paired correctly with the drug-conditioned compartment [31, 32, 112].

One advantage of the conditioned place preference paradigm is that the experiments are relatively simple, inexpensive, and less time-consuming to conduct than more involved procedures such as intravenous drug self-administration. In addition, conditioned place preference paradigms can be used to simulate various aspects of relapse. This is accomplished in one of two ways: (1) extinguishing an established conditioned place preference by repeatedly pairing the previously drug-paired compartment with saline, or (2) allowing the conditioned place preference to dissipate over a period of several weeks by repeated testing of place preference. Then, drug priming or stress can be introduced to the animal to reinstate the original conditioned place preference, a phenomenon that has been hypothesized to model drug-seeking behavior [75, 97, 138].

Despite its simplicity and ease of use, there are several disadvantages of the conditioned place preference paradigm. First and foremost, the animals do not actively self-administer the drug; it is passively administered as a bolus injection by the experimenter. In addition to potential pharmacokinetic differences in plasma and brain levels of the drug between passive and active self-administration, a substantial

amount of evidence has accumulated showing that active versus passive drug administration produces significant differences in neurochemical, endocrine, and other responses to drugs of abuse [42, 66, 76, 77, 123, 124]. These differences may underlie some of the discordant findings between studies using pharmacological or other experimental manipulations in the conditioned place preference paradigm and those utilizing active self-administration. In addition, the primary dependent variable measured in the conditioned place preference paradigm does not directly measure drug-seeking behavior but, rather, the motivation for drug-associated environments. Despite these limitations, the conditioned place preference paradigm undoubtedly has provided useful information on the neural substrates that underlie drug-environment conditioning and their contribution to addictive behaviors, as will be discussed later in this chapter.

Cue-Induced Enhancement of Drug Self-Administration

One of the most widely used paradigms to study drug addiction in animals is the intravenous self-administration paradigm (Fig. 2). In the case of rodents, a rat or mouse is surgically implanted with an indwelling intravenous catheter into the jugular or femoral vein, which exits the skin on the dorsal side of the animal and is connected to a vascular access port. Following recovery from surgery, the animal is placed in a self-administration apparatus chamber equipped with one or two levers that are interfaced to a computer and a syringe pump. In lieu of levers, some investigators utilize a nose-poke hole on the wall of the self-administration apparatus, whereby a nose-poke into the correct hole triggers the delivery of a reinforcer. A positive reinforcer is defined as a stimulus that increases the likelihood the response will occur again in the future

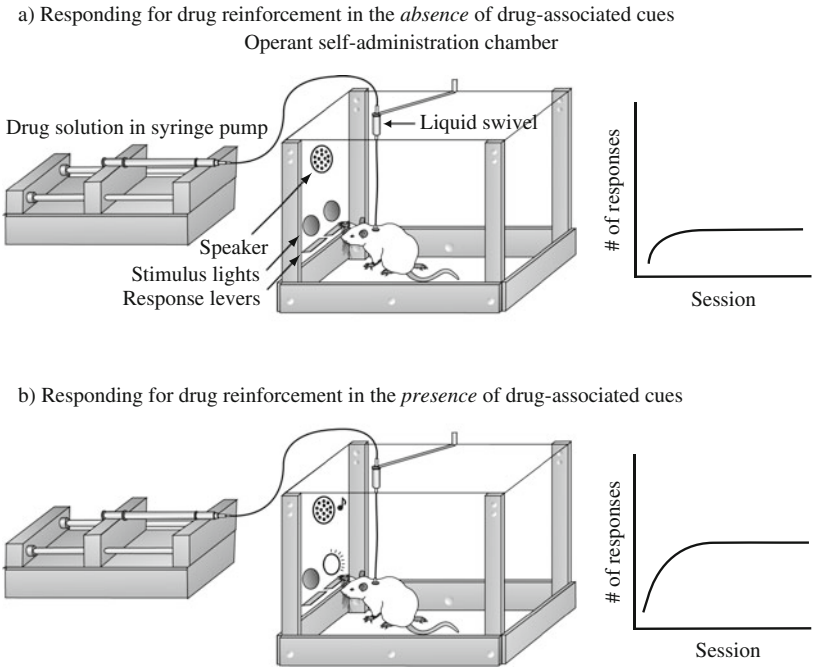

Fig. 2 Cue-induced enhancement of drug self-administration. (**a**) Animals trained to perform an operant task (such as a lever-press or nose-poke) in the absence of simultaneous presentation of any discrete cues (i.e., light, tone, or olfactory stimulus) show relatively low levels of responding for the drug alone. (**b**) In animals trained to self-administer the drug with concomitant presentation of discrete cues, responding for drug reinforcement is increased

(e.g., an addictive drug), while a negative reinforcer is defined as a stimulus that decreases the likelihood the response will occur again (e.g., an aversive stimulus such as an electric shock). In order to learn the operant task (i.e., lever-press or nose-poke), the animal is often initially trained to perform the task in order to receive a natural reinforcer such as a food or sucrose pellet. (The animal is mildly food-restricted to increase its motivation to seek food during initial training.) However, not all investigators use this initial food restriction and training, since it changes the nutritional and metabolic state of the animal. Instead, some investigators may choose to capitalize on the intrinsic exploratory nature of rodents, since over time the animal will eventually exert the correct operant response, receive an intravenous drug infusion, and, with repeated training sessions, learn that this correct response results consistently in the delivery of the drug solution.

The drug solution is delivered by a computer-controlled syringe pump located outside the self-administration apparatus. The pump contains a drug solution that is connected to a single-channel liquid swivel, which allows free rotation of the animal while maintaining a continuous flow of fluid. Plastic tubing is then housed in a stainless steel spring tether and is attached to the animal via a vascular access port implanted on the dorsal side of the animal, which is connected to the indwelling venous catheter.

In the case of alcohol, intravenous self-administration procedures are used less frequently since this method lacks the face validity and pharmacokinetics of human oral alcohol consumption, and the ability of intravenous ethanol to function as a reinforcer is less reliable. Thus, most animal models of alcohol self-administration utilize an experimental apparatus by which—instead of a syringe pump delivering the drug solution intravenously—a dilute ethanol solution (usually 8–12% v/v) is delivered into a receptacle located near the lever or nose-poke orifice, where the animal can consume it orally. However, because of the aversive orosensory nature of ethanol, many researchers often initially train animals to consume alcohol solutions sweetened with sucrose or saccharin to increase its palatability. Then, slowly over a period of weeks, the concentration of the sweetener is gradually reduced until eventually the animal performs the operant task to consume an unsweetened ethanol solution.

There are many advantages of the operant self-administration paradigm as a model for human drug-taking behavior, including: (1) the drug is administered voluntarily by the animal (as opposed to passive administration by an experimenter); (2) the drug-taking behavior can be temporally examined within and between self-administration sessions; (3) candidate therapeutic pharmacological compounds or other experimental manipulations can be administered to determine their effects on drug self-administration; (4) the number of responses that must be exerted by the animal in order to receive the drug can be gradually increased (called a "progressive ratio") until the animal "gives up" and no longer performs the operant task (called the "breakpoint")—this method is used to measure the level of motivation to self-administer the drug as well as the efficacy of the reinforcer, and, finally, (5) the procedure is amenable to the study of relapse-like behavior (see Section "Cue- and Context-Induced Reinstatement of Drug-Seeking Behavior").

One additional advantage of operant self-administration procedures is their amenability to the study of the role of conditioned cues in the reinforcing effects of drugs of abuse. In addition to delivery of the drug, many researchers also use environmental cues such as the presentation of stimulus light, auditory tone, olfactory cue, or combinations thereof that are simultaneously paired with the intravenous delivery of the drug solution. Over successive self-administration sessions, the animal learns to associate these cues with availability of the drug and its pharmacological effects. Studies have shown that, for most drugs of abuse, the presence of drug-associated cues greatly increases the number of operant responses exerted per

test session, compared with when the drug is self-administered in the absence of such cues (Fig. 2) [22–24, 34, 49, 50, 58, 59, 72, 87, 102–105, 111, 122, 141]. These findings suggest that in addition to the primary reinforcing effects of the drug itself, drug-associated stimuli (also termed secondary reinforcers or conditioned stimuli) regulate drug self-administration behavior, a phenomenon referred to by experimental psychologists as "stimulus control" of behavior. This stimulus control has also been demonstrated in human cocaine users in a laboratory setting [106]. In the case of psychostimulants, this enhancement of drug reinforcement by drug-associated cues has been hypothesized to be a result of the augmentation of the impact of sensory information caused by this class of drugs [48].

Second-Order Schedules of Reinforcement

Another experimental paradigm that exemplifies the ability of drug-associated cues to exert stimulus control over behavior is the *second-order schedule of reinforcement* [47, 116]. In this paradigm, animals are initially trained to self-administer a drug of abuse intravenously (or orally, in the case of alcohol) as described in the previous section; each operant response results in drug delivery and the simultaneous presentation of a discrete cue (i.e., a light, tone, and/or olfactory stimulus). After successful training of the animal under this "primary" schedule reinforcement, the contingency of drug delivery upon completion of the operant task is removed, such that only the drug-associated stimulus is presented following each operant response. Thus, each lever press or nose-poke results in presentation of the drug-associated cue stimulus (secondary reinforcer) but no drug delivery (primary reinforcer). The primary advantage of this paradigm is that it allows the investigator to examine "drug-seeking" behavior in the absence of drug delivery, similar to the cue- and context-induced reinstatement discussed in the next section. Thus, the effect of pharmacological or neurobiological manipulations on responding for the secondary reinforcer can be performed without the potential confound of the psychoactive effects of the primary reinforcer. Acquisition of responding on a second-order schedule can be enhanced by non-response-contingent exposure to a sensitizing regimen of the drug (i.e., cocaine) following the primary reinforcement phase [36] (Fig. 3).

However, in order to avoid the extinction of drug-seeking behavior due to the absence of primary reinforcement, a response-contingent delivery of the drug solution must be given at a fixed time interval (i.e., every 30 or 60 min), after the completion of a certain number of operant responses, or at the end of the test session. This allows the animal to receive the primary reinforcer and thus maintain the associations between the drug and responding for drug-associated cues.

Further evidence for the motivational salience of drug-associated cues lies in the fact that when animals are subject to extinction procedures (i.e., when the primary drug reinforcer is withheld in subsequent test sessions following responding under a second-order schedule of reinforcement), response-contingent presentation of the light/tone/olfactory stimulus during extinction trials results in enhanced responding and a slowing of the rate of extinction in rats trained to self-administer cocaine [6], suggesting that the drug-associated cues maintain their motivational salience despite the fact that the primary drug reinforcer is no longer available. This phenomenon has also been demonstrated during extinction following primary drug reinforcement [117, 118]. However, slowing of the rates of the extinction following second-order heroin reinforcement by response-contingent presentation of the drug-associated cues during extinction trials has not been observed [3], suggesting that discrete heroin-associated cues exert a lesser degree of stimulus control over behavior than those associated with cocaine.

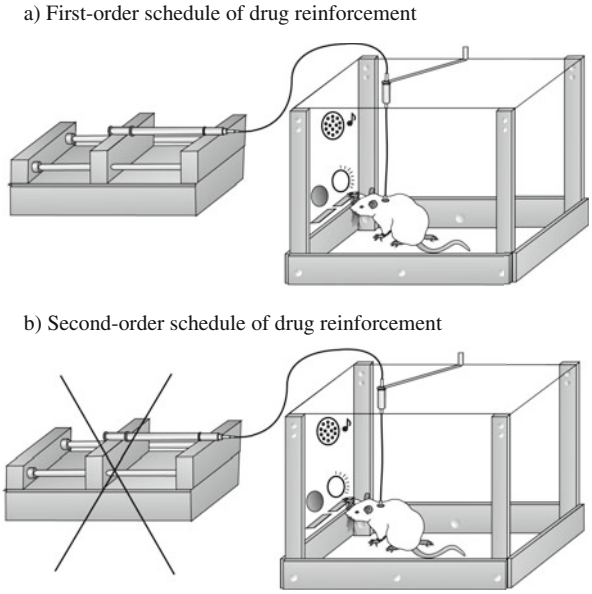

Fig. 3 First- and second-order schedules of reinforcement. (**a**) In a first-order schedule of reinforcement, each correct operant response (i.e., lever-press or nose-poke) results in the delivery of the drug solution as well as simultaneous presentation of discrete drug-associated stimuli. (**b**) Following sufficient training on a first-order schedule of reinforcement, a second-order schedule of reinforcement can be initiated whereby each correct lever response results in the presentation of the drug-associated cue, but infusion of the drug solution is withheld until a fixed time point or the end of the test session

Cue- and Context-Induced Reinstatement of Drug-Seeking Behavior

Relapse is one of the most problematic aspects in the treatment of drug addiction, as it can occur months or years following the last episode of drug intake. Fortunately, animal models have been developed that appear to mimic the phenomenon of relapse in humans. The most widely used animal model of relapse is the *reinstatement paradigm* [44, 45, 79, 100, 101, 115]. In this paradigm, animals are trained to self-administer a particular drug of abuse as described in the Section "Cue-Induced Enhancement of Drug Self-Administration". Following stabilization of patterns of self-administration, animals are then subject to extinction training, where the operant response that previously resulted in drug delivery either has no consequences or results in the delivery of a non-reinforcing substance such as saline. During extinction training, the animal learns that the operant response no longer results in drug delivery and subsequently decreases the number of operant responses exerted. Once specific extinction criteria have been reached (for example, the number of operant responses performed during an extinction trial is less than 20% of those that were observed prior to the commencement of extinction training), the animal is then exposed to one of three types of stimuli that are known to trigger relapse in human addicts: brief exposure to the drug (drug priming), exposure to drug-associated cues, or stressors. The animal then exhibits a significant increase in the number of operant responses that previously resulted in drug delivery; in other words, drug-seeking behavior has been *reinstated*. It should be noted, however, that in the reinstatement model, performing the operant task does not actually result in drug delivery; the behavior is not reinforced by the drug, and, therefore, the reinstatement of drug seeking is relatively

short-lived. Herein lies one of the fundamental (and often criticized) aspects of the reinstatement paradigm where it diverges from the human condition of relapse, since in humans drug-seeking behavior is usually followed by drug self-administration [44]. In the reinstatement paradigm, execution of the operant response does not result in drug availability and self-administration. Nevertheless, the reinstatement paradigm offers a particularly unique method for studying the neural basis of relapse, since *drug-seeking* behavior is inherently parsed out from actual *drug-self-administration* behavior, and the behavior of the animal can be observed and recorded in the absence of psychomotor-altering effects of the drug itself.

With regard to the study of the influence of conditioned cues on drug-seeking behavior, the reinstatement paradigm offers the possibility of studying two distinct phenomena. First, if the discrete cues (i.e., a tone, light, or olfactory stimuli) that were presented to the animal during each drug delivery prior to extinction procedures are re-introduced to the animal in a response-contingent manner, presumably the animal expects that the drug is now available and exerts a significant increase in the number of operant responses that previously resulted in drug delivery. Alternatively, some investigators present the drug-associated cues in a non-response-contingent manner. Regardless, this phenomenon is known as *cue-induced reinstatement*, and has been used extensively to study the role of discrete drug-associated cues in the control over drug-seeking behavior (see Fig. 4).

During the phase of the experiment where animals are actively self-administering the drug, the animal makes associations not only between the drug and the discrete cues presented upon its delivery but also between the drug and the physical environment in which the drug is self-administered. This is particularly relevant to drug addiction in humans since drug-taking behavior is usually performed ritualistically in distinct physical locations (i.e., in the addict's bedroom, local crack house, etc.). The role of the physical environment in controlling drug-seeking behavior can be modeled in animals through what is known as *context-induced* or *contextual reinstatement* [5, 19, 30, 82, 128, 149]. In this paradigm, animals are trained to self-administer the drug in a particular self-administration apparatus. However, subsequent extinction training is conducted in an apparatus that is contextually distinct from that where the active drug self-administration phase occurs (i.e., with different colored walls, different textured flooring, the presence of a different odor, etc.). After extinction criteria have been met, the animal is placed back in the original apparatus where the initial drug self-administration was performed. As a consequence of the drug-environment associations formed during active drug self-administration, the animal then displays a significant increase in the number of operant responses that previously resulted in drug delivery. (This phenomenon is sometimes referred to as a *renewal* effect.) As with cue-induced reinstatement procedures, during context-induced reinstatement, no drug is actually delivered as a result of the operant response, so as to provide a model of contextual influences over drug-seeking rather than drug self-administration behavior.

Neural Substrates of Drug Conditioning: Results from Animal Studies

Studies utilizing the aforementioned animal models of drug conditioning have yielded a wealth of information regarding the neural mechanisms underlying the ability of drug-associated stimuli to control drug-seeking behavior in the absence of primary drug reinforcement. The results of these studies have identified several brain regions that subserve stimulus control over drug-seeking behavior, namely the amygdala, nucleus accumbens, dorsal striatum, hippocampus, frontal cortex, and ventral tegmental area, with both glutamatergic and dopaminergic transmission in many of these regions being implicated (see Fig. 5).

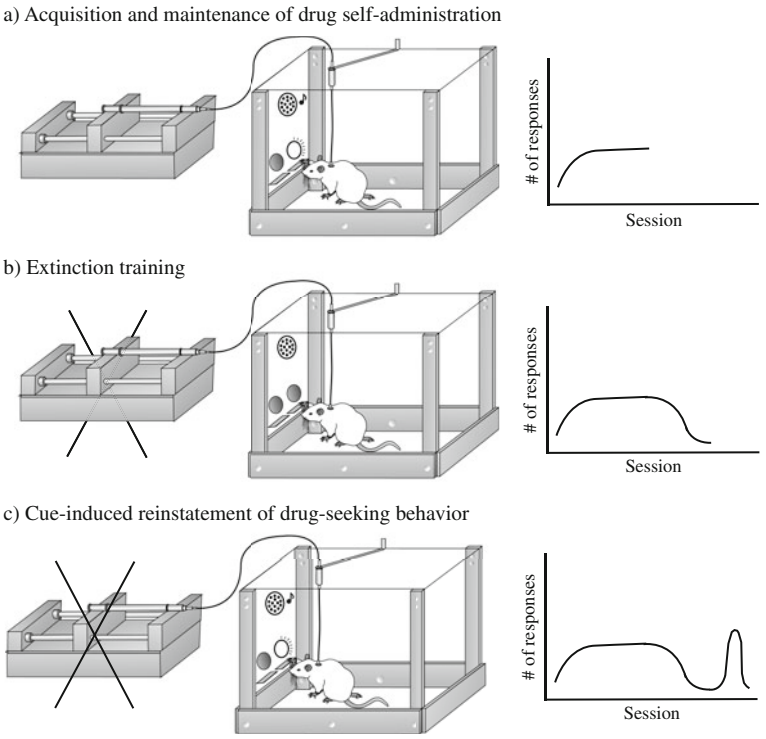

Fig. 4 Cue-induced reinstatement of drug-seeking behavior. (**a**) The animal is first trained to self-administer the drug solution under a standard first-order schedule of reinforcement in the presence of discrete drug-associated cues during drug delivery. This schedule of reinforcement is maintained until response patterns stabilize. (**b**) During extinction training, each correct operant response that previously resulted in drug delivery either results in infusion of saline or has no programmed consequences. Extinction training is performed until predefined extinction criteria have been met. (**c**) During cue-induced reinstatement testing, discrete cues that were previously paired with drug delivery are presented to the animal in a response-contingent or non-contingent manner. Most investigators conduct reinstatement testing in the absence of actual drug delivery so as to separate drug-seeking behavior from actual drug-self-administration behavior, as well as to avoid the potential confounds of psychomotor effects of the drug on operant performance

The amygdala, or amygdaloid complex, is a small set of nuclei found in the temporal lobe that receives a considerable amount of input from cortical regions involved in sensory processing as well as other cortical, subcortical, and limbic structures. In turn, the amygdala provides efferent output to many of these same regions. Everitt and colleagues were among the first to show that the basolateral portion of the amygdala is important for stimulus-reward associations when they demonstrated that lesions of the basolateral amygdala abolished the expression of a conditioned place preference for sucrose [46]. These investigators subsequently expanded their investigation into the role of the amygdala in processing stimulus-reward associations to drug rewards by demonstrating that lesions of the basolateral amygdala reduced the ability of rats to respond for cocaine under second-order reinforcement [144]. In this latter study, rats were still able to acquire cocaine self-administration, suggesting that this region is not involved in the acquisition of primary cocaine reinforcement. However, another study by this group showed that lesions of the basolateral amygdala did not alter second-order heroin reinforcement [2], suggesting that drug class may determine whether the basolateral amygdala mediates the acquisition of second-order drug reinforcement. Thus, the basolateral amygdala appears to mediate

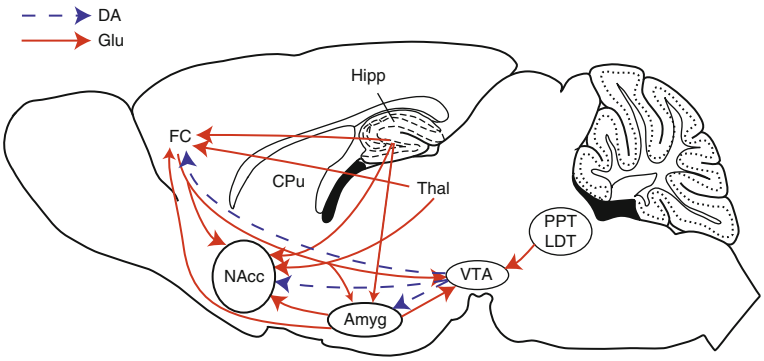

Fig. 5 Sagittal section of the rat brain showing the neural circuitry underlying conditioning processes in drug addiction. The ventral tegmental area (VTA) sends dopaminergic (DA) projections (*blue dashed lines*) to the nucleus accumbens (NAcc), frontal cortex (FC), and amygdala (Amyg), and this pathway is believed to mediate the primary reinforcing effects of most drugs of abuse. These structures also receive substantial glutamatergic (Glu) input (*red solid lines*). For example, the hippocampus (Hipp) and FC send glutamatergic projections to the FC, NAcc, and Amyg, while the thalamus (Thal) also innervates the NAcc and FC with glutamatergic input. Finally, the VTA receives glutamatergic input from many of the aforementioned regions as well as the pedunculopontine tegmentum (PPT) and laterodorsal tegmentum (LDT) in the brainstem. CPu = caudate putamen (for color figures see online version)

the motivational salience of cocaine-associated cues. In agreement with this, numerous other studies have shown that lesions or inactivation of the basolateral amygdala also attenuate cue- and/or context-induced reinstatement of cocaine-seeking behavior [53, 63, 81, 85, 89, 90, 109, 145].

Cocaine-associated stimuli increase the expression of neuronal activation markers such as the immediate early gene c-fos in the basolateral amygdala [28, 64, 92, 93, 98]. Cocaine- and amphetamine-conditioned stimuli also elicit the release of dopamine in the basolateral amygdala [65, 127, 141], and microinjection studies have shown that dopamine acting on D_1-like receptors [4, 119] or $D_{2/3}$-like receptors [35, 67] in the basolateral amygdala mediates the encoding of stimulus control over drug-seeking behavior. Studies using the conditioned place preference paradigm have shown that *de novo* protein synthesis in the basolateral amygdala is required for long-term maintenance of morphine conditioned place preference [91] and that activity in this nucleus is necessary for reinstatement of heroin conditioned place preference [113]. On the other hand, ionotropic glutamate receptors in the basolateral amygdala do not appear to be involved in cue-induced reinstatement of cocaine-seeking behavior [119]. Thus, the basolateral amygdala appears to play a critical role in the ability of conditioned cues to exert control of drug-seeking behavior and drug reward, and these effects appear to be mediated primarily by dopaminergic transmission in this region.

Another brain region known to be involved in the neural coding of drug-associated cues is the nucleus accumbens, located within the ventral striatum of the rostral forebrain. The nucleus accumbens receives dense dopaminergic projections from the ventral tegmental area of the midbrain as well as glutamatergic projections from the prefrontal cortex, hippocampus, amygdala, and thalamus. Neurons in the nucleus accumbens are primarily of the medium spiny type that utilize the inhibitory amino acid gamma-aminobutyric acid—as well as various neuropeptides—as transmitters in its outputs to the ventral pallidum and ventral tegmental area. Lesions of the nucleus accumbens core, but not the shell subregion, selectively impair acquisition of second-order heroin reinforcement [1, 71, 74] while having no effect on maintenance of responding. Likewise, inactivation of the nucleus accumbens core, but not the

shell, attenuates cue-induced or contextual reinstatement of cocaine-seeking behavior [40, 54, 109]. Despite the fact that response-independent presentation of cocaine-associated cues elevates extracellular levels of both dopamine and glutamate in the nucleus accumbens core [11, 69, 73] and increases nucleus accumbens core neuronal firing [20, 68], glutamatergic signaling in the nucleus accumbens may be more important than dopamine signaling in drug-conditioned stimulus control of behavior. Evidence for this comes from studies showing that blockade of α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)/kainic acid-type glutamate receptors in the nucleus accumbens core reduces second-order responding for cocaine [37], whereas blockade of D_3 receptors in the nucleus accumbens shell has no effect on second-order cocaine reinforcement [35].

Drug-associated stimuli and environments also increase the expression of various transcriptional regulators including Fos, ets-like gene 1, extracellular signal-related kinase, and cyclic adenosine monophosphate-responsive element binding protein [92–94, 98], and some of these molecular signaling intermediates as well as de novo protein synthesis in the nucleus accumbens appear to be necessary for retrieval of drug-associated contextual memories [91, 94]. More recently, some investigators have determined that in addition to the nucleus accumbens, the dorsal striatum (particularly the dorsolateral region) plays a role in cue-controlled cocaine seeking [40, 52], with both dopamine and glutamatergic transmission being involved [10, 131].

An elegant study by Di Ciano and Everitt demonstrated a functional interaction between the basolateral amygdala and the nucleus accumbens core in mediating drug seeking under a second-order schedule of reinforcement [39]. In this study, bilateral antagonism of dopamine but not AMPA receptors in the basolateral amygdala impaired second-order cocaine reinforcement, whereas the reverse was true when these manipulations were performed in the nucleus accumbens core. When unilateral injections on opposite sides of the brain were performed in a disconnection procedure, dopamine receptor blockade in the basolateral amygdala combined with blockade of AMPA receptors in the contralateral nucleus accumbens core produced the same effect as the bilateral injections. A similar disconnection procedure recently showed that unilateral dopamine receptor antagonism in the dorsal striatum combined with a unilateral lesion of the nucleus accumbens core impairs second-order cocaine responding [10].

The prefrontal cortex and many of its subregions also play a significant role in drug conditioning and stimulus control of behavior. Lesions of the orbitofrontal cortex impair second-order responding for cocaine [108], whereas lesions of the medial prefrontal cortex actually increase responding for cocaine under a second-order schedule of reinforcement [142]. In this latter study, however, omission of the conditioned stimulus did not reduce these elevated patterns of responding, suggesting that the medial prefrontal cortex may not encode the motivational salience of drug-associated cues but rather control behavioral inhibition. Discrete drug- and alcohol-associated stimuli increase c-fos expression in frontal cortical regions such as the medial prefrontal/prelimbic cortex [28, 33, 92, 93, 146], infralimbic cortex [64, 93], and anterior cingulate cortex [98, 146], and it has been shown that dopamine D_1-like receptors play a role in increasing cue-evoked immediate early gene expression [28]. Inactivation of the dorsomedial/prelimbic, ventral prefrontal, and lateral orbitofrontal cortices attenuates cue- or context-induced reinstatement of drug-seeking behavior [41, 53, 55, 89] and drug priming-induced reinstatement of cocaine conditioned place preference [147], and retards the extinction of amphetamine conditioned place preference [70].

Another region involved in drug conditioning is the hippocampal formation, which is involved not only in episodic memory storage but also in spatial navigation and the influence of environmental contexts on behavior. Inactivation of the dorsomedial hippocampus attenuates contextual reinstatement of cocaine-seeking behavior [53], whereas inactivation of slightly more ventral portions of the hippocampus reduces

cue-induced reinstatement [114]. However, conflicting evidence exists over whether inactivation of ventral output regions of the hippocampal formation (i.e., the subiculum) mediates cue-induced reinstatement evoked by discrete drug-associated cues [12, 125]. Given the relatively large size of various regions of the hippocampus, it is likely that differences in anatomical localization of microinjection guide cannulae contributed to these disparate results. Certain regions of the hippocampus, such as the CA1 region and dentate gyrus, show elevated expression of c-fos expression when animals are exposed to an environment previously associated with cocaine self-administration [98]. Similar to the basolateral amygdala, *de novo* protein synthesis in the hippocampus is required for long-term maintenance of morphine conditioned place preference [91]. Thus, the hippocampus appears to play a role in the ability of drug-associated contexts to influence drug-seeking behavior.

One final brain region involved in drug conditioning is the ventral tegmental area, which receives glutamatergic afferents from various cortical and subcortical regions and sends dense dopaminergic projections to the nucleus accumbens and prefrontal cortex and less dense projections to the basolateral amygdala and ventral pallidum. While the ventral tegmental area-nucleus accumbens dopamine projections have long been considered to be a part of the "reward circuit" of the brain [140], there are several recent studies to suggest that glutamatergic input to the ventral tegmental area modulates the ability of drug-associated cues to influence drug-seeking behavior. For example, suppression of glutamate transmission in the ventral tegmental area by local infusion of a type 2/3 metabotropic glutamate receptor agonist, which suppresses glutamate release by stimulating presynaptic metabotropic glutamate receptor 2/3 autoreceptors, attenuates contextual reinstatement of heroin-seeking behavior [14]. Likewise, temporary inactivation of the ventral tegmental area attenuates second-order responding for cocaine [38]. Thus, there is evidence to suggest that the ventral tegmental area controls both primary and secondary drug reinforcement.

Neural Substrates of Drug Conditioning: Results from Human Imaging Studies

Advances in imaging of the living human brain have greatly added to our understanding of the neural basis of reactivity to drug-associated cues [61, 133]. Such imaging studies have shown repeatedly that cues associated with drug intake activate forebrain regions such as the anterior cingulate, dorsolateral prefrontal, and orbitofrontal cortices, the insular cortex, and striatal and limbic regions such as the amygdala and nucleus accumbens [13, 18, 27, 56, 60, 62, 83, 84, 88, 95, 134–136, 139, 143]. Activation of these brain regions is highly correlated with drug craving. These findings correlate well with the animal studies reviewed in the previous section, and suggest that cortical, striatal, and limbic structures are highly involved in processing drug cue-related information. A recent study showed that when drug-associated stimuli were presented to subjects for a period of time too brief to be processed at a conscious level (33 ms), similar regions of the brain were activated [25]. However, additional increased activity was observed in a transition zone between the amygdala and ventral pallidum, suggesting that some regions of the brain are activated by drug-associated visual stimuli even when "unseen" at the conscious level. Clearly, further research in this area is needed to identify an anatomical rodent correlate of this amygdalar/ventral pallidal transition zone and its potential role in mediating stimulus control of drug-seeking behavior (Fig. 6).

Strategies for Extinguishing Drug Conditioning and Reducing Cue-Elicited Drug Craving: Focus on Glutamate

Reactivity to drug-associated cues is an important determinant of propensity to relapse among drug addicts [21, 26]. However, exposure

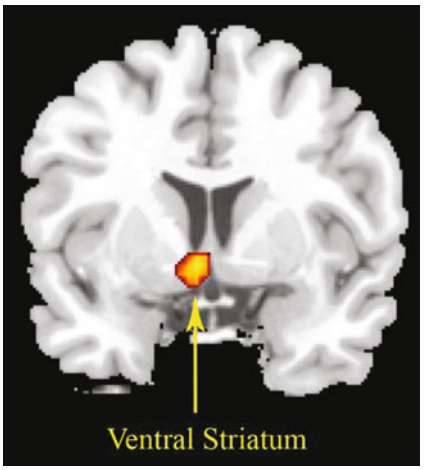

Fig. 6 Coronal section of the human brain showing activation of the ventral striatum by drug-associated cues. Alcohol-dependent individuals were exposed to images of either alcohol-related cues (e.g., a glass of wine) or a neutral image (e.g., a light switch) while undergoing functional magnetic resonance imaging of the brain. A significant increase in activity in the ventral striatum (which contains the nucleus accumbens) was observed following exposure to an alcohol-related cue. Image courtesy of Dr. Hugh Myrick and Mr. Scott Henderson, Center for Drug and Alcohol Programs, Medical University of South Carolina

therapy, whereby the addict is desensitized to the craving evoked by drug-associated cues by repeated exposure to the cues—and is taught coping skills on how to curb drug craving if he or she encounters a drug cue—has been shown to be only moderately effective in reducing rates of relapse [29]. The unsuccessful outcomes of exposure therapy are most likely due to the high degree of context specificity of extinction, whereby extinction of craving evoked by drug-associated cues in one context (i.e., the therapist's office) fails to generalize to the "real world" where such cues are encountered more frequently and in different contexts [16, 17].

Extinction of the motivational salience of drug-associated cues is a process of active learning and involves many of the neurobiological signaling mechanisms underlying normal learning and memory processes, including neuroadaptations in glutamatergic neurotransmission [120, 126]. Thus, one potential pharmacological mechanism by which to enhance extinction processes is via mild stimulation of glutamatergic neurotransmission, since excessive augmentation of glutamate transmission would likely produce central nervous system hyperexcitability and excitotoxic effects. Recently, studies in both animals and humans have shown that the *N*-methyl-*D*-aspartate receptor partial agonist *D*-cycloserine is effective at facilitating the extinction of conditioned fear [132]. Similarly, it has been shown in animals that *D*-cycloserine accelerates the extinction of cocaine conditioned place preference [15]. Stimulation of type 5 metabotropic glutamate receptors, which are positively coupled to *N*-methyl-*D*-aspartate receptor function, also facilitates the extinction of cocaine conditioned place preference [57].

An alternative method by which to stimulate glutamatergic transmission and thus enhance extinction learning is by administration of the cystine pro-drug *N*-acetylcysteine. Once *N*-acetylcysteine enters the body, it is converted to cystine, where it acts as a substrate for the cystine-glutamate exchanger. This exchanger is an antiport protein localized to glial cells in the brain that exchanges extracellular cystine molecules for intracellular glutamate. Withdrawal from repeated exposure to cocaine is accompanied by reduced basal extracellular levels of glutamate in the nucleus accumbens [110], and it has been shown that administration of *N*-acetylcysteine to cocaine-withdrawn rats reduces the ability of cocaine priming injections to increase extracellular glutamate in the nucleus accumbens and, as a consequence, reduces cocaine-primed reinstatement of cocaine-seeking behavior [7, 8, 96]. *N*-acetylcysteine also reduces extinction responding following heroin self-administration and produces long-lasting reductions in the ability of drug-associated cues to reinstate heroin-seeking behavior [148]. Translating these basic research findings to the clinic, LaRowe and colleagues recently demonstrated that *N*-acetylcysteine reduces drug craving and cue reactivity in cocaine addicts [86]. Thus, normalization of extracellular levels of glutamate in the nucleus accumbens during drug withdrawal

may be a novel avenue by which to facilitate extinction of the motivational salience of drug-associated cues and, therefore, reduce the incidence of relapse in human addicts.

Conclusions

Although drug addiction is a chronic and multifaceted disease that has numerous genetic, socioeconomic and behavioral causes, one of its key features is an increased incentive salience of drug-associated stimuli and impaired executive inhibitory control of drug craving elicited by these cues [78, 80]. These manifestations of the addictive state are mediated by dysfunction of limbic and prefrontal-accumbens circuitry. Therefore, it is of clinical interest to restore the normal functioning of these circuits during the course of treatment of the addict so as to allow him or her to extinguish the motivational salience of drug-associated cues and regain inhibitory control of drug-seeking and drug self-administration behaviors. Clearly, more research is needed to parse out the neurobiological substrates of drug conditioning at the molecular, cellular, and systems levels, and how this conditioning can be "reversed" in the addicted state. In addition, increased attention needs to be given to novel methodology—both behavioral and pharmacological—that is designed to facilitate the extinction of drug conditioning, particularly with regard to the generalization of extinction to "real world" situations.

Introduction

Vulnerability to addictions is a complex trait with strong genetic influences from family, adoption, and especially twin studies. These genetic factors underlying addiction-related phenotypes can be identified with linkage and association approaches in humans and animal models. This traditional tracing of the defects to particular altered genes is commonly referred to as forward genetics. Many loci with nominally significant linkage to addiction phenotypes have been identified for most common addictions in linkage-based genome-wide scans, typically with genetic markers approximately every 1/300–400th of the genome. The genetic regions identified by linkage analysis are relatively large, at which a gene or genes implicated in addictions may reside in the proximity of the genetic marker. Further effort can be made to refine gene mapping to a single gene or a single genetic variant by the association analysis approach, which employs an increased density of genetic markers such as single-nucleotide polymorphisms

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_9,

(SNPs), the most common form of genetic variation between individuals occurring once several hundred bases or so. Until now, many candidate genes containing allelic variants have been identified as being associated with different addiction phenotypes. Recently, with the aid of the Human Genome Project, International HapMap Project, and chip technology, genome-wide association studies have revealed previously unsuspected genetic components that predispose to substance abuses [9, 55, 78, 79]. Despite these advances, the final proof that a candidate gene association study has truly captured the relevant gene(s) requires a collection of converging evidence drawn from a wide range of genetic and non-genetic analyses. As such, the number and identity of genes that are susceptible to drugs of abuse remain largely unknown.

The expense and limitations inherent in human genetic research have led to an increase in the use of genetic animal models to elucidate the pathways from gene to addiction behavior. Particularly, the mouse is one of the most favorite models because of its smaller size, its relatively low cost of maintenance, a generation time that measures only 9 weeks from being born to giving birth, and a large amount of inbred strains available. [Please refer to the Mouse Genome Informatics at the Jackson Laboratory (http://www.informatics.jax.org) for the inbred strains and their phenotypes.] Genome projects have revealed that mouse and human genome sequences are quite similar. Both mice and humans have approximately 30,000 genes. About 99% of the genes are shared by both species, and only about 300 genes are unique for each species. Moreover, 90% of the genes associated with diseases are identical in the human and mouse. Exploiting synteny between mouse and human disease loci has thus been proposed as a cost-effective method for the identification of human susceptibility genes. Much effort has been undertaken to map genes associated with addictive behaviors (especially alcohol dependence) in mice, using the quantitative trait locus (QTL) mapping approach. Because the addictive behavioral traits in mice are continuous and determined by multiple genetic and environmental factors, each of the genetic factors responsible for such quantitative traits is defined as a QTL. Many QTLs have been identified for drug response phenotypes in mice [7, 59, 77], and a significant convergence between these QTLs in mice and those from human genome-wide association studies of dependence on various addictive substances has also been revealed [77], further indicating that the genetic discovery in mice can be extended to human population studies for confirmation, and vice versa.

Classic forward genetic analyses are performed by observing a phenotype, designing the necessary cross-matings, and using the resulting population to perform statistically significant experiments to find the mutation and to understand the function of the altered gene. This method has been successfully applied for identifying genes that function in a particular biological process. Recombinant DNA technology and the explosion in genome sequencing have made possible a different type of genetic approach, reverse genetics. Starting with a particular gene with interesting properties, one can proceed to make mutations and create mutant organisms so as to analyze the gene's function in the development or behavior of the organism. Using reverse genetics, one can examine the hypothesis proposed or prove the conclusion drawn from forward genetics. In addition, one can investigate the function of all genes of interest, something not easily done with forward genetics. Thus, reverse genetics is an important complement to forward genetics. However, due to ethical problems, most reverse genetics can only be done in animal models.

A normal gene can be altered in several ways in a genetically engineered organism. (1) In the transgenic approach, the normal gene or its mutant is simply added to the genome. The overexpression of the introduced normal gene or mutant gene overriding the function of the endogenous normal gene may provide useful information about the gene function. (2) In the knockout approach, the normal gene can be disrupted completely, for example, by making a

large deletion within it. The resulting phenotypes in development or behavior of the organism may thus be studied. (3) In the knockin approach, the normal gene can be replaced by a mutant copy of the gene, which may provide information on the activity of the mutant gene without interference from the normal gene. The effects of small and subtle mutations may thus be determined. (4) In the knockdown approach, the engineered genes introduced into the organism can produce antisense RNA, small interfering RNA, short hairpin RNA, or microRNA, which is completely or partially complementary in sequence to the normal gene and can reduce expression of the normal gene. The effects of gene expression reduction may thus be investigated. These powerful approaches of manipulating genes in intact organisms can be combined to examine gene function in the context of the intact organism, such as addictive behaviors.

In this chapter, we provide a brief description of gene targeting technology, including strategies for knockout, knockin, and conditional gene modification. We also provide an overview with some examples of gene targeting applications in reverse genetic studies of drug addictions, demonstrating the power of gene targeting technology in advancing our knowledge of gene functions.

Basics of Gene Targeting

A fragment of genomic DNA introduced into a mammalian cell can locate and recombine with the endogenous homologous genomic sequences but not integrate in any other loci in the genome. This type of homologous recombination is known as gene targeting. The technique was developed in the late 1980s by Mario R. Capecchi [73], Martin J. Evans [41], and Oliver Smithies [21], who shared the 2007 Noble Prize in Physiology or Medicine for their pioneering works. Now, gene targeting has been widely used, particularly in the mouse model, to make a variety of mutations in many different loci so that the phenotypic consequences of specific genetic modifications can be assessed in the organism. In theory, any deletion, point mutation, inversion, or translocation can now be modeled in mice.

The process of gene targeting includes three major steps: (1) generation of a DNA targeting construct; (2) homologous recombination in embryonic stem cells, and (3) production of genetically engineered mice. A simplified schematic illustration of the gene targeting procedure is demonstrated in Fig. 1.

Targeting Construct

A targeting construct is designed to recombine with and mutate a specific target chromosome locus. Typically, a targeting construct contains three components: (1) bacteria plasmid backbone for DNA manipulation; (2) genomic DNA sequences that are homologous to the desired chromosomal site for DNA integration, and (3) positive and negative selection markers for strong recombination selection in embryonic stem cell clone screening.

When a targeting construct is transfected into mammalian cells, it can be integrated either specifically into its target locus or randomly into chromosomal sites. The relative ratio of gene targeting to random integration events depends on a number of factors that cannot be experimentally controlled, such as the location of the target gene in the genome. In most cases, the frequency of random integration is far greater than that of gene targeting, which is only about one in every 10^5–10^6 treated cells. Increasing the efficiency of homologous recombination will thus determine the ease with which targeted embryonic stem clones can be identified in the following screening step and is one of the major concerns in the targeting construct design.

One aspect to affect the targeting frequency is the length and sequence of the homologous sequences in the targeting construct. As a general rule, the greater the length of the homolog, the higher is the recombination frequency; on the other hand, the more difficult

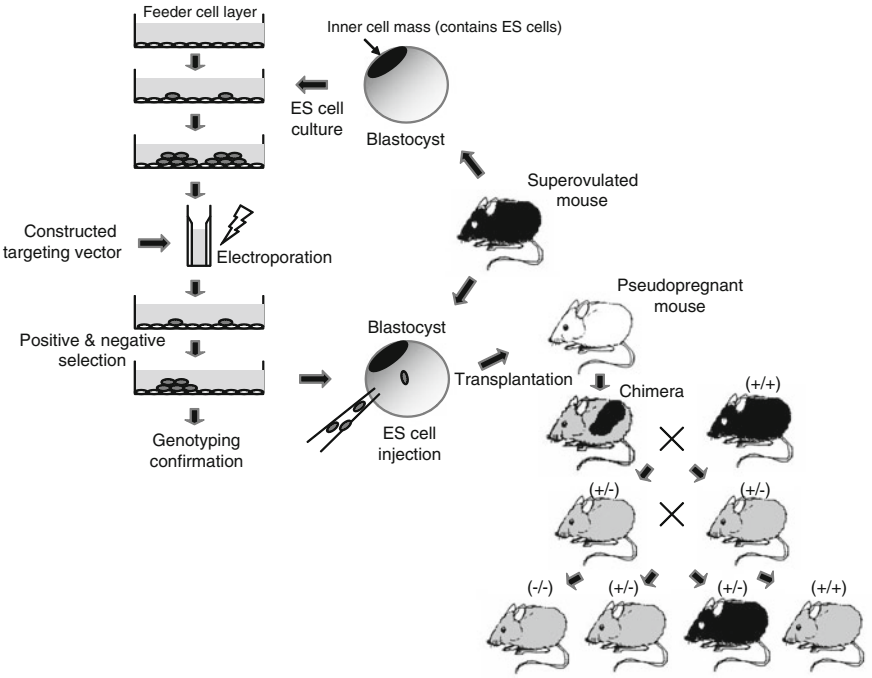

Fig. 1 Schematic illustration of gene targeting procedure. Embryonic stem (ES) cells are isolated from the blastocyst and cultured on the feeder cell layer. The constructed targeting vector is introduced in the embryonic stem cells by electroporation. Embryonic stem cell colonies resistant against positive-negative selection are screened and verified by genotyping. Targeted embryonic stem cells are then injected into the blastocyst, which is then implanted in the uterus of a pseudopregnant mouse. Coat color strategy is often used as an early marker of a successful lineage contribution of the targeted embryonic stem cells. The resulting chimeric mice are mated with wild-type mice to confirm germline transmission. Homozygous mice are finally produced with further breeding of heterozygous mice

are the DNA cloning and manipulation. An ideal length of homolog is recommended in a range of 5–10 kilobases. Additionally, the homologous sequences should be derived from genomic libraries isogenic with the specific line of embryonic stem cells used in the targeting experiment. The existence of sequence mismatches between the homolog in the vector and the target locus will reduce the targeting frequency.

Another aspect to enrich the representation of targeted clones within a transfected population is to apply the positive-negative selection technique, which can significantly reduce the number of embryonic stem clones with random integration. In this selection scheme, the positive marker serves to isolate rare transfected cells that have stably integrated the construct DNA, irrespective of the targeted or random incorporation, whereas the negative marker serves to kill transfected cells that have incorporated the construct DNA at a random location (Fig. 2). Both positive and negative selection cassettes contain a promoter to drive expression of an antibiotic-resistance gene and a polyadenylation signal to terminate efficiently the antibiotic-resistance gene transcription. The commonly used antibiotic-resistance genes for positive selection include the neomycin resistance gene *neo*, puromycin resistance gene *pur*, and hygromycin resistance gene *hyg*. Those for negative selection are the thymidine kinase gene *TK* and diphtheria toxin A gene *DTa*. Since the most common gene targeting is to ablate the function of a target gene, the positive selection marker can also serve as a mutagen, for instance, if it is inserted into the coding exon of a target gene or replaces the coding exon(s).

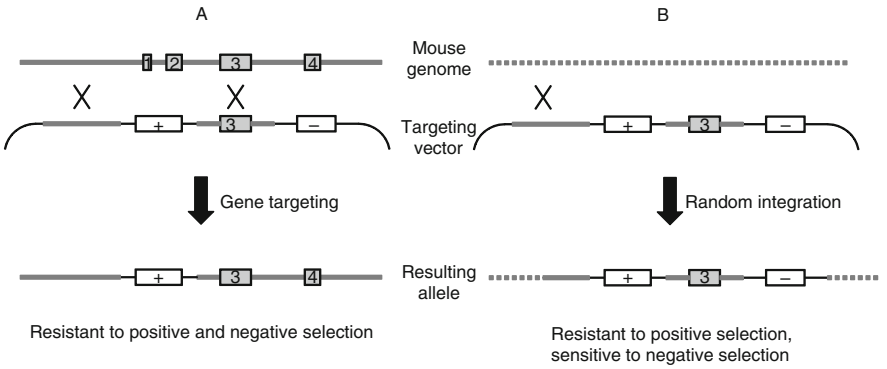

Fig. 2 Illustration of positive-negative selection for gene targeting. *Filled box with number* inside represents an exon of a target gene. *Box with "+" or "–"* inside represents a positive or a negative selection cassette. Both selection cassettes contain a promoter, an antibiotic-resistance gene, and a polyadenylation signal. Thick line represents mouse target genomic DNA; dashed line represents mouse non-homologous genomic DNA, and thin line represents non-mouse DNA. "X" represents an integration site. (**a**) A targeted integration event removes the negative selection marker. (**b**) A random integration event results in inclusion of the negative selection marker

In addition to the selection scheme, screening techniques required to identify the recombined clones by polymerase chain reaction or Southern blotting should also be considered in the design of a targeting construct and tested prior to the embarkment of a targeting project. Most of all, the principal consideration to design a targeting vector is the strategy of gene targeting and the type of mutation to be generated, which will be discussed in detail below.

Manipulation of Embryonic Stem Cells

An embryonic stem cell is an unusual type of cell that has virtually unlimited powers of differentiation. Embryonic stem cells are primarily isolated from the inner cell mass of a mammalian blastocyst [23, 48], which is an early stage of embryonic development comparable to the blastula stage. Murine pluripotent embryonic stem cells have been derived from primordial germ cells [50], epiblasts [11], preblastocyst embryos [72], and blastomeres [16].

Pluripotency of embryonic stem cells can be maintained by culturing them in vitro under conditions where the cells grow and proliferate. The embryonic stem cells are then transfected with a constructed targeting vector, routinely using electroporation. In eletroporation, cells are mixed with DNA in cuvettes containing electrodes that deliver a brief electric pulse. Application of the current causes the plasma membrane to become transiently permeable to DNA molecules, some of which find their way into the nucleus. By mechanisms that are poorly understood but are similar to what occurs during meiosis and mitosis when homologous chromosomes align along the metaphase plane, the engineered targeting construct finds the target gene and recombination takes place within the homologous sequences. The recombination may take place anywhere within the flanking DNA sequences, and the exact location is determined by the cells and not the investigators. Through this procedure, embryonic stem cells that are heterozygous for the target gene are produced (Figs. 1 and 2).

The transfected embryonic stem cells are cultured and grow in the presence of antibiotics for colony selection. In cases when both *neo* and *TK* are used in the targeting vector, neomycin and ganciclovir (or 5-iodo-2′-fluoro-2′-deoxy-1-β-D-arabino-furonosyluracil; FIAU) are added in the culture medium for positive and negative

selection, respectively. Cells without the targeting construct incorporation will often die, because they contain no neomycin resistance gene, as well as cells with the targeting construct inserted randomly in the genome, because they contain an intact thymidine kinase gene. The grown colonies of embryonic stem cells are isolated, screened, and analyzed by polymerase chain reaction and/or Southern blotting to detect the desired homologous recombination in the specific target locus. The average frequency to identify a positive clone is about one in 100–200 colonies, although less than 1/500th is not unusual.

Generation of Gene-Targeted Mice

A number of individual embryonic stem cells from the identified positive clone are taken up into a fine glass micropipette and injected into the blastocele of a recipient early mouse embryo. The recipient embryo is then implanted into the oviduct of a female pseudopregnant mouse that has been hormonally prepared to carry the embryo to term. As the embryo develops in its surrogate mother, the injected embryonic stem cells join and collaborate with the host embryo's own inner cell mass and contribute to formation of embryonic tissues, including the germ cells of the gonads, in favorable cases. Most often, embryonic stem cells are utilized selectively from a strain with a coat color different from the strain that donates the recipient blastocysts. A highly chimeric mouse can be identified by looking at the color of its fur (e.g., mostly brown and only a few black spots). The greater the level of chimerism, the greater the chance that the embryonic stem cell has contributed to the germ cells during embryonic development. The highly chimeric mice are then mated to a member of an inbred strain to produce the heterozygous offspring, which contain one normal and one mutant copy of the target gene in all of their cells. When the heterozygotes, confirmed by germline transmission by Southern blotting or polymerase chain reaction, are in turn bred to one another, theoretically one-fourth of their progeny will be homozygous for the altered gene (Fig. 1). These are the gene-targeted mice.

Gene Targeting and Transgenesis

Compared with the development of gene targeting in the late 1980s, the transgenic technology appeared in the early 1980s, with the first transgenic mouse reported in 1980 [29]. The transgene constructs are microinjected into the pronucleus of the fertilized eggs isolated from the ampulla of the oviduct. The injected eggs are then implanted into the oviduct of a pseudopregnant female. The linearized transgene constructs can randomly integrate into the mouse genome as a single copy or multiple copies (up to 200 in tandem head-to-tail array) by the mechanisms that are not well understood. Transgenic founders are later identified by polymerase chain reaction or Southern blotting, usually around 15–20% among born pups. Although most transgenic founders have the transgene integrated at a single and yet different locus, 10–15% of the founders can have the transgene integrated at 2–3 different loci. Thus, transgene expression is highly variable from one founder to another, due to the copy number of the transgene and the influences of DNA sequences flanking the integration site(s). In contrast to gene-targeted mice, transgenic mice can be generated in a shorter period with relatively lower cost and effort.

The simplest transgenic construct consists of an enhancer/promoter, a transgene of interest, and a polyadenylation signal. The promoter determines when and where the transgene is expressed, either ubiquitously or in a tissue/cell-specific fashion, being constitutive or time-dependent, or even being drug-inducible. The transgene of interest in the transgenic construct is often derived from a cDNA sequence. However, to enhance transgene expression, a

heterologous intron containing a splice donor and an acceptor can be inserted at the 5′ or 3′ end of the transgene to increase mRNA stability and to improve the optimal chromosomal domain [56, 68]. The transgenic construct also contains a pre-engineered heterologous polyadenylation signal such as the rabbit β globin poly(A) to serve as part of the machinery for transcription termination and polyadenylation. In addition to these basic elements, several featured elements could be added into the transgenic vector to facilitate specific transgene expression. The internal ribosomal entry site, an element that allows for translation initiation in the middle of an mRNA sequence, can be introduced to express two transgenes at the same time with only one construct. The chicken 5′ β-globin insulator (cHS4) flanking the transgenic construct can effectively block the tissue-specific position effects and profoundly increase transgene expression in all tissues [61]. A transcriptional stop element can be used as an insulator for conditional transgenesis [43].

The generation of transgenic and gene-targeted mouse models facilitates the in vivo study of mammalian gene function. Combining the transgenic and gene targeting technologies provides investigators with more strategies and the freedom to design an optimal model to study the function of a gene in a specific tissue/cell during development or in postnatal life. As we will mention below, the various transgenic mice of recombinases are crucial for the realization of a variety of conditional gene targeting.

Strategies of Gene Targeting

Gene targeting is a complex technology with many factors and strategies involved. In the following subsections, we introduce some of the strategies for knockout, knockin, and conditional gene targeting. For more extensive coverage and fuller details of gene targeting, we suggest that readers refer to two textbooks about gene targeting [40, 76].

Knockout

The most commonly used application of gene targeting is to inactivate an endogenous gene by replacing it or disrupting it (by insertion) with an artificial piece of DNA, usually the positive selection marker. Homologous recombination allows investigators to remove completely one or more exons from a gene, which results in the production of a mutated or truncated protein or, more often, no protein at all. The phenotypes of knockout mice in appearance, behavior, and other observable physical and biochemical characteristics may thus provide valuable clues about what the target gene normally does, which helps to understand better how a similar gene can cause or contribute to disease in humans.

However, the phenotypes of knockout mice can be very complex because all tissues of the mouse are affected, though it is not uncommon for a knockout mouse to display embryonic lethality (developmentally essential) or to show no phenotype at all (nonessential). In some cases, it is possible that the absence of the gene product is compensated for by the product of another member of a gene family or an entirely different gene. Compensation by one gene for another can then be verified by producing mice that lack both of the genes in question (i.e., a double-knockout).

Knockin

The knockin strategy can be used to generate a site-directed transgene model with an insertion vector or a subtle site-directed mutation model with a replacement vector.

For transgene knockin, the insert is flanked by DNA from a selected non-critical locus, and homologous recombination allows the transgene to be targeted to that specific, non-critical integration site. In this way, the transgene does not incorporate itself into multiple locations, and the genetic environment surrounding the expression cassette is completely controlled. Compared

with the traditional transgenic mouse model, this site-specific knockin is present as a single copy and results in a more consistent level of expression from generation to generation. Because the knockin transgene is not likely interfering with other critical loci in the genome, it will be more certain to elucidate that any resulting phenotype is due to the exogenous expression of the gene. Several loci such as ROSA26 [66], hypoxanthine guanine phosphoribosyl transferase 1 locus [74], and procollagen type I α1 locus [4] have been favored for transgene knockin. Although the generation of knockin mouse does avoid many problems of a traditional transgenic mouse, this procedure requires significantly more time and effort.

For subtle mutation knockin, homologous recombination allows a fragment of DNA to be replaced by the DNA fragment that has been altered in vitro by site-directed mutagenesis without alteration of the rest of the genome. In this way, a single amino acid in an active site of a protein or a single nucleotide in a transcription promoter region of a gene can be changed purposely. As such, the method is quite useful to investigate the variations identified in forward genetic studies that confer susceptibility to human disorders. To get rid of the concomitant presence of an intragenic positive selection marker, the promoter of which often deregulates the targeted gene or the neighboring genes and generates a hypermorph, techniques such as "double-replacement" [67, 81], "hit-and-run" [35], and using the Cre-*loxP* recombinase system (see below) have been developed.

Conditional Gene Targeting

Many genes that participate in interesting genetic pathways are essential for mouse development, viability, or fertility. Therefore, a traditional knockout of the gene (ablation of the gene function) may never lead to the establishment of a knockout mouse strain for analysis. The development of the site-specific Cre-*loxP* and Flp-*FRT* recombination technology allows investigators to modify conditionally the gene of interest in only a subset of tissue/cells or at only a particular time, circumventing lethality (Fig. 3; or refer to an in-depth review [10]). The Cre-*loxP* recombination system is identified from the bacteriophage P1, whereas the Flp-*FRT* system is from *Saccharomyces cerevisiae*. Both *loxP* (*l*ocus *o*f *x*-over in *P*1) and *FRT* (*F*lipase *R*ecognition *T*arget) sites are small, 34-base-pair DNA fragments (8-base-pair asymmetric spacer plus two 13-base-pair inverted repeats) specifically recognized by their particular recombinases, 38 kD Cre (Circularization recombinase) and 48 kD Flp (Flipase), respectively. The pair of elements, recombinase and its specific site, work together to provide versatile tools for in vivo genetic engineering of associated DNA—deletion, insertion, inversion, or translocation. In Fig. 3, we demonstrate a couple of examples using the site-specific recombination systems for conditional gene modification.

Because gene targeting can be modulated both spatially and temporally by controlling the recombinase expression, the function of a given gene can thus be studied in the desired cell types and/or at a specific time point if an inducible promoter is applied for the recombinase expression. This refined genetic dissection with conditional gene modification allows investigators to define gene function in development, physiology, or behavior.

Knockouts in Addiction Studies

Since the development of gene targeting technology, hundreds of mice carrying various null alleles have been generated by disrupting the endogenous genes. A comprehensive and public resource for all publicly available knockout mice is available at the Web site of the KnockOut Mouse Project, a trans-National Institutes of Health initiative (http://www.komp.org or http://www.knockoutmouse.org). Valuable information has been obtained by the analysis of animals carrying these mutations.

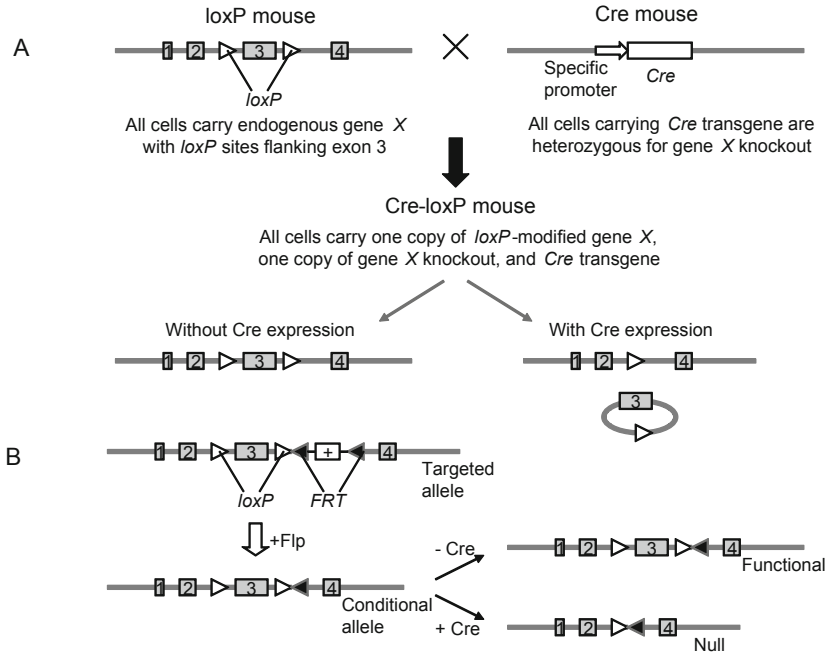

Fig. 3 Conditional gene targeting using the site-specific recombination system. (**a**) Cre-*loxP* recombinase-mediated gene disruption. Two *loxP* sites are inserted on each side of an essential exon (3) of the gene (i.e., *X*) by homologous combination, which does not disrupt gene function. Expression of transgene *Cre* is driven by a tissue/cell-specific promoter designed for temporal and spatial control. The expression of recombinase Cre in the Cre-loxP mouse, produced from the mating of a loxP mouse and a Cre mouse, will result in a deletion of the *loxP*-flanked (floxed) exon 3 with the precise excision at the *loxP* sites. (**b**) Application of both Cre-*loxP* and Flp-*FRT* recombination systems. The positive selection cassette (box with "+" inside) is flanked with two *FRT* sites (flrted) and can be removed by the expression of Flp recombinase, whereas the floxed exon 3 can be conditionally knocked out by the expression of Cre recombinase

Knockout Genes and Addictive Traits

Until now, more than 100 mouse gene knockouts and transgenics have been tested in the alteration of addiction-related behaviors [28]. Most of them have known functions and are suspected to influence addictive traits directly or indirectly. These genes include: (1) receptors and their subunits for neurotransmitters such as acetylcholine, dopamine, inhibitory γ-aminobutyric acid, excitatory glutamate, and serotonin; (2) neuropeptides and their receptors such as neuropeptide Y, substance P, neurokinins, and corticotropin-releasing factor; (3) receptors for other substances such as endocannabinoids and opioid peptides; (4) neurotrophins and their receptors such as brain-derived neurotrophic factor, neurotrophin-3, neurotrophin-4, and Trk receptors; (5) monoamine transporters such as the dopamine transporter, serotonin transporter, norepinephrine transporter, and vesicle monoamine transporter 2; (6) metabolic enzymes for neurotransmitters such as dopamine β-hydroxylase, tyrosine hydroxylase, monoamine oxidase, and catechol-*O*-methyltransferase; (7) metabolic enzymes for drugs of abuse (e.g., alcohol) such as alcohol dehydrogenase and aldehyde dehydrogenase; (8) gene products involved in signaling pathways relevant to addiction such as G-proteins coupled to metabotropic receptors, protein kinase A, protein kinase C, dopamine- and cyclic AMP-regulated phosphoprotein, and cyclin-dependent kinase 5, and (9) transcription factors such as ΔfosB and cyclic AMP-response element binding protein. For the most part,

these genes have been revealed to contribute to the development of addiction to various drugs of abuse [19, 54], indicating their significant roles in the responses to drugs of abuse and the vulnerability for addiction. Recently, knockouts of circadian rhythm genes such as *Period 1*, *Period 2*, and *Clock* have also been shown to be involved in the development of addiction [52], reflecting the diversity of pathways leading to addiction and the complexity of addictive traits.

The knockout mice with ablation of a particular gene product are subjected to a variety of behavioral tests to assess their responses to drugs of abuse. The phenotypic traits most often used in mice to model human addictive behaviors include sensitivity and tolerance to addictive drugs, withdrawal syndrome, locomotor activity, locomotor sensitization, conditioned place preference and/or aversion, voluntary drinking (for alcohol addiction study), self-administration, and conditioned reinforcement paradigms. For details about addiction behavioral tests in rodent models, please refer to the other chapters in this textbook.

Double-Knockout

Almost all drugs of abuse induce increased levels of neurotransmitter dopamine in the mesolimbic circuitry, which has been postulated to be an integral mediator of a reward response causing certain aspects of addiction. The signaling effects of neurotransmitter dopamine are mediated by dopamine receptors in neurons. However, the released dopamine in the synaptic cleft is removed by the dopamine transporter and deposited back into surrounding neurons, thereby terminating the signal of the neurotransmitter. As one of the plasma membrane monoamine transporters, the dopamine transporter is recognized as an important integral protein in the mesolimbic dopaminergic system to facilitate regulation of the dopamine signal.

Cocaine blocks the dopamine transporter by binding directly to the transporter and reducing the rate of transport, thus increasing extracellular dopamine levels. In homozygous dopamine transporter knockout mice ($Dat^{-/-}$), dopamine persists at least 100 times longer in the extracellular cleft [27], demonstrating the critical role of the dopamine transporter in regulating dopamine neurotransmission. However, the mice lacking the dopamine transporter surprisingly express intact cocaine reward in conditioned place preference [65] and self-administration paradigms [62], although the cocaine-induced locomotor hyperactivity is absent [27]. The results indicate that the reinforcing effects of cocaine are beyond the dopamine transporter, although not beyond dopamine, challenging the theory of the dopamine transporter as the major target for cocaine's reinforcement effects. Due to the constitutive elimination of the dopamine transporter, it was suggested that developmental compensatory mechanisms might occur. Other monoamine transporters such as the serotonin transporter and the norepinephrine transporter are most likely to take over the charge, mediating the reinforcing effects of cocaine beyond the dopamine transporter. Subsequent evidence revealed that in the absence of the dopamine transporter, there is greater participation of the serotonin transporter and norepinephrine transporter in cocaine reward. Both serotonin transporter and norepinephrine transporter blockers (fluoxetine and nisoxetine) produced significant conditioned place preference in $Dat^{-/-}$ mice but not in wild-type mice [34]. In contrast to $Dat^{-/-}$ mice, homozygous serotonin transporter knockout mice ($Sert^{-/-}$) have enhanced cocaine reward as assessed in the conditioned place preference paradigm [65]. Similarly, the mice lacking the norepinephrine transporter ($Net^{-/-}$) are hyper-responsive to locomotor stimulation induced by cocaine [82].

To investigate the developmental compensation between monoamine transporters, double-knockout mice have been generated. Whereas the dopamine transporter and serotonin transporter combined double-knockout mice ($Dat^{-/-}$/$Sert^{-/-}$) strikingly eliminate cocaine reward [64], the norepinephrine transporter and serotonin transporter combined

double-knockout mice ($Net^{-/-}/Sert^{-/-}$) display greater increased cocaine reward [34]. These studies bring together evidence that cocaine acts through diverse and not exclusive mechanisms. To explain dynamically cocaine's rewarding and reinforcing effects, several genes in monoaminergic systems, particularly in dopaminergic and serotonergic systems, would need to be investigated.

Knockins in Addiction Studies

Whereas knockout generally disrupts endogenous genes by insertion or replacement, knockin can subtly modify endogenous genes by replacement. As genes that confer susceptibility to human addiction disorders are identified in forward genetics, introducing corresponding mutations into the mouse genome and generating a knockin model will be possible and useful for studying the pathophysiology and treatment of addictive behaviors. We provide below two examples of the application of knockin gene-targeting technology in addiction genetic studies, both of which applied the Cre-*loxP* recombinase system to remove the selection marker (*neo*) for subtle point mutation.

Knockin Mouse Model of Brain-Derived Neurotrophic Factor (BDNF) Met Allele

As the most abundant neurotrophic factor in the brain, brain-derived neurotrophic factor plays established roles in neuronal survival, differentiation, and synaptic plasticity. BDNF exerts its influence in the brain through two receptors: high-affinity TrkB receptor (a tyrosine kinase receptor) and low-affinity p75 receptor. Since BDNF gives trophic support and contributes to the survival and differentiation of midbrain dopamine neurons, the center of the reward system that is activated by most drugs of abuse, BDNF is suggested to be one of the pivotal players in drug addiction. In animal studies, cocaine self-administration and subsequent withdrawal from the drug result in profound long-lasting increases in BDNF within the mesolimbic dopamine system [32]. Infusion of BDNF into the mesolimbic dopamine system dramatically enhances the rewarding effects of cocaine as measured by the conditioned place preference paradigm [37] and self-administration trait [30]. In contrast, injection of antibody against BDNF decreases potently the animal's motivation to work for cocaine [30]. Although homozygous Bdnf knockout mice ($Bdnf^{-/-}$) display profound neuronal loss and often die prior to their third postnatal week, heterozygous knockout mice ($Bdnf^{+/-}$) are viable and display roughly half of the wild-type Bdnf levels [18]. As assessed in the conditioned place preference paradigm and locomotor activity, $Bdnf^{+/-}$ mice are less responsive to cocaine's rewarding and locomotor activating effects [33, 37].

Forward genetic studies have also revealed modest associations of BDNF with substance abuse, including smoking and nicotine dependence [8, 44], methamphetamine and heroin [15, 38], alcohol [51, 75], and others [46, 83]. Specifically, a functional SNP G196A (dbSNP ID rs6265), producing valine (Val)-to-methionine (Met) substitution at codon 66 (Val66Met) of the BDNF prodomain region, has received extensive attention through linkage and association approaches in several psychiatric disorders and measures of cognitive function, in addition to addictive behaviors. A recent meta-analysis restricted to individual case-control studies demonstrated that the Val/Met and Met/Met genotypes of the Val66Met variant in BDNF confer a 21% protective effect in substance-related disorders and increase the risk for eating disorders up to 33%, whereas the homozygous carrier Met/Met has a 19% increased risk of schizophrenia with respect to the heterozygous state [31]. In in vitro neuronal culture studies, the Val66Met polymorphism does not affect mature BDNF function, but it has been shown to alter the intracellular tracking and packaging of the BDNF

precursor (pro-BDNF) and, thus, to affect regulated secretion of the mature protein [14, 22].

Polymorphism Val66Met is found only in humans and is common in human populations with an allele frequency of approximately 18% in Caucasians and approximately 41% in Asians. To address fundamental questions about in vivo consequences of this SNP in humans, Chen et al. generated a $Bdnf_{Met}$ knockin mouse model that reproduces the phenotypic hallmarks in humans with the variant Met allele [13]. Because the transcription of the knocked-in $Bdnf_{Met}$ allele is regulated by endogenous Bdnf promoters, the expression levels of Bdnf in heterozygote $Bdnf^{+/Met}$ and homozygote $Bdnf^{Met/Met}$ mice are similar to those of wild-type controls. Although no difference is observed in constitutive secretion of either $Bdnf^{+/Met}$ or $Bdnf^{Met/Met}$, a significant decrease of regulated secretion in hippocampal-cortical neurons is shown from both $Bdnf^{+/Met}$ and $Bdnf^{Met/Met}$. This decrease of Bdnf-regulated secretion in $Bdnf_{Met}$ knockin mice is somehow comparable to the roughly 50% expression loss of $Bdnf_{Met}$ in heterozygous knockout $Bdnf^{+/-}$ mice, resulting in a significant reduction of hippocampal volume, a significant decrease in dendritic complexity in dentate gyrus neurons, significantly less context-dependent memory, and increased body weight, intermale aggressiveness, and anxiety-related behaviors, as compared with wild-type mice. The results are consistent with human studies reporting that humans heterozygous for the Met allele have smaller hippocampal volume [12, 57, 70], and help to foster the argument of whether the Met allele has significant genetic association with an increased anxiety trait [13, 39, 69].

The majority of BDNF is released from the regulated secretory pathway in neurons [47]. Impaired regulated secretion from $Bdnf^{Met/Met}$ neurons represents a significant decrease in available BDNF, comparable to that in $Bdnf^{+/-}$ neurons. Accumulating evidence on BDNF function suggests that the Val66Met polymorphism may be a critical modifying genetic factor in the expression of a number of normal and abnormal brain conditions. Thus, $Bdnf_{Met}$ knockin mice represent a unique model that links directly the variant of BDNF to a defined set of in vivo consequences. Although the addictive behaviors of $Bdnf_{Met}$ knockin mice remain to be investigated, results from human genetic studies and Bdnf knockout mice suggest that $Bdnf_{Met}$ knockin mice may serve as a valuable model for us to gain a better understanding of the neurobiology of BDNF contributing to addictive behaviors and to identify novel pharmacologic approaches to treating addictive disorders.

Knockin Mouse Model of Nicotinic Acetylcholine Receptor (nAChR) α4 Subunit

The neuronal nAChRs are a family of pentameric ligand-gated ion channels widely expressed in the central and peripheral nervous systems. They are activated by the endogenous neurotransmitter acetylcholine, as well as by nicotine, the primary addictive component of tobacco smoke. Activation of nAChRs can potentiate neurotransmitter release (when expressed at presynaptic terminals) and neuronal excitability (when expressed at postsynaptic terminals) throughout the brain. As a result, nAChRs contribute to a wide range of brain activities that include cognitive functions and neuronal development and degeneration. Nicotine dependence is initiated through the activation of nAChRs. Chronic nicotine exposure produces the long-lasting physiological and behavioral changes associated with addiction, including nAChR up-regulation, gene expression alteration, and long-term potentiation and depression induction at glutamatergic synapses.

Of the heteromeric and homomeric nAChR subtypes formed by 12 nAChR subunits (α2–α10 and β2–β4) identified so far, the highest-affinity and most abundant nicotine binding in the brain is the subtype of nAChR containing α4 and β2 subunits (denoted α4β2*). Compared with wild-type mice, α4 and β2 knockout mice do not

respond with increased release of the pleasure-causing brain chemical dopamine [49, 60], a reaction thought to be a key factor in the development of nicotine addiction, although α4 knockout mice express a higher basal level of striatal dopamine. In addition, β2 knockout mice self-administer cocaine but fail to maintain self-administration when the cocaine is switched to nicotine [60], whereas α4 knockout mice exhibit a prolonged motor activity response to cocaine [49]. Results from both α4 and β2 knockout mouse models suggest that α4β2* nAChRs are necessary for proper regulation of dopamine release and the maintenance of self-administration and reinforcement. In contrast, human genetic analyses in genes *CHRNA4* and *CHRNB2*, encoding α4 and β2 subunits, respectively, detected a significant association of *CHRNA4* [25, 45], but not *CHRNB2* [24, 45, 63], with nicotine dependence in various populations.

The necessity of the α4 subunit in the development of nicotine addiction has been indicated in genetic studies of humans and animal models. To address the question of whether the nAChR with the hypersensitive α4 subunit is sufficient to initiate the addictive behaviors, Lester and colleagues produced α4 knockin mice by point mutations [42, 71]. The substitution of leucine (Leu) with serine (Leu9'Ser) or alanine (Leu9'Ala) within the putative pore-forming M2 domain of the α4 subunit renders the α4* nAChR hypersensitive to nicotine and acetylcholine. However, knockin of Leu9'Ser results in a severe phenotype: perinatal death of animals that carry either a single copy of the dominant *neo*-deleted allele (heterozygote of subtle knockin) or two copies of the *neo*-intact mutant allele (homozygote of knockin containing the *neo* selection marker). The viable *neo*-intact heterozygous α4 knockin mice exhibit increased anxiety, impaired motor learning, excessive ambulation that is eliminated by very low levels of nicotine, and a reduction of dopaminergic function upon aging [42]. In contrast, both homozygous and heterozygous Leu9'Ala animals are viable and fertile in subsequent knockin mice generation. Intriguingly, the genetically modified Leu9'Ala mice are exceptionally sensitive to the effects of nicotine and show dependence-related behaviors, including reward, tolerance, and sensitization, in addition to functional nAChR up-regulation when exposed to nicotine doses that are far too small to cause similar effects in unmodified mice [71]. The results suggest that activation of the α4* nAChR is likely sufficient for nicotine addiction, and the work represents a significant step forward in understanding how nicotine hijacks the brain's normal signaling process. Because of the dramatically increased sensitivity in Leu9'Ala knockin mice, one can selectively and potently activate the α4* nAChR by applying low doses of agonists that do not activate other nAChR subtypes. In view of this, the Leu9'Ala knockin mice represent an excellent model for studies on molecular, behavioral, and pharmacological aspects of nicotine addiction.

Conditional Gene Modification in Addiction Studies

The brain is a complex nervous system with many individual molecules fulfilling distinct functions within neurons and neural circuits, depending on their sites and time of expression. Molecular mechanisms of specific brain disorders such as addiction may be restricted to subsets of neurons at specific time points during development and maturity. Therefore, the complete elimination of a specific gene expression throughout the nervous system with conventional knockout may prove ineffective toward understanding fine molecular processes in higher brain functions. As such, conditional gene targeting, which is able to control gene knockout both spatially and temporally and to circumvent the potential for lethality and developmental perturbations, has become a powerful approach for the refined investigation.

Cre Mice and Conditional Knockout in Addictive Behavior Studies

Many conditional gene targetings have been conducted in the nervous system [26]. Of them, the Cre-*loxP* recombination system is the most popular one applied to control the inactivation of genes of interest. Since Cre expression is crucial for the success of conditional gene modification, a variety of Cre mouse lines expressing Cre recombinase under various promoters have been developed [26] and are expanding rapidly. These promoters driving Cre expression are responsible for the temporal and regional control of the conditional genetic recombination. A definitive Cre mouse database can be found in the Nagy Laboratory's Web site (http://www.mshri.on.ca/nagy/Cre-pub.html).

So far, only a few conditional knockouts have been done to address molecular mechanisms of addictive behaviors. Using the CamKII-Cre transgenic line in which Cre expression is driven by the calcium/calmodulin-dependent protein kinase II promoter, the conditional knockout of the adenosine A_{2A} receptor (*Adora2a*) impaired behavioral sensitization and augmented locomotor responses to repeated amphetamine administration [3]; the conditional knockout of Bdnf attenuated opiate withdrawal reactions [2], whereas the conditional knockout of calcineurin (*Ppp3ca*) maintained the locomotor stimulatory effects of amphetamine [53]. Using the Nestin-Cre transgenic line in which Cre expression is driven by the nestin promoter, the selective inactivation of the transcription factor cyclic AMP-response element binding protein reduced the behavioral expression of morphine abstinence but had no modification of motivational responses to morphine and cocaine [80]; the selective inactivation of the glucocorticoid receptor (*Nr3c1*) flattened the dose-response function for cocaine self-administration and suppressed behavioral sensitization [20], whereas the selective inactivation of neurotrophin-3 decreased somatic symptoms and aversion of opiate withdrawal [1]. In addition, more conditional ablation data have been accumulated in exploring the molecular basis of synaptic plasticity underlying learning and memory processes, locomotion activity, and emotional responses [26], all of which may contribute significantly to our understanding of the complex biological mechanisms underlying drug addiction.

Conditional Knockout of Cyclin-Dependent Kinase 5 (Cdk5)

Cyclin-dependent kinase 5 is a serine/threonine protein kinase that has been implicated as an important player in the cellular and physiological responses to drugs of abuse [5]. It regulates numerous aspects of neuronal function, including cyclic AMP and Ca^{2+} signaling transduction cascades, presynaptic machinery, and synaptic plasticity. In the mesolimbic circuitry involved in reward-motivated behavior, Cdk5 controls dopamine neurotransmission through the regulation of the protein phosphatase-1 inhibitor, dopamine- and cyclic AMP-regulated phosphoprotein, and presynaptic components of dopamine synthesis and release.

Constitutive Cdk5 knockout mice are perinatal lethal and have congenital abnormalities, which hamper the study of Cdk5 function in behavioral paradigms. To generate a Cdk5 conditional knockout mouse model, exons encoding vital Cdk5 catalytic-domain components were flanked with *loxP* elements. When homozygous floxed Cdk5 mice were crossed with a CamKII-Cre transgenic line, the mice losing Cdk5 in the adult forebrain increased the psychomotor-activating effects of cocaine and enhanced the incentive motivation for food. These behavioral changes were accompanied by increased excitability of medium spiny neurons in the nucleus accumbens. When homozygous floxed Cdk5 mice were injected locally in the nucleus accumbens region with the recombinant adeno-associated viruses expressing Cre recombinase, the virus-mediated gene transfer caused region-restricted loss of Cdk5. This regional targeted

knockout of Cdk5 facilitated cocaine-induced locomotor sensitization and conditioned place preference for cocaine [6]. In addition, homozygous floxed Cdk5 mice were crossed with animals bearing an inducible Cre-ERt recombinase transgene under the control of the prion protein promoter. The Cre-ERt is a chimeric protein with Cre recombinase fused to the mutated ligand-binding domain of the estrogen receptor, the activity of which is dependent on the presence of an anti-estrogen, tamoxifen or hydroxytamoxifen [24]. Conditional Cdk5 knockout was then achieved by administration of hydroxytamoxifen, which induces Cre-ERt recombinase activity. It was revealed that conditional knockout of Cdk5 in the adult mouse brain improved performance in spatial learning tasks and enhanced hippocampal long-term potentiation and *N*-methyl-*D*-aspartate receptor-mediated excitatory postsynaptic currents [36]. This example with homozygous floxed Cdk5 mice demonstrated multiple strategies for cell-, region-, and time-specific conditional knockout. The findings from these intelligently designed conditional knockout experiments disclosed significant roles of Cdk5 in the behavioral effects of cocaine, motivation for reinforcement, and learning, memory, and plasticity, which definitely advanced our understanding of the molecular mechanisms underlying addictive disorders and substance abuse.

Summary and Perspective

With the development of the gene targeting approach, genetically engineered mouse models have become increasingly useful for assessing individual genes and genetic polymorphisms contributing to specific behaviors in mice. The technology has provided a very useful alternative to the pharmacological approach to dissecting complex biological mechanisms, and has shown great promise in animal behavioral research. However, attention must be paid to interpreting the behavioral phenotypes relevant to addiction. First, addictive behaviors are complex, may compete with each other, and do not occur in isolation. Thus, it is important to place the focus of analysis on the behaviors themselves rather than allowing a single behavior to represent the complexity of addiction liability. Second, addiction is a complex trait that is not mediated solely by a single gene. Thus, it is important to recognize that the observed behaviors are from the collective effects of multiple genes' interaction in addition to the focused single gene. Third, gene-targeted mice are usually generated on a mixed genetic background. The phenotypic consequences of targeted mutations may be influenced by modifying genes that differ among various inbred strains. In some cases, phenotypic abnormalities have been lost when mutants are bred to a new genetic background [17, 58]. Thus, it is important to use restricted controls with the same genetic background as the experiment group. Also, it is useful to examine the persistence of mutant phenotypes in the context of several genetic backgrounds. Fourth, in constitutive gene targeting, the potential for developmental perturbations is an additional concern. It is somehow difficult to determine whether a mutant phenotype reflects a normal adult role for the gene of interest or an indirect effect of the mutation attributable to perturbed development. Such an effect may lead to over- or under-estimation of the functional significance of the target gene in adult animals.

Translating complex traits into their constituent genetic influences is not an easy task. However, as forward genetic analysis data are accumulating from humans and animals, more and more genes and genetic polymorphisms will be identified with certainty as being associated with various addictive behaviors. Nonetheless, proof of their function will require examination in laboratory animal models. The application of genetic-engineered mouse models not only provides insights into the functional significance of particular genes in neural processes relevant to addictive behaviors, but resembles features of human disorders and provides platforms for the trials of therapeutic prevention and treatment. Fortunately, the pace of development of the relevant technologies in both

forward and reverse genetic studies is accelerating. Genome-wide association studies with millions of SNPs are becoming widespread in addiction genetic research. Combinatorial application of transgenic, gene-targeting, knockdown, and virus-mediated gene transfer technologies with intelligent designs is facilitating the uncovering of neural mechanisms through which mutations alter neural systems to impact addiction behaviors. Such integrated multidisciplinary translational research brings us increasing hope that our converging knowledge of the molecular mechanism underlying addictive behaviors could lead to better therapeutic prevention and treatment of addiction disorders in humans. Of note, although multiple genes are involved in complex disease traits, it may not be necessary to identify all the influential genes to devise novel strategies for prevention and treatment.

Family, Adoption, Twin, and Molecular Genetic Data Each Support Substantial Polygenic Heritability for Addictions

Current models for the genetic architecture for substance dependence in the population are

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_10,

based on information from family, adoption and twin studies that each support substantial heritability for addictions. Twin data, in which concordance in genetically identical monozygotic and genetically half-identical dizygotic twins are compared, also document that most of this heritable influence is not substance-specific. Further, linkage-based (and genome-wide association) studies fail to provide evidence for genes of major effect (e.g., for any single gene whose variants produce substantial differences in addiction vulnerability) for substance dependence.

Support for the idea that vulnerability to addictions is a complex trait with strong genetic influences largely shared by abusers of different legal and illegal addictive substances [60, 128, 131, 138] comes from classical genetic studies. Family studies document that first-degree relatives (e.g., siblings) of addicts display greater risk for developing substance dependence than more distant relatives [89, 138]. Adoption studies find greater similarities between levels of substance abuse between adoptees and their biological relatives than between adoptees and (genetically unrelated) members of their adoptive families [138]. Twin studies consistently show differences in concordance between genetically identical and vs. genetically half identical fraternal twins. These twin datasets provide major support for our understanding of the heritability of vulnerability to addictions [1, 45, 48, 60, 63, 64, 130, 148]. Based on these data, it has been proposed that about 50% of the total addiction vulnerability is heritable.

Twin data also allow us to separate the environmental influences that are shared by sibs from those that are not. Consistent data indicate that the environmental influences on addiction vulnerability that are not shared among members of twin pairs are much larger than those that are shared by members of twin pairs. Thus, e2 > c2 in nearly every such study. Most environmental influences on human addiction vulnerability are thus likely to come from outside of the immediate family environment.

Twin Data Document that Most of this Heritable Influence Is Not Substance-Specific But Provides "Higher Order" Pharmacogenomics

We can also evaluate the extent to which the genetic influences on addiction vulnerability are specific to one substance. Data from studies of identical vs. fraternal twin pairs assesses the degree to which one twin's dependence on a substance enhances the chances of his/her co-twin becoming dependent on a substance of a different class. Results of these analyses document that many of the genetic influences on addiction vulnerability are common to dependence on multiple different substances, although others appear to be substance-specific [1, 63, 131]. These features suggest that many of the genetic influences on vulnerability to addiction are more likely to be related to underlying brain mechanisms that are common to addictions, and that fewer may be specific to the primary pharmacological properties of specific drugs, such as aspects of absorption, distribution, metabolism or excretion.

Elsewhere [135] we have suggested levels of analysis for pharmacogenomics and pharmacogenetics: (1) "primary" pharmacogenomics that describes the genetics of individual differences in the adsorption, distribution, metabolism and/or excretion of a drug; (2) "secondary" pharmacogenomics that describes individual differences in drug targets, such as the G-protein coupled receptors, transporters, and ligand-gated ion channels that are the primary targets of opiates, psychostimulants, and barbiturates, respectively, and (3) "higher order" pharmacogenomics that provide individual differences in post-receptor drug responses. Such post-receptor drug responses are more likely to be common to actions of abused substances that come from several different chemical classes and act at distinct primary receptor or transporter sites in the brain. Based on the twin data that are currently available, we thus postulate that much of the human genetics of addition vulnerability represents "higher order" pharmacogenomics.

Failure to Document Evidence for Substance Dependence Genes of Major Effect in Most Populations

There are few careful studies of the ways in which most human addiction vulnerabilities move through families (e.g., segregation analyses). No such study indicates a "major" gene effect on addiction vulnerability in most current populations. There is an exception: the "flushing syndrome" variants at the aldehyde dehydrogenase and alcohol dehydrogenase loci in Asian individuals do provide genes of major effect in this population. Individuals with these gene variants are at lower risk of becoming dependent on alcohol than individuals with other genotypes [22] in Chinese [23, 126], Korean [117], Japanese [50, 51, 52, 86, 92, 125] and other populations [83, 112]. Homozygous aldehyde dehydrogenase ALDH2*2 individuals are strongly protected from alcohol dependence [50, 51]. This locus thus provides a good example of "primary" pharmacogenomics, though in a restricted population.

Quantity-frequency data for smoking also provide evidence for a replicable "secondary" pharmacogenomic effect of moderate magnitude. Markers in the chromosome 15 gene cluster that encodes the α3, α5 and β4 nicotinic acetylcholine receptors display different allelic frequencies in heavy vs. light smokers in each of several studies [10, 11, 109]. This chromosome 15 locus is likely to provide a good example of "secondary" pharmacogenomics, since it has not been associated as reproducibly with dependence on other substances.

Linkage-based analyses for addiction vulnerabilities would be expected to reproducibly identify many of the genes whose variants exerted major influences on human addiction vulnerability. However, existing linkage data for human dependence on alcohol, nicotine and a number of other substances fails to provide any highly reproducible results that would support any major gene locus ([24, 41, 47, 53, 71, 76, 81, 99, 110, 135, 152] and references therein). These results appear to point to a negative conclusion: that no locus individually contributes a large fraction of the vulnerability to dependence on any addictive substance in most individuals. There are caveats. Many of these data come from subjects with largely European ethnic/racial backgrounds [9, 12, 28–31, 34, 40, 47, 97, 100, 101, 106, 108, 113, 150, 152]. Rare variants might well contribute disproportionate amounts to the vulnerability of individuals within a relatively few pedigrees. Nevertheless, as with many complex human disorders in which initial hopes for a easier (e.g., oligogenic, caused by variants in only a few genes) underlying genetic architecture supported use of linkage approaches, the linkage peaks that are identified in each individual study may be more likely to arise on other bases when the underlying architecture is, in fact, polygenic [46].

Current Models for the Genetic Architecture of Human Dependence

Our current understanding of the genetic architecture of vulnerability to dependence on legal and illegal addictive substances in the population is thus that each is influenced roughly 50% by polygenic genetic influences, that is by variants in individual genes that each contribute modest amounts to this overall genetic vulnerability. These models for genetic architecture indicate that many of these genetic vulnerabilities increase risk for addcition to several pharmacologic classes of abused substances, but that some of these genetic influences are specific to drugs of one class [135].

Analyses of twin data for vulnerability to develop dependence on a substance fit with large additive genetic components (a^2), large components for nonshared environmental influences (e^2) and small components for c^2 terms that represents familial or other environmental influences that are shared between members of the twin pair [1, 45, 48, 60, 63, 64, 130, 148]. What about the possibility that there could be large interactions between these genetic and environmental terms (G × E interactions)? Such large

interactions might even reduce the validity of additive models for genetic and environmental contributions to addiction vulnerabilities.

G × E correlations of three types have been described [98, 111]. In one terminology, "passive" G × E correlation occurs when parents transmit both genetic and environmental influences on a trait [84, 103]. "Active" G × E correlation occurs where subjects of a certain genotype actively select environments that are correlated with that genotype. "Reactive" G × E correlation occurs when an individual's genotype provides different reactions to stimuli that come from the environment. Small values for c^2 influences of common environments shared by members of sib pairs appear to provide evidence against "passive" G × E correlations. "Active" and "reactive" G × E correlations remain possible. One influential train of thought [35, 103] suggests that G × E correlations are best regarded as parts of the genetic variance because "... the non-random aspects of the environment are ... consequence(s) of the genotype(es)...".

Large interactions between genetic and environmental components would be likely to lead to differences in estimates of heritability from samples obtained in different environments and to differences in molecular genetic findings in individuals from different environments. As we have noted, data from studies of twins who were sampled from a number of different environments is nevertheless similar. Such convergence supports relatively modest G × E interactions between genetic and environmental influences on addiction vulnerability, at most. Modest G × E influences are also consistent with genome-wide association molecular genetic results that identify substantial overlaps between molecular genetics of vulnerability to dependence on illegal substances in samples from substantially different environments, such as the United States and Asia (see below).

Gene—gene interactions (G × G) of some magnitude appear likely, a priori, to make at least some contributions to addiction vulnerability. However, if there were large amounts of epistasis, G × G interactions in which specific alleles at one gene locus are required for expression of the effects of allelic variants at a second gene locus, segregation analysis data might provide uneven patterns of familiality. With large amounts of epistasis, second-degree relatives (e.g., cousins) of addicts would be much less likely to display specific combinations of G × G alleles than first-degree relatives (e.g., siblings). Substance dependence rates would thus drop more precipitously between first- and second-degree relatives of addicts than they would if most risk alleles exerted largely independent effects on addiction vulnerability.

There in only a modest amount of family data that allows us to compare concordance in first- vs. second-degree relatives. However, the existing evidence does not support less concordance in second-degree relatives than we would anticipate based on the observed concordance in first-degree relatives and the assumption that most risk alleles produce largely independent effects ([15] and T. Thorgeirsson et al. (2008), "personal communication").

The Genetic Architecture for Substance Dependence in Individuals

What about the genetic architecture for substance dependence in individuals? Both "between-locus" heterogeneity and "within-locus" heterogeneity are likely. Polygenic models for addiction vulnerability imply that each dependent individual might even display a nearly distinct set of risk-elevating or risk-reducing allelic variants. As an illustrative example, we might postulate that (a) an individual must display at least 75 risk alleles to significantly elevate his likelihood of acquiring a substance dependence disorder and (b) there are 300 genes that contain common allelic variants that can augment addiction risk. Under such circumstances, it is easy to see that the exact genetic recipe for addiction vulnerability found in one addicted individual might be replicated in only a relatively few other addicted individuals.

Such an underlying genetic architecture would be consistent with the failure of linkage-based methods to provide reproducible results in addictions, since linkage relies on identifying consistent patterns in the ways that specific DNA markers and phenotypes move through many families that display high densities of the disorder.

As noted above, the best documented genetic heterogeneity for addictions comes from the chromosome 4 major gene effects found in poorly alcohol-metabolizing ("flushing") Asian individuals [50, 51, 52, 83]. The best documented substance-specific influence comes from the chromosome 15 nicotinic acetylcholinergic receptor gene cluster. There are likely to be other examples of between-locus genetic heterogeneity and of genes whose variants exert substance-specific effects on use and/or dependence that have yet to be elucidated.

We also postulate that within-locus heterogeneity is likely, though not yet clearly documented in addiction, to our knowledge. Many common Mendelian disorders and rarer Mendelian phenocopies of common disorders display substantial heterogeneity within their pathogenic loci [32, 121]. Evidence for within-locus heterogeneity in complex disorders is just beginning to be accrued; such evidence now includes data from neurexin gene family variants in autism [2, 3, 4, 122].

"Epigenetics" and Individual Differences in Vulnerability to Addiction and Related Phenotypes

"Epigenetics" is now used with both classical and a more recent definitions. Classical defintions of "epigenetic" emphasize influences of variations that are not encoded in primary DNA sequence but nevertheless inherited "... a change in the state of expression of a gene that does not involve a mutation, but that is nevertheless inherited in the absence of the signal (or event) that initiated the change" [105]. More recent definitions of "epigenetic" emphasize gene regulatory mechanisms that do not alter primary DNA sequence while paying less attention to documenting heritability [105].

In the context of this chapter, heritable epigenetic influences are most relevant. One example of a classical, heritable epigenetic influence is imprinting. Imprinting conveys information from parent to child through mechanisms that include DNA methylation or histone acetylation. These mechanisms retain the primary DNA sequence but can dramatically alter function of specific genes. DNA methylation at CpG sequences in the promoter regions of genes can profoundly alter gene transcription. Since methylation during the course of maternal oocyte (or paternal sperm) development is key to this process, familial patterns of gender-specific transmission can provide evidence for this subset of heritable epigenetic influence.

The modest quality of current family datasets for addiction renders them a relatively weak basis for any strong inferences concerning parent-of-origin effects. Nevertheless, there is no segregation data of which we are aware that supports strong parent-of-origin effects on substance dependence. Thus, while there are obvious and large roles for nonheritable "epigenetic" influences in the biology of addiction, there is no current compelling evidence that there are any strong effects of overall heritable "epigenetic" influences, as classically defined. We nevertheless need to be alert for such influences as we unravel effects of variants in specific genes.

The Nature (and Likely Evolutionary Sources) of the Allelic Variants Likely to Contribute to Individual Differences in Vulnerability to Addiction and Related Phenotypes

A number of the assumptions about genetic architecture and analytic strategies for identification of the individual allelic variants that predispose to addiction vulnerability are based

on the idea that common disease/common allele models hold for many of the variants that alter vulnerabilities to addiction and related phenotypes [72]. Rare variants may also explain significant fractions of the genetic risk for addiction and other common diseases. However, increasing evidence supports roles in addiction vulnerability for allelic variants that are currently common and are thus likely to be "old" in an evolutionary sense. Data indicating that such variants can be identified in diseased individuals from European, African, and Asian genetic backgrounds also point, in general, to variants of substantial age.

Our current understanding of human history increasingly points to long periods when most humans lived in Africa in relatively small groups that remained in relative genetic isolation from each other for many millenia [7]. Such small groups can be viewed as "competing" with each other to provide the ancestry of most modern humans within and outside Africa.

In thinking about how genetic selection might act on common functional allelic variants, it is thus important to consider how selective processes might act in early African environments of small groups of humans. No study of these early environments finds any strong evidence for the presence of any potent addictive substance, to our knowledge. We thus need to consider the ways in which selective proceses might have operated in the absence of both addictive substances and in the absence of selective evolutionary pressures that can be attributed to use of addictive substances.

As one starting point, it is conceivable that some currently common allelic variants could exert polygenic influences on addiction vulnerability without exerting any significant positive or negative selective effects during lengthy evolutionary histories. However, most such neutral variants would be expected to display evidence for genetic drift and related stochastic mechanisms that would provide fixation for their alleles long before current human populations were born (e.g., one allele would disappear on stochastic grounds).

It thus also seems likely that many allelic variants that influence addiction vulnerability must have provided balancing selection. Balancing selection provides one of the few theoretical means for maintaining common allelic variants over extended periods of time. "In the era of molecular population genetics, … balancing selection (refers to) loci (that display) levels of nucleotide polymorphism that exceed neutral expectation" [91]. We think of balancing selection as providing influences that are favorable in some individuals or organs or circumstances and unfavorable in other individuals or organs or circumstances.

Thinking about such balancing selection could have several consequences:

(1) First, the biology of some genes might allow for common, functional allelic variants that could escape selective pressures or exert balancing selection over many generations. By contrast, other genes might not be able to harbor such allelic variations without engendering selective pressures that would reduce the frequency of all but one of the allelic variants in the population over time.

    Common allelic variants that are able to influence addiction vulnerability are thus likely to be restricted to a subset of the genes whose products are involved in addictive processes. An important consequence of this logic follows: if a gene fails to display variants that influence vulnerability to addiction, the gene's products are not at all excluded from involvement in addiction.

(2) Secondly, the nature of balancing selection suggests strongly that addiction vulnerability alleles that display great evolutionary ages were likely to experience both positive and negative selection pressures that "balanced" based on their effects on other pheotypes, not addiction. Below, we summarize some of the current evidence that many addiction-vulnerability allelic variants might provide "pleiotropic" influences on a variety of related, heritable phenotypes.

In the context of this evolutionary discussion, balancing selection thus requires that an allelic variant influence a phenotype that can be subjected to balancing selection pressures in the absence of addictive substances. Put in another way, convincing data that implicates a gene's common variants in addiction should prompt us to consider mechanisms whereby such variants might provide balancing (e.g., both positive and negative) selective influences in the differing environments through which the ancestors of current human populations have passed.

It is important to note that this logic is different from the logic of many other brain disorders that: (1) are also influenced by complex genetic determinants, but (2) which lead to reduced fertility in current populations and are thus likely to have provided substantial negative selection pressures in older environments [54]. Such logic would lead to the conclusion that more "newer" allelic variants would be identified for these disorders.

How does this discussion of common disease/common allele hypotheses relate to the postulates of genetic heterogeneity noted above? None of the above discussion about common alleles and common variants precludes (or even reduces the likelihood of) contributions of rarer (or even "private") allelic variants, including those that have arisen more recently in evolutionary time. Recently arising variations would be much more likely to persist for a number of generations even in the face of even moderately negative influences on survival or fertility. Indeed, based on experience with other genetic disorders, it may be worthwhile to actively search for effects of rarer "phenocopy" variants in genes that are initially identified based on common (and evolutionarily older) allelic variants [124]. A rarer copy number variant might contribute to addiction vulnerability by altering levels of expression of a gene that also contains more common allelic variants that alter expression via SNPs in other gene elements, for example [2–4, 122]. Such considerations support searches within identified loci for molecular genetic heterogeneity relevant to addiction.

Genome-Wide Association Results for Addiction

Genome-Wide Association

Genome-wide association is now increasingly the method of choice for identifying allelic variants that contribute to complex genetic disorders, especially those with polygenic genetic bases (e.g., derived from effects at many gene loci, each with modest effects, as well as from environmental determinants) [6, 11, 25, 33, 37, 42, 75, 114, 144]. Substance dependence was one of the first complex phenotypes for which replicated association-based genome scanning data was reported [11, 56, 78, 79, 127, 141]. There is now a torrent of information from genome-wide association studies of both substance dependence and other heritable brain-based phenotypes that co-occur with addictions more than expected by chance and are thus good candidates to display genetic overlaps with addiction (reviewed in [136]). Genome-wide association (also termed "whole genome association" or "association genome scanning") [11, 58, 78, 79, 109, 137, 139, 140, 141, 144] asks how addiction phenotypes and genetic markers (genotyped approximately every 1/500,000th to every 1/1,000,000th of the genome in current datasets) are found together in nominally unrelated individuals (although we are all distantly related to each other, of course). We and others have developed these methods, relying on the increasing densities of single nucleotide polymorphism markers that can be assessed using "single nucleotide polymorphism chip" microarrays of increasing sophistication [58, 78, 79, 137, 139, 140, 141]. Genome-wide association gains power as densities of genomic markers increase. Association identifies much smaller chromosomal regions than linkage-based approaches. Association thus allows us to identify variants in specific genes rather than in large chromosomal regions. Genome-wide association fosters pooling strategies that preserve confidentiality and reduce costs, as we discuss below [16, 17, 18, 58,

78, 79, 87, 88, 95, 115, 141]. Genome-wide association provides ample genomic controls. Proper genomic controls can minimize the chances that disease vs. control differences are confounded by occult stratification, such as the stratification that might arise from unintended occult ethnic mismatches between disease and control samples.

It is important to note that there is no single approach to designing genome-wide association studies or to analyzing genome-wide association data is now universally accepted. There is now no universal standard for considering genome-wide association results "significant" in ways that allow us to identify polygenic allelic variants in reasonably sized single experiments.

In analyzing data from addiction vulnerability samples, we focus here and in a recent review [136] on clusters of genomic markers whose allele frequencies distinguish control individuals from those with substance dependence or addiction-related phenotypes. We identify chromosomal regions that contain clusters of such nominally positive results in replicate samples for addiction vulnerability. We then describe evidence for generalization that arises from identification of overlapping chromosomal locations of clustered positive results for different phenotypes. These data thus support pleiotropic influences (e.g., contributions of the same allelic variants to multiple phenotypes) of common allelic variants on several of the brain-based phenotypes. The data thus document overlapping heritable influences on several interesting brain phenotypes.

In the analyses presented in this chapter, we focus on addiction-associated allelic variants that lie in genes. Evolutionarily old common haplotypes (e.g., groups of nearby variants that travel together through generations) that lie within genes are among the most likely to be tagged by single nucleotide polymorphism markers that are represented on current microarrays. Haplotypes that involve genes are thus among the most likely variants to exist in currently reported datasets. It seems reasonable to postulate that many of these allelic variants that lie within genes provide regulatory variants that alter expression or regulation. Other variants are likely to alter mRNA halflives or mRNA splicing. Variants that alter mRNA splicing could occur at the locus of the affected gene (*cis*) or at genes at different loci that alter generic mRNA splicing processes (*trans*). Reproducible association of A2BP1 gene variants with addiction vulnerability, for example [78], provide a good candidate for *trans* effects on mRNA splicing, since this gene's product regulates splicing and thus are likely to modify the functions of a number of other genes expressed in brain. It seems likely that only a minority of the addiction-associated variants will involve missense effects on expressed proteins.

It also seems likely that many addiction-associated variants will lie outside of genes, at least as we currently understand them. Loci reproducibly associated with diabetes/body mass, for example, lack conventional hallmarks of "genes", such as expressed sequences [37]. While the analyses in this chapter focus on the identification of variants within genes, we should also remain alert for roles for "intergenic" variations in chromosomal regions that lie between currently understood genes.

Samples for Genome Studies of Human Addiction Vulnerabilities and Related Phenotypes

As we have recently reviewed [136], genome-wide association data for addiction vulnerability samples from European, African and Asian genetic heritages is now available. As of this writing, these data come from European-American research volunteers, African-American research volunteers, Asian individuals who largely presented to emergency facilities with methamphetamine psychosis and matched controls, dependent and non smokers, largely of European ancestries and individuals sampled as parts of epidemiological studies.

These data can be compared to data from four studies of individuals of European ancestries

with bipolar disorder compared matched controls, individuals of European ancestry who were assessed for ratios between frontal and intracranial brain volumes based on magnetic resonance imaging scans, smokers of European ancestry who participated in clinical trials for smoking cessation, African-American individuals who participated in tests of cognitive ability, individuals of European ancestry with Alzheimer's disease and individual of European ancestry studied for personality triats.

Substance Dependence vs. Controls

Substance dependent individuals, when compared to control individuals, reproducibly display association signals of modest sizes that identify genes. Monte Carlo simulations provide a basis for assessing how often there reproducible association signals might be found by chance. In comparison of the data from a number of samples, these simulations identify convergent data that is virtually never found by chance (reviewed in [136]).

These analyses provide some of the strongest molecular genetic support for the classical genetic studies of addiction vulnerability. They also provide substantial support for the idea that many of the allelic variants that predispose to addiction vulnerability are evolutionarily "old", since strongly convergent findings are found in comparing substance dependent to control individuals of European-, African- and Asian genetic backgrounds. These analyses also provide support for the idea that dependence on substances of different classes is influenced by substantially overlapping genetic influences. We have identified overlaps that are much greater than chance for dependence on a number of illegal substances (including methamphetamine), alcohol and nicotine (reviewed in [136]). None of the results that compare substance dependent vs. control individuals identifies any gene's allelic variants that appear to provide large effects. These observations are consistent with the failure of linkage-based studies for substance dependence to identify any highly reproducible loci, even though similar *Diagnostic and Statistical Manual of Mental Disorders* and Fagerstrom diagnoses were used for linkage.

We list some of the genes that are identified by these reproducible findings in Table 1. While the nature of these genes is likely to be complex for many readers of this chapter, it is worth noting that many of these genes' products are expressed in the brain and that many are likely to be involved with the ways in which the brain forms and adapts during adulthood. These genes thus fit with the memory-like components that are clinically observed as major parts of addiction, as we have reviewed elsewhere [135].

Genome-Wide Association Results for Other Heritable Phenotypes that Co-Occur with Addiction and Display Overlapping Molecular Genetic Findings

Phenotypes that Might have Contributed to Balancing Selection of Addiction-Related Alleles

It is interesting to speculate about the phenotypes that may have provided the basis for balancing or other selective processes for the common allelic variants that are observed in several current populations and influence vulnerability to substance dependence in current environments. Heritable, interrelated influences on cognitive abilities and brain volumes, especially of the frontal lobe, provide interesting examples of such phenotypes. Both of these phenotypes are substantially heritable in data from twin studies. The heritability of both of these phenotypes is substantially correlated in twin study data. Samples of substance dependent individuals, though of modest size, reproducibly display smaller frontal lobes and poorer performance on tests of cognitive function. It is easy to see how cognitive function might have provided a selective

Table 1 "Cell adhesion" and "drug target" genes identified in multiple genome-wide association studies of addiction and related disorders

Chr	Base pair	Gene symbol	Description	Samples with clustered positive SNPs (from [136])	Monte Carlo convergence p value

Columns list gene symbol, gene description, chromosome, basepair of gene start, samples in which clustered nominally positive single nucleotide polymorphisms (SNPs) are found and overall p value for this gene in this entire dataset, based on 100,000 Monte Carlo simulation trials. Note that genes that are identified strongly in a single sample will not be included on this list. Sample numbers are: 1–6 substance dependence, 7–9 bipolar disorder, 10–11 brain volume, 12–14 success at quiting smoking, 15–16 cognitive abilities, 17 neuroticism

Adapted from Uhl et al. [136]

pressure. When we consider the substantial mortality that cephalopelvic disproportion is likely to have caused in the environments in which our distant ancestors lived, it is easy to develop a plausible "balancing selection" hypothesis.

We have identified substantial, reproducible data for both of these phenotypes from genome-wide association datasets, and identified large overlaps between the genes identified on the basis of cognitive abilities vs. the genes identified on the basis of frontal lobe brain volumes, as expected (reviewed in [136]).

Interestingly, there is also significant overlap, more than expected by chance, between these sets of genes and those identified in comparing addicted vs. control samples (reviewed in [136]).

Personality traits that display substantial evidence for heritability are also found in substance dependent individuals at rates different from those in the general population [26]. A genome-wide association dataset for the most addiction associated personality feature, neuroticism, displays highly significant overlap with data for substance dependence as well.

Psychiatric and Neurologic Comorbidity

Data for the highly heritable psychiatric diagnosis, bipolar disorder, is now available from four largely independent samples from European ancestries. Our clustering analyses for these datasets provide ample evidence of overlap between the results for bipolar disorder (59). Interesting, these data also overlap with the molecular genetic results for substance dependence to extents greater than chance.

Success in Smoking Cessation

Twin studies support the idea that at ability to successfully quit at least one of the major addictive substances, tobacco smoking, is substantially heritable (reviewed in [136, 140]). Much of this heritability apparently is not the same as the heritability for vulnerability to substance dependence, although some does overlap. We have recently reported genome-wide association analyses of three datasets of smokers who were successful vs. unsuccessful in quitting smoking in the context of a clinical trial. These results display gratifying convergence with each other and more modest, but still significant, overlap with results from vulnerability to become substance dependent, as would have been predicted by the results of classical genetic studies.

Failure of Control Experiments to Support Alternative Hypotheses for the Observed Genome-Wide Association Results

There is also no evidence that many of the clustered, reproducibly positive single nucleotide polymorphisms identified in these data cited above and a number of control comparisons, including controls for occult racial/ethnic differences and assay noise within each comparison group.

Ethical Issues in High-Density Genotyping of Individuals Who are Selected Due to Self-Reported Illegal Behaviors

Individuals who are individually genotyped in relationship to addiction and related phenotypes are subject to a number of potential risks. Some of these risks are shared with individuals who are subjected to high-density genotyping in relationship to other disorders and phenotypes. Other risks are more likely to come to the fore in studies of illegal behaviors.

Concerns relating to insurability, employability, paternity determination and providing (or not providing) genotyped individuals with

access to their genotypes and/or genetic counseling are shared by individuals with other complex disorders [70, 82, 147]. Recent passage of genetic nondiscrimination legislation in the United States mitigates several of these concerns.

However, as we review elsewhere [136], high-density, individual genotyping of DNA from individuals who are addicted to illegal substances raises additional issues. Many of these individuals are likely to have experienced involvement in criminal activities that goes beyond use of illegal substances. Since the risks of high-density individual genotyping in this population have not been as generally discussed elsewhere, we provide several lines of information that may inform thinking about these special ethical issues.

Increasingly ubiquitous DNA testing related to criminal activities lies at the heart of these concerns. In the United States, each state has a DNA database that collects information from crime scenes and from offenders convicted of particular offenses. A combined DNA index system (CODIS) operates local, State, and national DNA profile databases from convicted offenders, unsolved crime scenes and missing persons. Numerous suspects have been identified through matches between DNA profiles from crime scenes and profiles from convicted offenders. A relevant website reports that the "success of CODIS is demonstrated by the thousands of matches that have linked serial cases to each other and cases that have been solved by matching crime scene evidence to known convicted offenders". The European Union is just one of the other international entities with a similar system (http://www.interpol.com/Public/Forensic/dna/dnafaq.asp).

"Core" CODIS data comes from genotypes at 13 simple sequence length polymorphic loci. These loci lie near single nucleotide polymorphism markers that provide information about virtually all of these loci, providing a ready means of translating between single nucleotide polymorphism and simple sequence length polymorphic genotypes. Other mitochondrial, sex chromosome and autosomal markers are also genotyped on substantial numbers of these DNA samples.

A recent, October 2007 analyses of the CODIS-linked DNA index system revealed individually identifying genotype profiles for more than 5 million convicted offenders, as well as almost 200,000 DNA profiles from crime scenes (www.fbi.gov/hq/lab/codis/).

Classes of Genes that are Identified in Multiple Genome-Wide Association Samples for Multiple Phenotypes: Focus on Cell Adhesion-Related Genes

One approach to describing the convergence between the datasets, presented above, relies on the overall convergence between the results obtained in each study. A different approach focuses on convergence of data concerning specific genes and classes of genes, especially when most are expressed in the brain. Many of the genes that we identify in this analysis of convergent genome-wide association findings are involved in "cell adhesion" processes whereby neurons recognize and respond to features of their environments that are important for establishing and maintaining proper connections (Table 1). Others are involved in enzymatic activities, protein translation, trafficking and degradation; transcriptional regulation, receptor, ion channel and transport processes, disease processes and cell structures.

Cell Adhesion-Related Genes

The genes whose products are involved in cell adhesion processes provide a number of especially interesting results (Table 1). Cell adhesion mechanisms are central for properly establishing and regulating neuronal connections during development. Cell adhesion mechanisms can play major roles in mnemonic and other

neuroadaptive processes in adults [8, 145]. It is interesting to note that most of the cell adhesion related genes that we identify in these genome-wide association studies are expressed in developing and adult brains. Altered expression of several of these genes can alter neurite extension [21, 38, 62], activate signaling pathways [27, 55, 57, 66, 96, 149] and alter mnemonic processes [62]. Almost all of these cell adhesion-related genes are expressed in memory-associated brain regions that include hippocampus and cerebral cortex (http://brainmap.org) [65, 69, 74, 123]. By contrast, substantial expression in mesolimbic/mesocortical dopamine "reward system" neurons is not documented for many of them.

"Cell adhesion" related genes identified by these genome-wide association studies encode members of several structural cell adhesion molecule subfamilies. Those that are anchored to cell membranes by glycophosphoinositol anchors, those that display apparent single-transmembrane topologies, those that display apparent seven transmembrane topologies and those that produce soluble products are each represented.

Cell Adhesion Molecules with the Strongest Levels of Cumulative Support

One of the cell adhesion molecules that achieves the most striking nominal p values in these analyses is an "atypical" member of the cadherin gene family, CDH13. Cadherin 13 is a glycophosphoinositol-anchored cell adhesion molecule. CDH13 is expressed in neurons in brain regions that are likely to play roles in addiction, including hippocampus, frontal cortex, and ventral midbrain [123]. CDH13 can inhibit neurite extension from select neuron populations [38, 123] and activate a number of signaling pathways [55, 57, 66, 96]. It is thus a strong candidate for roles in brain mechanisms important for both developing and quitting addictions.

Other cell adhesion related genes that manifest intermediate p values in these analyses include BAI3, CLSTN2, CNTNAP2, CSMD1, CTNNA2, DAB1, DSCAM, NRXN1, PTPRD and SGCZ. Data from NRXN1 associations in smoking have been recently reviewed [93]. We discuss several of the other genes here.

DSCAM

DSCAM is a single-transmembrane domain cell adhesion molecule with immunoglobulin and fibronectin domains that is expressed strongly in brain [5, 149] and in hippocampus in ways that are required for appropriate neuronal connections to form in memory-associated circuits in model organisms [21, 62]. Different dendritic processes of the same neuron do not often cross each other; this self-avoidance mechanism depends on expression of a large array of tightly regulated DSCAM isoforms [39, 146]. Simplifying this repertoire substantially disrupts appropriate formation of neuronal networks *in vivo* [49]. Indeed, flies with altered DSCAM expression display altered memories for both rewarded and punished behaviors [62].

CLSTN2

CLSTN2 contains allelic variants that are identified in genome-wide association studies of individual differences in memory and executive function as well as the cognitive ability/Alzheimer's disease vulnerability and frontal brain volume phenotypes reviewed here [67, 77]. CLSTN2 is expressed in frontal cortex and hippocampus [74]. CLSTN2 is well-positioned to provide calcium-dependent cell adhesion functions in the brain regions that include hippocampus and in the postsynaptic densities where it is highly expressed. The structure and expression of CLSTN2 make it a good candidate to function as a single transmembrane domain

cell adhesion molecule in which variants could alter the ways in which neuronal and synaptic connections develop, the ways in which they are maintained and reorganized in adult brains or both.

DAB1

DAB1 interacts with and participates in signaling from several cell adhesion molecules. DAB1 has long been identified with signaling through the cell adhesion molecule reelin in ways that alter formation and maintenance of neuronal processes [85]. More recent evidence also supports roles for DAB1 in signaling through other cell adhesion/cell regulatory mechanisms, including those that utilize the amyloid precursor protein cell adhesion molecule [151]. DAB1 expression in many brain neurons includes those in hippocampus and mid to deep cerebral cortical layers [74] (http://brain-map.org). Mice with DAB1 disruption display substantial alterations in cerebral cortical development accompanied by gross motor and other behavioral phenotypes [116].

BAI3

BAI3, a seven transmembrane domain cell adhesion molecule, as well as PTPRM, a single transmembrane receptor tyrosine kinase that mediates homophilic cell recognition and is supported at a more modest level of statistical confidence, are both expressed in vasculature [61, 68]. Identifying these genes fits with the idea that control and regulation of angiogenesis and vascular functions plays important roles in determining the richness of cerebral cortex and other areas of adult brains [61] in ways that have consequences for a variety of interesting brain-based phenotypes. In addition, there is substantial neuronal expression of PTPRM in cortical and cerebellar cortical neurons [68, 74].

PTPRD

PTPRD is expressed in brain, and displays prominent hippocampal expression. Its extracellular ligands have not been elucidated, though it can bind to liprin [94]. PTPRD knockout mice display altered hippocampal long-term potentiation and spatial learning [133], which fit well with the human phenotypes related to cognitive function. Mice with deletions of both PTPRD and a related PRP sigma (but not with either knockout alone) die at birth due to failure to innervate appropriately [132]. SCGZ participates in protein complexes with cell adhesion-like [19]. High levels of SGCZ expression in the brain are confirmed by Allen brain atlas images [74]. Biochemical studies identify expression in Schwann cells of peripheral nerves [19]. SCGZ can be found in complexes with αδ or with εβδ sarcoglycans, demonstrating specificity of the context of its function in brain [118].

CSMD1

CSMD1 is substantially expressed in adult brain regions that include hippocampus [69]. High levels of CSMD1 expression in growth cones of neurons cultured from developing brain support substantial roles in development as well [69]. Less striking levels of evidence implicate variants in CSMD family members CSMD2 and CSMD3 in several of these brain related phenotypes [73].

Potential Roles for Cell Adhesion-Related Genes

The cell adhesion genes identified here provide an attractive way to bridge the gap between (1) the remarkable observed overlap between the molecular genetics of the clinical and cognitive phenotypes reviewed here and (2) the brain differences, especially those that might manifest in

the quantity and/or quality of neuronal connections, that might underlie these shared heritable influences.

Summary and Conclusions

It is an exciting time to be able to summarize and review the rapidly emerging data on the complex genetics of human addiction vulnerability and of related phenotypes. Genome-wide association results for dependence on several different classes of addictive substances converge with each other in striking fashion that is highly unlikely to be due to chance. Studies of dependence phenotypes in samples of individuals from several different racial and ethnic backgrounds support the idea that many of the allelic variants that predispose to these common disorders are so evolutionarily old that they are present in members of each major current human population. These data, combined with the varying results from linkage-based studies, fit a genetic architecture for addiction that is based on polygenic contributions from common allelic variants. Such a genetic architecture is quite consistent with data from family, adoption and twin classical genetic studies.

The identification of genes with markers whose allelic frequencies distinguish addicts of several different ethnicities from matched controls supports "common disease/common allele" genetic architecture [90] for at least much of addiction vulnerability. The convergent data derived from studies of individuals with addictions to substances in several different pharmacological classes supports the idea that "higher order pharmacogenomic/pharmacogenetic" variations enhance vulnerability to many addictions. These results do not exclude additional contributions to addiction vulnerability from genomic variants that influence vulnerability to specific substances or variants that are found only in specific populations. Nevertheless, the findings presented here provide promise for enhancing understanding of features that are common to human addictions in ways that could facilitate efforts to personalize prevention and treatment strategies for debilitating addictive disorders.

Identification of addiction-associated variants in genes that are likely to alter the quality of brain connections provides a first step toward defining a new neurobiology for the underpinnings of specific diseases and phenotypes. For many of these diseases and phenotypes, only little current research focuses on direct study of brain connections. The "connectivity constellation" concepts that we introduce here support studies that develop and use current and novel means for assessing the qualities and quantities of brain connections, especially in contexts in which they assess their functional properties. We have identified contributions of connectivity constellation genes to volumes of the same brain regions in which many of these genes are expressed. This convergence may provide new insights into data that documents individual differences in frontal lobe volume and/or in function, detected by volumetric, deoxyglucose positron emission tomography and/or functional magnetic resonance imaging, for virtually all of the "connectivity constellation" phenotypes or disorders noted here [20, 114].

The addiction vulnerability genes identified in this work contribute to the growing body of data that implicates cell adhesion and related memory-like and other cognitive processes in addiction. Studies that alter reconsolidation and other memory-related processes using knockout mice, protein synthesis inhibitors and/or pharmacologic treatments demonstrate powerful influences on addictions [142, 143]. This empirical evidence enriches theoretical work that increasingly recognizes memory-like features for addiction [134] and work that implicates memory-associated brain regions in relapse to addiction . Such work also complements clinical observations which document that addicts' enhanced vulnerabilities to substance abuse relapse can persist for decades after their last prior use of addictive substances.

There is also substantial evidence for generalization of these results from addiction. This evidence comes from the significant overlaps

between the molecular genetics of addiction and the molecular genetics of a number of related phenotypes and disorders. Overlap with bipolar disorder provides one of several likely psychiatric diagnoses for which shared genetic influences are likely a priori, based on the substantial heritabilities of both addiction and the high frequency of addiction/bipolar disorder comorbidity [119, 120]. This same logic suggests that abundant shared genetics may well also underpin the frequent comorbidities between addictions and antisocial personality/conduct disorders [107]. Less compelling evidence points to overlaps with other depressive, anxiety and schizophrenic disorders as well [107].

We have sought evidence for genetic influences that are shared between addiction and (1) frontal lobe brain volumes and (2) cognitive function. Hypotheses about such shared genetic influences are based, in part, on initial observations that so many of the genes that we and others have identified in addiction genome-wide association relate to cell connections. These molecularly based hypotheses were reinforced by the evidence for substantial, complex genetic components to each of these phenotypes. These hypotheses were strengthened by evidence, though often from small samples, that appears to document (1) small frontal lobe volumes in samples of addicts [36, 80], (2) lower performance levels on tests of cognitive and executive function in samples of addicts [13, 14, 44], and (3) large roles of heritability vs. little role for the drug exposure itself in determining the cognitive abilities of twin pair members who are discordant for cannabis use [129]. These hypotheses are further reinforced by twin data that document strong shared genetic influences on frontal brain volumes and cognitive function measures [102, 104].

Disease-associated markers both within and between genes can all begin to allow us to assess individual differences in vulnerability to addiction based on profiles of genotypes. In settings in which prevention of addiction is sought, addiction vulnerability genomic profiles could help to target more (or different) prevention resources to individuals at the most (or at different) genetic risk. When a therapeutic opiate is being considered for chronic, non-cancer pain, for example, the costs of engendering substance dependence are likely to be sufficient to justify genotyping even if the results provide only partial information about risk assessment and minimization for prescribing physicians. When treatment for an established dependence on nicotine, opiates or alcohol is being contemplated, a number of different therapeutic options with different pharmacological mechanisms of action are now available [43]. Subsets of the single nucleotide polymorphisms that we have associated with success in quitting smoking appear to provide selective influence success in responding to bupropion, while others appear to provide selective influences on success in response to nicotine replacement. Replication and extension of these observations to treatments for alcohol, opiates and other addictive substances will make it more and more likely that single nucleotide polymorphism markers will increasingly aid "personalization" of antiaddiction therapies within the near future, in ways that are now impacting the design of clinical trials in this area.

This work, taken together, supports the idea that the heritable brain bases for individual differences in addiction vulnerability lie squarely in the midst of the repertoire of common complex determinants of individual differences that are manifested in many heritable complex brain disorders and phenotypes. Such conclusions place the biology of addictions squarely in the midst of important biologies of a number of brain phenotypes and disorders, hopefully in ways that will benefit them all.

Glossary

A priori: Existing in the mind prior to and independent of experiments.

Balancing selection: A natural process that results in the survival and reproductive success of individuals or groups best adjusted to

their environment and that leads to the perpetuation of genetic qualities best suited to that particular environment.

Between-locus heterogeneity: A single disorder, trait, or pattern of traits caused by mutations in genes at different chromosomal loci.

Common disease and common allele model: The illness results from the cumulative impact of multiple common small-effect, genetic variants, interacting with environmental exposures to exceed a biological threshold.

Complex genetic phenotype (polygenic and multifactorial traits)*:* Any *phenotype* that results from the effect of multiple *genes* at two or more loci, with possible environmental influences too.

Epigenetic: Changes in the regulation of the expression of gene activity without alteration of DNA sequence.

Epistasis: A mutation in one gene masks the expression of a different gene.

Genetic heterogeneity: A single disorder, trait, or pattern of traits caused by genetic factors in some cases and non-genetic factors in others.

Genetic selection: Differential and non-random reproduction of different genotypes, operating to alter the gene frequencies within a population.

Genome-wide association study: Any study of genetic variation across the entire human genome that is designed to identify genetic associations with observable traits (such as blood pressure or weight), or the presence or absence of a disease or condition.

Linkage: The tendency for genes or segments of DNA closely positioned along a chromosome to segregate together at meiosis and therefore be inherited together.

Linkage analysis: Testing DNA sequence polymorphisms that are near or within a gene of interest to track within a family the inheritance of a disease-causing in a given gene.

Linkage disequilibrium: In a population, co-occurrence of a specific DNA marker and a disease at a higher frequency than would be predicted by random chance.

Pharmacogenetics: The study focused on specific genes, such as drug-metabolizing enzymes.

Pharmacogenomics: The study of how an individual's genomic system affects the body′s response to drugs.

Pleiotropy: Multiple, often seemingly unrelated, physical effects caused by a single altered gene or pair of altered genes.

Segregation analysis: The determination of the number of progeny that have inherited distinct and mutually exclusive phenotypes.

Susceptibility gene: A gene mutation that increases the likelihood that an individual will develop a certain disease or disorder. When such a mutation is inherited, development of symptoms is more likely but not certain.

Transitive: Passing over to or affecting something else.

Within-locus heterogeneity: A single disorder, trait, or pattern of traits influenced by several different variants at a single chromosomal locus

Acknowledgments We thank the subjects for each of these samples. We also thank our collaborators, including H Ujike and the JGIDA methamphetamine investigators, SK Li and the Taiwan methamphetamine investigators, Jed Rose, Caryn Lerman, Ray Niaura, Sean David, Gary Swan, Christina Lessov-Schlaggar. We are grateful to Framingham study investigators, the NicSNP group and the Wellcome Trust Case-Control Consortium for access to genotype data analyzed here. S Seshadri and J Pollock were of especial help with obtaining access to the Framingham and NicSNP datasets cited here. We are grateful for dedicated help with clinical characterization of NIDA subjects from Dan Lipstein, Fely Carillo, Carlo Contoreggi, Fred Snyder and other Johns Hopkins-Bayview support staff. We benefited from passionate discussions of statistical issues with Dr Daniel Naiman and from the Baltimore Epidemiology Catechment Area follow up study that was generously provided by Dr J Anthony. We thank NHLBI staff and the twin study technicians and investigators, PA Wolf, BL Miller, T Reed, L Epstein, L Hawk, P Shields, F Patterson, A Pinto, M Rukstalis, W Berrettini, R Brown, E Richardson, FM Behm, P Kukovich, EC Westman and G Samsa for their rigor in overseeing data collection at their research sites. We acknowledge financial support from NIH-IRP (NIDA), DHHS and are also grateful for support for some of the studies discussed in detail here from the Taiwan and Japanese Ministries for Science and Technology, NIH grants

Introduction

The Genetics of Vulnerability and the Pharmacogenetics of Addictions

Addictions are multi-step pathologies featuring persistent, compulsive, and uncontrolled use of an agent or activity. Repetitive use induces neuroadaptive changes that establish tolerance, craving, withdrawal, and affective disturbance. These problems persist after consumption of the addictive agent ceases and serve as a basis for cue- and stress-induced relapse and rapid reinstatement of use. Genetic variations that play roles in the addictions act at various levels, including: (1) inborn emotionality, behavioral control, and cognition, (2) the initial and adaptive responses to addictive drugs, and (3) differential responses to medications used to treat addictions to drugs and other agents. The heritability of addictions and progress in mapping genes predisposing to vulnerability are discussed elsewhere in this volume and have been reviewed elsewhere [25, 40]. In this chapter, we tell the story of the role of pharmacogenetic variation determining differences in response to addictive drugs and differences in responses to medications used to treat addictions. The pharmacogenetics of

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_11,

addictions overlaps with the genetics of vulnerability, but it will be seen that it is primarily a story of the action of specific functional alleles involved in drug metabolism and response. It is not the purpose of this chapter to review comprehensively the linkage studies of addictions, but it is notable that several of the genes that have emerged from linkage studies of addictions fall in the category of pharmacogenetic factors. An alcoholism-linked region of chromosome 4q contains the alcohol dehydrogenase gene cluster [45], and a chromosome 4p region contains a gamma-aminobutyric acid receptor-A gene cluster [1, 18, 20, 41]. In the Collaborative Study on the Genetics of Alcoholism sample, there is evidence for linkage of alcoholism to chromosome 2 at the location of an opioid receptor gene [54] and for linkage of cannabis dependence to a cannabinoid receptor [2]. Nicotinic acetylcholine receptors are important gatekeepers for nicotine's action, and a nicotinic acetylcholine receptor gene (CHRNA5) has emerged as an important candidate from genome-wide association studies of nicotine dependence [4–7, 49].

Pharmacokinetic and Pharmacodynamic Variation

Pharmacogenetic variation can be pharmacokinetic or pharmacodynamic in nature. Pharmacokinetic variation encompasses ingestion, absorption, distribution, metabolism, and excretion. Drugs of abuse are ingested by different routes, leading to the potential for pharmacogenetic variation at that level. The effects of pharmacokinetic variation can be powerful and unexpected. For example, in mice, a major genetic influence on preference for morphine in a liquid diet is the quinine taste locus although a second major opioid preference quantitative trait locus contains the mu-opioid receptor [3]. Reduced sensitivity to bitter taste may contribute to the risk of smoking [21] and alcohol dependence [30]. Once ingested, many drugs are metabolized to active metabolites that are long-lived in the body and that can cause different secondary effects, as has been observed with several antipsychotic medications. The result is differing profiles of treatment response, side effects, and addictive potential. Methylphenidate, as compared with amphetamine, is useful more directly as an agonist therapy for attention-deficit hyperactivity disorder because of its slower absorption and distribution. Methadone, as compared with heroin, is useful more directly as an agonist therapy of opioid addiction as compared with heroin and other opioids because of its long half-life. Also, the addictive liability of several drugs, including nicotine, opioids, amphetamine, and cocaine, is related directly to the ability to administer them in ways that people find acceptable and such that there is a very rapid upslope in concentration of the drug, thereby overwhelming rapid tolerance. As will be discussed, ethanol's active metabolite, acetaldehyde, exerts a variety of effects: it can discourage drinking via the flushing reaction; it is a carcinogen responsible at least in part for the carcinogenicity of alcohol, and—in the brain—it also may be rewarding. From these few initial observations, it is apparent that any pharmacogenetic variation that disturbs the delicate balance of absorption, distribution, metabolism, and excretion is likely to alter a drug's addictive profile and the treatment profile of medications used to treat addiction.

Other Concepts: Gatekeeper Genes, Allostatic Shifts, and Teratogenicity

Pharmacodynamic genetic variation in the reaction of cells and tissue to particular drugs influences both the initial and chronic responses to drugs. It includes variation in the ability to smell or taste the drug, thus altering palatability and appeal. Pharmacodynamic variation includes differences in receptors, which are gatekeepers for the actions of specific drugs. It includes variation in modulatory pathways.

Long-lasting neuroadaptive changes lead to allostatic shifts in the function of the brain stress system and the function of the hypothalamic-pituitary-adrenal axis [37], and certain genetic polymorphisms influencing stress response have already been shown to play important roles in addictions, in this context. These long-lasting effects are due in part to changes in brain structure as well as cellular changes. At the cellular level, long-lasting epigenetic changes lead to altered gene expression accompanying and enabling changes in neuronal function.

The developing brain is more sensitive to drug exposures. A pharmacodynamic consequence is drug-induced teratogenic disorders, including fetal alcohol syndrome and fetal alcohol spectrum disorders, which affect 1 out of 100 live births at an annual cost of >$20,000 each, cigarette-induced low birth weight, and drug × gene interactions during development that potentially enhance liability to addictions but also other disorders, including schizophrenia. As will be discussed, the pharmacogenetics of these drug-induced teratogenic and developmental disorders is poorly developed yet critically important.

Pharmacogenetic Effects Independent of Addiction Diagnosis

Clinically Under-Recognized Differences in Level and Pattern of Use

A deficiency of the *Diagnostic and Statistical Manual of Mental Disorders*' proposed treatment of addictions is that it does not capture quantitative and qualitative aspects of drug use that affect pharmacokinetics. Mode of administration and level and pattern of use are substantially irrelevant to the *Diagnostic and Statistical Manual of Mental Disorders* diagnoses even though these are profoundly important for outcome. For example, binge drinking—a pattern of alcohol use characterized by episodic bouts of intense drinking—is common and, while generally seen in the context of alcohol dependence, is a strong independent predictor of problems in all four *Diagnostic and Statistical Manual of Mental Disorders* addiction major symptom areas: social, work, physical, and violence/lawlessness [45]. Level and pattern of alcohol consumption and associated factors including diet correlate with risk of developing organ damage such as liver cirrhosis at both the individual and population levels [24]. Genetic variation interacts with alcohol exposure to determine vulnerability to cirrhosis. The distinction between intravenous and oral consumption of drugs is important from a clinical perspective. Intravenous drug users are at dramatically higher risk for HIV infection, infection, and pulmonary disease. They also may have a different profile of vulnerability factors and require different counseling approaches. Susceptibility to infections associated with intravenous drug use is itself modified by a host of genetic factors, such as the chemokine (C–C motif) receptor 5, which moderates risk of progression to AIDS following infection with HIV. However, a starting point for assessment of vulnerability to these negative outcomes is the understanding that the individual is an intravenous drug user, even if intravenous use is only occasional.

Genetic Modifiers of Drug Consequences Independent of Addiction Diagnosis

Drug use that does not meet *Diagnostic and Statistical Manual of Mental Disorders* criteria for abuse or dependence constitutes a critical problem, leading, to violence and dyscontrolled behavior, motor and cognitive impairments critical in the causation of accidents, problems with the law, and loss of livelihood. In this regard, the circumstances, pattern, and quantity of use are frequently critical to whether the use of the drug, which might never be repeated more than once, has a devastating impact on the person's life.

The alcohol-naïve young woman who becomes intoxicated, drives, and dies in a motor vehicle accident is equally as dead as the alcohol-dependent individual who has suffered the same sad fate. These negative outcomes also can be influenced by pharmacogenetics. With reference to this example, and as will be discussed, some individuals are more sensitive to alcohol than others, such that a first exposure would more likely lead to an automobile accident. Finally, the general population is at high risk for suicide, with a lifetime risk of about 1%; however, the risk in various populations of addicted individuals is several-fold higher, varying with the addictive agent.

Gene/Stress Prediction of Suicide Risk

As shown in Fig. 1, in populations of addicted individuals, genotype can interact powerfully with environment to alter the risk of suicide.

Teratogenicity and Developmental Effects

In the United States, approximately 30% of women consume alcohol during pregnancy. Alcohol crosses the placental barrier, thereby entering the fetal circulation, and can impair fetal brain development even if exposure occurs in the third trimester. As a result, fetal alcohol syndrome occurs in 0.2–2.0 out of 1,000 live births. Fetal alcohol syndrome—induced cognitive disabilities include deficits in memory, attention, behavioral inhibition, and reasoning. Fetal alcohol syndrome children are more vulnerable to psychiatric disorders and addictions, perpetuating a cycle of risk. Furthermore, a broader spectrum of fetal alcohol spectrum disorders has been recognized, and fetal alcohol spectrum disorders occur in approximately 1 out of 100 live births. These numbers provide an intriguing indication that there is a strong pharmacogenetics of fetal alcohol syndrome; if 30% of pregnant women drink, why should the incidence of fetal alcohol syndrome be <1%? Studies performed in rodent animal models of fetal alcohol syndrome indicate that there is wide variation of fetal response to the same drug exposure because fetuses that share the same womb have different outcomes—one animal being affected and the other not. Also, some strains of mice are more likely to produce fetal alcohol syndrome offspring than are others. Finally, and most interestingly, there is wide variation in outcome even with inbred mouse fetuses in the same womb and sharing the same genotype. This suggests that small animal-to-animal differences, including differences in early epigenetic and cellular developmental states, influence outcome in profound ways.

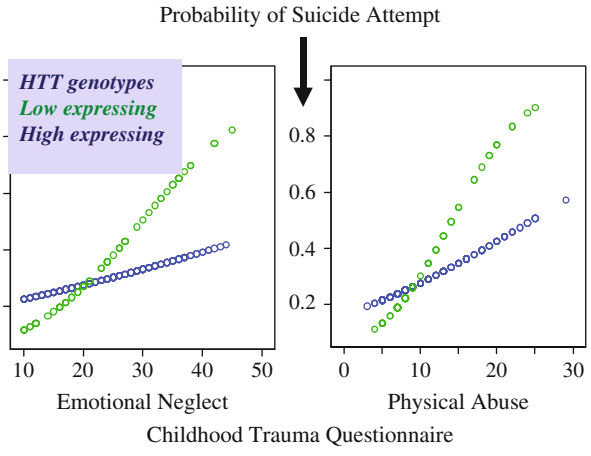

Fig. 1 Suicide risk in 306 African-American participants with addiction to cocaine, heroin, or alcohol was strongly modified by the effect of childhood neglect and trauma combined with a functional serotonin transporter (HTT) promoter polymorphism. Adapted from Roy et al. [46]

Longitudinal studies reveal that genes influence the risk of addictions both during development and across the lifespan. Certain addiction-related behaviors such as alcohol consumption are not heritable early in life, when the child is unable to independently choose, but become highly heritable later. This probably holds true for the consumption of other drugs as well as alcohol. In a study of the developmental expression of inherited vulnerability to addictions conducted in the Virginia Twin sample, Kendler and colleagues [36] found that gene effects that are undetectable in early adolescence gradually grow in importance and reach their peak in young adulthood, whereas the effect of common environment shared by siblings decreases. These data raise the issue of gene × environment correlation. To what extent does genotype shape drug exposure, rather than the response to drugs? Although adolescent alcohol and drug use is associated with adverse outcomes [26], age of first exposures—for example, the age at first drink—is itself genetically influenced [43], raising the question of whether early drug users already are different.

Pharmacogenetics of Intermediate Phenotypes

Addiction-Associated Intermediate Phenotypes and Endophenotypes

One way to better disentangle predisposition from exposure is to use predictive intermediate phenotypes that are heritable and stable and pre-exist exposure. Intermediate phenotypes that access mediating mechanisms in addictions have been a powerful tool for detecting the effects of genes. Endophenotypes are intermediate phenotypes that are disease associated and heritable [25]. Addiction-associated intermediate phenotypes include heritable variations of the resting encephalogram and evoked responses. Such phenotypes have frequently yielded promising genetic association findings [14, 33], although the basis of none of these is really understood.

Alcohol-Induced Flushing: Alcohol Dehydrogenase, Aldehyde Dehydrogenase, Alcoholism, and Cancer

Alcohol-induced flushing is a heritable phenotype that is protective against alcoholism but is a risk factor in the development of oropharyngeal cancer and perhaps also breast cancer [10, 11]. Acetaldehyde derived from the metabolism of ethanol is under ordinary conditions rapidly converted to acetate, and levels of acetaldehyde remain very low—i.e., in the nanomolar range. Acetaldehyde is a potent releaser of histamine, thereby triggering the aversive flushing reaction. Symptoms include headache, nausea, palpitations, and flushing of the skin, as shown in Fig. 2.

If aldehyde dehydrogenase is blocked by disulfiram (which is used to help alcoholics maintain abstinence) or certain medications used to treat protozoal infections (e.g., metronidazole), then the flushing reaction is observed after the ingestion of only small quantities of alcohol.

The genetic origin of alcohol-induced flushing is variation in alcohol metabolic genes.

Fig. 2 The alcohol flushing response. Facial flushing in a 22-year-old aldehyde dehydrogenase 2 heterozygote before (*left*) and after (*right*) drinking alcohol. The individual pictured in this figure has given written consent for publication of his picture using the PLoS consent form. Reprinted from Brooks et al. [11]

Alcohol dehydrogenase 1B and aldehyde dehydrogenase 2 are enzymes that catalyze consecutive steps in alcohol metabolism. In adults, these enzymes play an important role although there are also several other enzymes that can carry out both of these metabolic steps, including catalase, cytochrome P450, and additional enzymes in the alcohol dehydrogenase and aldehyde dehydrogenase gene families. In the liver, three alcohol dehydrogenase genes are expressed at high levels and to some extent at different times of development, and these three enzymes are primarily expressed in hepatocytes. However, despite this complexity of enzyme action in alcohol metabolism, individual functional alleles that alter the function of only one enzyme are sufficient to exert a major biochemical effect and an effect on risk. This probably is because of the relatively greater importance of alcohol dehydrogenase 1B in the adult liver and its lower K_m and higher capacity for metabolism as compared with some of the other enzymes.

The aldehyde dehydrogenase 2 enzyme is an aldehyde dehydrogenase that is encoded in the nuclear genome but translocated to the mitochondrion, where it plays a critical role in the ability of hepatocytes and other cells throughout the body to metabolize acetaldehyde. The main roles of the enzymes that have maintained these genes through at least 80 million years of mammalian evolution are in fact somewhat obscure. Mice and rats, in their natural environment, are not heavy consumers of alcoholic beverages! Yet our distant mammalian cousins possess a full complement of these enzymes. Perhaps the reason for this is that although the liver metabolizes ethanol ingested in beverages, it also has to utilize alcohols that are the product of bacterial fermentation in the gut.

As mentioned, acetaldehyde is a toxic intermediate that may react with a variety of biomolecules. Indeed, acetaldehyde adducts with DNA, and both it and alcohol are formally recognized as mutagens by the International Agency on Risks of Carcinogens. If acetaldehyde accumulates, the individual is at substantially increased risk of upper gastrointestinal cancer, and this can occur due to either pharmacologic blockade of aldehyde dehydrogenase or natural genetic variation. Both the alcohol dehydrogenase 1B and aldehyde dehydrogenase 2 polymorphisms, described below, have been associated with enhanced risk of cancers of the oropharynx and esophagus [10, 55]. These are factors that physicians may wish to consider in counseling individuals who drink despite carrying the common genetic variations that lead to elevated acetaldehyde levels [10, 11].

Nature has provided natural examples of genetic predisposition to alcohol-induced flushing, and it is not surprising that the enzyme variants that lead to flushing are protective against alcoholism. The most important functional loci at alcohol dehydrogenase 1B and aldehyde dehydrogenase 2 are the alcohol dehydrogenase 1B His47Arg missense polymorphism, in which Arg47 is a hyperactive allele acting in codominant fashion, and aldehyde dehydrogenase 2 Glu487Lys, in which the Lys487 allele inactivates aldehyde dehydrogenase 2 dominantly (a manifestation of the tetrameric structure of the enzyme). Higher activity of alcohol dehydrogenase 1B, conferred by Arg47, or lower activity of aldehyde dehydrogenase 2, conferred by Lys487, leads to accumulation of acetaldehyde following alcohol consumption and the flushing reaction. In East Asian populations (e.g., China and Japan), where both His47 and Lys487 are highly abundant, and Jewish populations, where His47 is abundant, many individuals carry genotypes that are protective against the development of alcoholism. The protective effect seems to vary across environments [51] and shows genotype–genotype additivity [48]. Both of these functional polymorphisms appear to be ancient in human populations, occurring on characteristic and highly diverged haplotypes. On that basis, it is unlikely that the Arg47 and Lys487 alleles were selected to high frequencies in East Asian populations as protective alleles against alcoholism. One possibility, which is still speculative, is that the polymorphism alters susceptibility to protozoal infections of the gut, including amoebiasis, because an action of metronidazole

(an antiprotozoal medication of unknown mechanism) is to inhibit aldehyde dehydrogenase [23]. However, regardless of the forces responsible for their high frequencies, the pervasive environmental exposure to alcohol that occurs in modern societies has added other dimensions to their effects.

As mentioned, the genetics of alcohol dehydrogenase is complex—there are seven genes in the alcohol dehydrogenase gene cluster on chromosome 4, and there are others with linkage disequilibrium (non-independence in populations) occurring for many of the variant loci. For example, alcohol dehydrogenase 1C has a pair of linked amino acid substitutions. Furthermore, within humans, the aldehyde dehydrogenase 1 gene also has common inherited functional variation. It is highly likely that these and other functional variations also will play a role in vulnerability to alcoholism.

Alcohol Response and the Gamma-Aminobutyric Acid-A Receptor

Low response to the effects of alcohol is a heritable intermediate phenotype (again, an endophenotype) [29] predictive of risk of alcohol use disorders [47], and it also predicts higher alcohol consumption in strains of rodents. In the prospective longitudinal study by Schuckit at the University of California, San Diego, alcohol response in young, relatively alcohol-naïve college males was the strongest predictor of future alcoholism [47]. In both humans and mice, the level of response to alcohol mainly reflects pharmacodynamic variation in response rather than metabolism.

An important target for the action of alcohol is activation of gamma-aminobutyric acid receptors, which are ligand-gated chloride channels that dampen neuroexcitability when activated. Gamma-aminobutyric acid is the primary inhibitory neurotransmitter in the brain, and its activations of chloride currents through the gamma-aminobutyric acid receptor-A receptor channels are facilitated by various drugs including ethanol, benzodiazepines, and barbiturates. Strong pharmacobehavioral evidence suggests that gamma-aminobutyric acid is involved in cross-tolerance among alcohol, benzodiazepines, and barbiturates. In the mouse, a series of ethanol-related behaviors, including preference, withdrawal, and sedation, map to regions where gamma-aminobutyric acid receptor-A receptor-gene clusters are located [24].

The human gene encoding the subunit alpha 6 of the gamma-aminobutyric acid receptor A has an amino acid substitution (Pro385Ser) that may alter level of response to both alcohol and benzodiazepines [32]. In the rat, an Arg100Gln missense variant located in the gamma-aminobutyric acid receptor-A alpha-6 subunit gene (GABRA6) was associated with variation in ethanol and benzodiazepine sensitivity [38]. GABRA2, which was originally implicated positionally in family linkage analysis, appears to alter vulnerability to alcoholism and is associated with alcoholism-related electroencephalographic variation—the same alleles and haplotypes having been replicated across studies [1]. GABRA2 also has been implicated in nicotine addiction and polysubstance use, but those findings are not well replicated [40].

Nicotinic Acetylcholine Receptors: Gatekeepers for Nicotine and Other Drugs?

Nicotinic acetylcholine receptor genes have been associated with nicotine dependence and lung cancer, seemingly as an example of the gatekeeper role of these receptors for nicotine's action. However, most of the 12 known nicotinic acetylcholine receptor genes are not required for nicotine's reinforcing actions, and several of these receptors also have been associated with vulnerability to alcoholism and cocaine addiction, pointing to the possibility of their wider involvement in the neuropharmacology of addiction. For nicotine response, a critical receptor

is the one formed by the alpha-4 and beta-2 subunits because mice lacking that combination do not self-administer nicotine or release striatal dopamine in response to nicotine [42]. These mice also show abnormalities in cocaine responses. As reviewed [40], there have been several positive association studies of CHRNA4 to nicotine dependence, but the evidence for CHRNB2 is less clear. Certain genes carry common functional variation, and others do not. Rarer CHRNB2 variants could be critical to the vulnerability of particular individuals.

The CHRNA5-A3-B4 cluster has been implicated in genome-wide association studies of nicotine dependence and lung cancer [4–7, 49]. For example, in one study, the phenotype for the nicotine addiction was number of cigarettes per day regularly smoked in two European populations totaling 7,500 persons. Although no genetic marker reached genome-wide significance, a trend toward association was found for a common haplotype in the CHRNA3–CHRNA5 nicotinic receptor gene cluster on chromosome 15, and this result was replicated in 7,500 additional Europeans [7]. Among the implicated variants is a missense allele in CHRNA5, which appears to play a role in nicotine dependence [6] as well as lung cancer, but may be protective in cocaine dependence [27]. This Asp398Asn substitution is common and non-conservative and may affect function via altered trafficking of the receptor.

Neuroimaging, a New Frontier in Pharmacogenetics

For pharmacogenetic studies of addiction, neuroimaging provides access to the neuronal mechanisms underlying emotion, reward, and craving and, therefore, represents an extraordinary tool to link genes to the neuronal pathways that produce behaviors. For example, amygdala activation after exposure to stressful stimuli predicts anxiety and captures inter-individual differences in emotional response and stress resiliency [28]. Amygdala activations and other brain responses are modulated by common functional genetic variants at genes such as the serotonin transporter promoter polymorphism [28] and the catechol-*O*-methyltransferase missense variant Val158Met [57]. Similarly, neuropeptide Y, an anxiolytic neuropeptide that shows moderate associations with alcoholism and anxiety, strongly predicts brain imaging responses to emotion and pain [56]. On the other hand, the activation of the prefrontal cortex during working memory performance is used to evaluate prefrontal cognitive function that is impaired in several psychiatric diseases including addictions, and these activations are modified by the same catechol-*O*-methyltransferase polymorphism [17]. The association of catechol-*O*-methyltransferase with addictions [19, 50, 52] is, therefore, likely to be complex and potentially mediated either by an effect on cognition and behavioral control or via effects on emotion and resilience. The combination of genetic analysis with brain imaging illustrates the power of cross-disciplinary science and its complexity (or, to put it another way, its limitations).

The Mystery of Comorbidity: Agent-Specific and Non-Specific Factors

Comorbidity among the addictions and between addictions and other psychiatric diseases occurs in excess of what would be expected based on the frequencies of these diseases [26] and by multiplying the probabilities of the events as if they were independent. Twin studies have shown that one origin of comorbidity is the existence of genetic factors shared between addictive agents, and these studies also showed that there are large substance-specific genetic factors [22, 34, 35].

The agent-non-specific genes include ones that affect neurobiological networks involved in responses and adaptations to many different types of addictive agents, as well as the vulnerability to other psychiatric diseases. Categories

of mechanisms that may underlie shared vulnerability include reward, stress resiliency, behavioral control, and personality. These can be viewed as pharmacodynamic effects. For example, dopamine activations are fundamental for the reward and reward-anticipation effects of addictive agents. The dopamine receptor DRD2 gene has been linked to different types of addictions [53], albeit with some inconsistencies. Similarly, opioid neurotransmitters play an important role in reinforcement, and a functional polymorphism of the mu-opioid receptor (OPRM1) has been associated with addictions, but again with some inconsistencies [39, 44].

Gene × Environment in Genes Affecting Pharmacodynamics

Addictions are similar to other complex diseases, including cancer, diabetes, cardiovascular diseases, infectious diseases, and hematologic diseases, where the effects of genetic variation have come to be understood first by their ability to moderate resiliency or vulnerability to environmental exposures (e.g., pathogens, carcinogens). The gene effects are much greater in the context of the measured exposures. Childhood stress and neglect increase vulnerability to multiple psychiatric diseases including addictions [16, 46]. However, there is wide inter-individual variation in stress resiliency. Functional loci that influence inter-individual variation in stress resiliency include monoamine oxidase A [12, 15], the serotonin transporter gene (SLC6A4) [13], catechol-O-methyltransferase [20], the corticotrophin-releasing hormone receptor 1 gene [9], neuropeptide Y [56], and FKBP5 [8]. Monoamine neurotransmitters, including serotonin, norepinephrine, and dopamine, are modulators of emotionality, cognition, reward, and behavioral response to stimuli. Therefore, it is unsurprising that genes encoding the enzymes and transporters that regulate synaptic levels of these neurotransmitters would be important in the addictions. These are, of course, not addiction specific and have been implicated in vulnerability to other psychiatric diseases and response to drugs that alter monoamine levels, and, for example, response to serotonin-specific reuptake inhibitors has been linked to SLC6A4 [31].

Pharmacogenetics in the Treatment of Addictions

The maintenance of abstinence for multi-year periods, reductions in drug use, and delay in the return to heavy drug use have enormous benefits. The multidimensional nature of addictions paradoxically increases the range of opportunities for interventions. The identification of genes altering liability and recovery could provide new

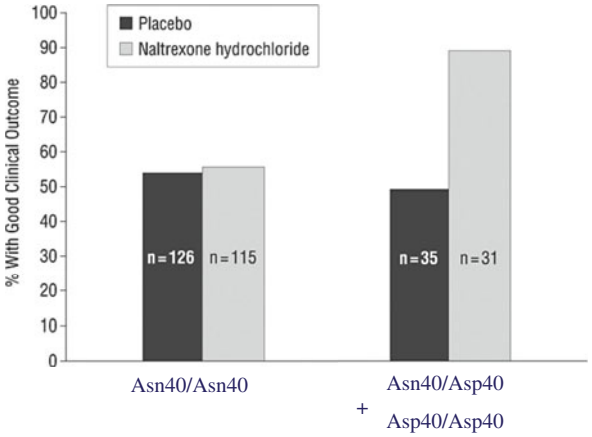

Fig. 3 A functional OPRM1 polymorphism (Asn40Asp) predicted good clinical outcome in alcoholics treated with naltrexone, but not placebo, in the multicenter COMBINE study. Adapted from Anton et al. [3]

therapeutic targets and an ability to individualize treatment. The common functional missense variant of the mu-opioid receptor (OPRM1 Asn40Asp) appears to predict good clinical outcome in alcohol-dependent individuals treated with naltrexone (Fig. 3) [3, 41] and may alter nicotine-mediated reinforcement [44] and therapeutic response in smokers treated with nicotine replacement [39].

Conclusion

Addictions are common, complex disorders in which genetic variation alters pharmacokinetic and pharmacodynamic responses, leading to differential vulnerability and differences in the liability to other negative outcomes consequent to drug exposure. Both the teratogenicity and carcinogenicity of alcohol are influenced by genetic factors. Addictions are consequent to a gene × environment interaction. Furthermore, several of the genes that alter addiction vulnerability work through the stress axis, providing a specific role for gene × stress interactions. In terms of the variance in liability explained, the pharmacogenetics of addiction is still a relatively young field, but the genes discovered so far act in a variety of ways including altered drug metabolism, drug receptor function, and general mechanisms of addiction.

What Is Metabolomics?

Metabolomics is the newest addition to the "omics" science. An "omics" has been defined as a neologism referring to a holistic view on biologic macromolecules, such as in genomics or proteomics [9]. Genomics aims to understand the structure and function of the genome by studying all nucleotide sequences, including the structural genes, regulatory sequences, and noncoding DNA sequences in the chromosomes of any organism. It also examines the molecular mechanisms that maintain genomic integrity, allow its transmission and the expression including any interplay of genetic and environmental factors in disease. Proteomics involves the identification and study of complete set of proteins in a species and the determination of their role in physiologic and pathophysiologic functions [2, 57]. Together with these and other "omics" technologies, metabolomics contribute to the detailed understanding of the in vivo function of gene products, biochemical analysis and regulatory networks. The metabolomics represents the collection of all low molecular weight molecules found in a given cell and can provide a "snapshot" of the physiology of a cell at a given time during development and differentiation including responses to food, drugs, and other challenges [19].

Biochemist view metabolomics as metabolites profiling or the quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_12,

or genetic modification [36]. Biologist, particularly geneticist on the other hand view it as the science of highly complex and organized biochemical network in which small molecules, such as metabolic substrates and products, lipids, small peptides, vitamins, amino acids, signaling molecules and other protein cofactors, are interacting between them and with other biological macromolecules in the metabolome [9]. These small molecules are acting usually at very low concentrations in tissue signaling functions [17]. Along with the understanding of the in vivo interaction of gene products, metabolomics also contributes a great deal in the mathematical description and simulation of the whole cell in the systems biology approach. Systems biology tries to integrate genomic, proteomic, transcriptomic and metabolomic information to give a more complete picture of living organisms (Fig. 1). Here, the biological events in organisms are systematically interpreted through the combination of complex measurements from various methods resulting in high-throughput data. In this chapter, we will discuss addiction as a problem of systems biology with emphasis on metabolomics.

Substance Abuse and Its Effect on Health and Economy

Substance use, abuse, and addiction that include but are not limited to alcohol [41, 62], nicotine [16], opioids [49], cocaine [35], cannabinoids [1], methamphetamine, and amphetamine [33] continue to be a significant public health concern and pose tremendous cost to our society. In the United States alone, in 1998 the economic cost associated with illicit drug use was estimated to be US$280 billion, for nicotine US$158 billion [7], and for alcohol abuse US$185 billion with an average annual increase of 3.8% per year [21]. This brings the combined total estimated economic impact of substance abuse in the United States to over half a trillion dollars [62]. Recent data indicate that approximately 1.6 million people in the United States abuse or are dependent on prescription opioids [49]. In the United Kingdom, the cost associated with alcohol abuse is approximately $39 billion each year [41]. Drug and alcohol abuse is a major cause of morbidity and mortality both in the United States and worldwide. Alcohol use disorders including

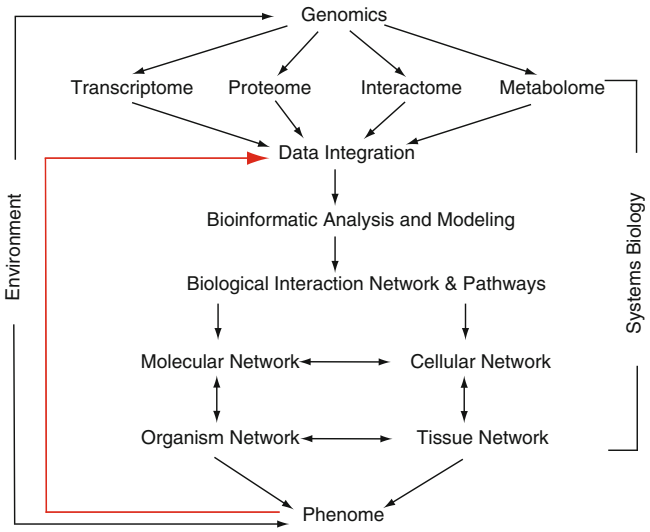

Fig. 1 Connection between "omics" sciences and systems biology. Functional genomics and other technologies are used to map the transcriptome (complete set of transcripts), proteome (complete set of proteins), interactome (complete set of interactions), metabolome (complete set of metabolites) and other "omics" knowledge bases. Bioinformatics analysis is done to model and infer network pathways from integrated data. Experimentally valid biological network of cells, tissues and organs from particular organism are integrated with phenome (complete set of phenotypes) to obtain the complete picture about specific mechanism and disease

liver and heart diseases account for 4% of the global burden of disease and cause 1.8 million deaths [41]. The excessive burden of drug abuse to our health and economy makes it necessary for us to better understand how these drugs affect metabolomics of our cellular systems, mechanism of action in different parts of the body and factors that determine the variability of addictive responses. A better insight into these mechanisms will offer a better understanding of the problem as well as identify effective treatment and preventative approaches for addiction that remains insidious in most societies.

Substance Abuse Leads to Addiction

At the center of the problem of substance abuse is addiction to these substances. It has been long hypothesized that the combination of genetic and environmental factors following drug use and abuse alter cellular physiology. This alteration is expected to be cell and organ specific. In due course, it may follow physiological adaptation leading to an urge for the drug response and the development of addiction [27, 37, 62]. Evidence for the involvement of genes in the process of drug addiction comes from classical epidemiological and genetic studies. Data from both animal and humans support the importance of genetic influences in substance abuse and dependence [4, 24, 34, 56]. Twin studies, for example, have shown robust genetic components for alcohol, opiate, cocaine, and tobacco addictions [28, 44, 55].

The major target of virtually all drugs in the human or animal body, either directly or indirectly, is the nervous system specifically one or more pathways deep within the brain [25, 26, 29, 39]. Drug-related, especially alcohol-related, brain damage and associated neurophychological changes have been well documented (see review [38, 39]). There is increasing evidence that long-lasting changes in the brain result from the progression of casual user to addict [37]. Acute drug intoxication is accompanied by highly localized and dynamic patterns of brain activation and deactivation [5, 48], as well as complex cascades of transcriptional reprogramming [63, 64].

All compounds with abuse potential have the ability to disrupt the processing of information in the brain by subverting or affecting the expression of gene(s) involved in one or more of the common neurotransmitter systems (i.e., gamma-aminobutyric acid, glutamate, acetylcholine, dopamine, serotonin, and opioid peptides). However, an early increase in dopamine signaling has been one of the most consistent observations across studies of the reinforcing effects of drugs of abuse [12, 40, 62]. Though studies with various knockout mice have emphasized the role of specific gene products working in the brain (see review [34]) such as Homer 2 [50], opioid receptors [8], and alpha 4 nicotinic receptors [51] in conferring either protection from or increased risks of addiction. It is also apparent that the contribution of any single gene in the development of addition for any drug is only a small part of the picture. Like most familial behavioral phenotypes, drug and alcohol use disorders result from the complex interaction of multiple genes [47]. This complexity may account for ongoing challenges associated with the development of addiction and solutions to deal with them. Needless to say that multiple genes exert their effects in the context of genetic networks, which are typically under the influence of environmental factors. These early effects initiated by the gene product induced by drugs or alcohol most likely cascades through the signaling pathways and generates a domino effect [60]. In order to understand the complete molecular or gene expression changes that may occur in the brain due to drug and alcohol effect, it is important to capture those changes as a whole and perform a systematic analysis. One very novel and effective approach that has been used in recent years to decipher and unravel this complex mystery is metabolomics.

Metabolomics: The Beginning

The completion of the human genome project has made it possible to investigate the whole genome using high-throughput technologies and analyze data via "systems approach" (Fig. 1). Derivation of molecular-based strategies, development of new computer application and technologies and the application of bioinformatics are accelerating the elucidation of molecular underpinnings of human diseases as well as to more effectively prevent, diagnose, and treat these diseases. These strategies can also be successfully applied in addiction related disorders.

Since the beginning of molecular biology, biological questions have been successfully approached mainly by studying individual gene function(s) and gene products, one or few at a time. Despite understanding the cause of many biological problems, however, many fundamental biological questions remain to be answered. This is mainly because the majority of gene products function together interacting with other gene product influencing multiple pathways. Therefore, biological processes should be considered as complex networks of interconnected components. In addition to studying the components individually, it is important to study the combined nature of these gene products in the metabolomic networks and pathways.

Metabolomics in Addiction Research: Current Approach

Selection of Technology to Capture Metabolomic Changes

Recent advances in latest technologies allow the profiling of all metabolic components in a biological system at any given time, investigating dynamic changes in components quantity or quality in a system under external stimuli or perturbation and finally analyzing the changes of one component in relation to another. The goal here would be to generate protein–protein, protein-DNA or other component-component mapping of the networking pathways involved. Gene expression microarray is one such high throughput technology that allows detection of cellular changes at the transcript level and has been used extensively in research on alcohol and other drugs of abuse [14, 15, 54]. Gene expression profiling using microarray chips has been proved to be the most successful genome-wide technology to capture the temporal-spatial expression pattern of a cell. Since the expression microarrays are RNA-based method, they are highly effective in the simultaneous identification and measurement of virtually all transcript that are differentially expressed between any two samples representing treatment (e.g., ethanol) and control. Transcript profiling using microarrays is the most widespread functional genomics technique because of their relative technical simplicity, low cost and short turnover time. In recent years the development of high-density microarray chips has allowed us to present the entire transcriptome of more complex organisms such as human and mouse on a single chip. The availability of improved algorithms and easy to use software has made it possible to interpret and analyze the microarray data without much computer knowledge. Of all the addictions, such studies have been extensively used in alcoholism.

During the last 5 years, studies on humans and animal models using microarray have contributed to our knowledge of the molecular effects of alcohol and identified a number of potential candidate genes of interest in the context of alcohol response alone. In addition, microarray experiments generate a large number of ethanol-responsive genes some of which are repeatedly identified as such in multiple reports regardless of experimental paradigm. However, it would be extremely difficult and time consuming to investigate this large number of genes using single or candidate gene approach. Since these genes belong to multiple biochemical pathways including stress response, gene regulation, apoptosis, cell growth and cell signaling [54, 58],

we need to analyze them altogether in the context of cell and tissue system.

Tissue and Organ of Interest

In order to investigate the effect on gene expression following drug or alcohol exposure, cells or tissues from participants and their matched controls are needed. In most cases brain and brain regions are viewed as most appropriate. However, matched samples of brains are not available for such studies. The next best option is to make use of brain bank samples. This too is not always practical. More importantly, matching participant and control brains is not an easy task as they differ in a large number of parameters that may affect gene expression. We will not discuss this issue any further except to state that in the lack of human brain matched samples, and due to the problem of manipulative experiments on humans most studies have relied on a number of animal models. Of course this approach has its own drawbacks. With this realization, we will focus this discussion on one of the favored animal model (e.g., mouse). It has a number of advantages. Established genetic strains of mice are available and widely used which differ in responses to various drugs including preference to voluntary alcohol consumption. For example, strain C57BL/6 J consistently demonstrate high ethanol preference which is about 60% in comparison to strains A/J (26%), BALB/CJ (30.4%) and DBA/2 J (11.8%) given the free choice of water and 10% ethanol over a 14 day period [31]. Once a suitable genetic animal model is selected and their drug preference phenotype is reconfirmed with in-house study, they can be used in necessary experimental treatment with the drug under study following suitable methods. It allows collection of desired organ following appropriate treatment along with strain/genotype, age and sex matched controls. The drug treatment may involve various modes and durations as appropriate. It is also possible to include various environmental manipulations including stresses before or after the exposure to the addictive drug being investigated. The tissue of interest (e.g., brain) is collected at appropriate time and processed for studies on DNA, RNA, and protein including structural and developmental alterations that may be affected in any drug response including addiction. Although such studies in the past have concentrated on the RNA and protein including cellular changes, it is important to point out that futuristic studies may include DNA and protein changes reflecting epigenetic modifications. In fact it is likely that the addiction for a drug which is acquired following repeated exposures may involve epigenetic changes (DNA methylation, histone modification including chromatin alterations), that has remained on the side line of such a research. We will not go in any detail except to point out that such changes will explain a variety of RNA and protein changes that have been reported in response to drugs and drug addictions. For the main stream research in the new genome era, the tissues of interest are harvested from an experimental animal model and used for RNA isolation. The purified RNA is hybridized to a suitable expression array, which allows identification of genes that are affected as a result of drug exposures.

Generating Gene List

Microarray is hybridized, scanned and analyzed following manufacturer's recommended method and software. Microarray experiments generate a large number of genes which are analyzed further using bioinformatics tools and software. It is beneficial to develop a list of genes that show significant difference in expression between treatment, gender and age or any other selected parameters. This list can be further refined by primarily excluding genes for which no information is available in the public databases such as NCBI (http://www.ncbi.nlm.nih.gov/), Ensembl (http://www.ensembl.org/index.html), GO (http://www.geneontology.org/), UCSC (http://genome.ucsc.edu/), etc. (see [60] for

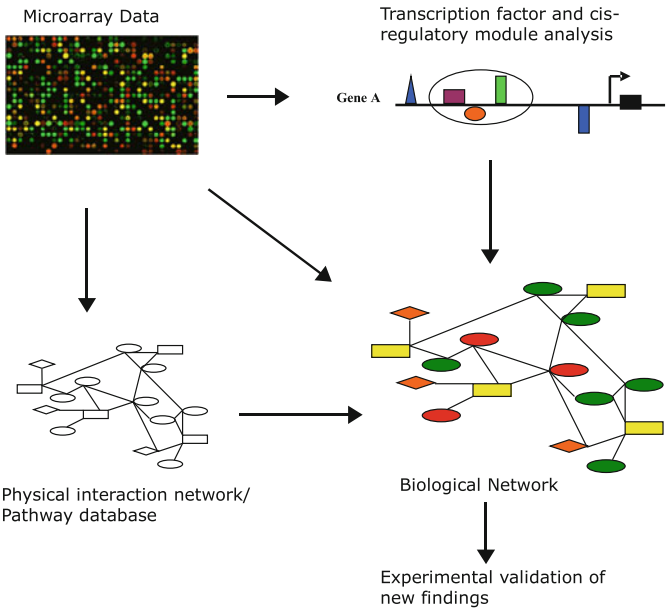

Fig. 2 Overall view of an integrated approach to constructing pathway or regulatory interaction network. Data generated from microarray experiment can be used to perform transcription regulatory network and/or biological interaction network

an example). These genes are used in the subsequent analysis as explained in Fig. 2.

Bioinformatics Tools and Analysis

It is apparent that in most cases a single gene may carry out several functions in the cell by interacting with other genes in the network. In this way, the action of one gene product dynamically affects the action of others in a cascading fashion in the cellular pathways, generating a complex global network [22]. In order to identify how a particular gene interacts in a subsystem, how all the subsystems co-ordinate into a particular pathway, and how the collective actions of multiple implicated pathways emerge into a global network in the metabolome causing multi-faceted alcohol or drug effect, the genes are analyzed using specialized software to predict biological association network. Currently there are many biological pathway analysis and visualization software available today. Some of the commercial and free software is listed in Table 1.

Genes from the list above are used as input in pathway analysis software to study the neuro-metabolomics and to predict biological association (Fig. 3). These programs are generally connected with underlying database(s) and allow user to query the database(s) for genes of interest. These databases for human, mouse, rat, yeast or any other organisms are compiled by retrieving relevant published scientific information from public databases such as PubMed (http://www.ncbi.nlm.nih.gov/pubmed/) using automated natural language processing or other data mining techniques. The retrieved information is then curated and stored in the database for example, in the form of cellular events such as regulation, interaction and modifications among proteins, cell processes and small cellular molecules. Upon query to the database, the software program will construct a biological interaction network and provide visualization in a graph format for further exploration, examination and prediction. Some of the program also has built-in Gene Ontology search while others have additional features such as integrated transcription factor and *cis*-regulatory sequence analysis option, e.g., Bibliosphere. Commercial pathway analysis software are generally easy to

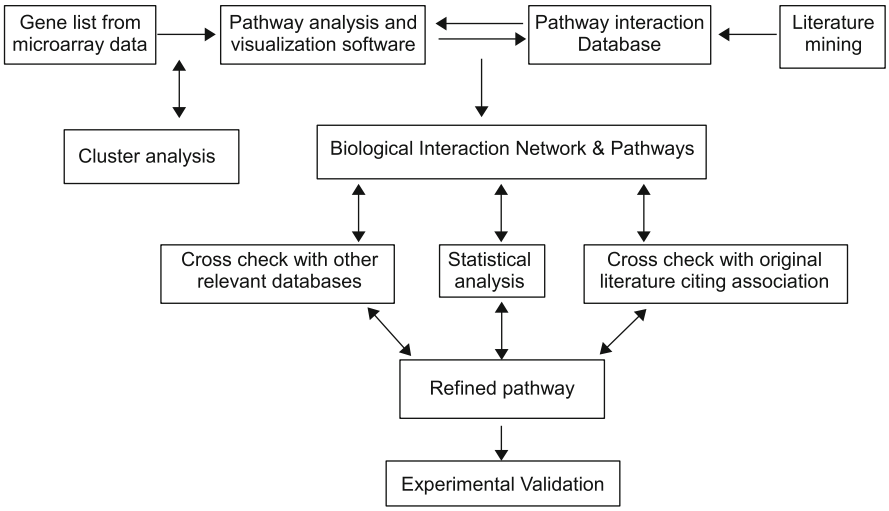

Fig. 3 Workflow of constructing meaningful biological interaction network and pathways from microarray data

use with available guides and tutorials where the open source or free software requires an extra learning curve and customization based on user's need.

An initial output from such analysis may generate a network graph that may seem highly complex due to the presence of all possible association among all matching gene products upon query to the database. Figure 4 is showing an example of a simplified view of one such initial output from PathwayStudio pathway analysis software. In this example, mouse affymetrix chips were used to assess the relative expression of genes in the brain in response to acute ethanol treatment on two genetic strains of mice (DBA/2 J or D2 and C57BL/6 J or B6) that are known to differ with respect to their responses to alcohol [54]. The expression array results showed that the genes fall into two main categories, which are strain-specific and strain-specific ethanol-responsive genes. Only ethanol-responsive gene data set containing about 60 genes was then used in cluster analysis to predict genes that tend to co-express in response to ethanol treatment. The results revealed that eight of the genes show down-regulation at the same level in both B6 and D2 mice in response to ethanol and nine demonstrate upregulation which is higher in D2 mice than in B6 mice, while 24 of the genes show up-regulation at the same magnitude in both B6 and D2 mice. This last cluster was further analyzed in the PathwayStudio software. The output was filtered to include only protein, cell complex, functional class, cell process and cell object. All irrelevant interactions and association were removed from the network and the result as shown in Fig. 4 represents the most relevant biological associations among 24 ethanol-responsive genes. A network graph like this one is generally composed of "nodes" and "lines". Nodes are shown by symbols of different shapes and sizes (e.g., circular, oval, triangle, rectangle etc. of different colors) which can represent any biomolecule such as protein, enzyme, cell complex, cell process, treatment, DNA, RNA, and metabolite. Nodes are connected by lines (straight or curved) representing physical interaction, association or relationship between nodes, e.g., protein–protein, protein-DNA, protein-cell process, etc. The lines can also be of different types to indicate the type of association such as binding, regulation and expression. A positive or negative sign can be associated with each type to represent the specific nature of the interaction. Color code can be used to include metabolomic category of the genes being studied. In a transcription regulatory network the nodes generally represent transcription factors, cofactors and DNA *cis*-regulatory elements. Lines in a regulatory

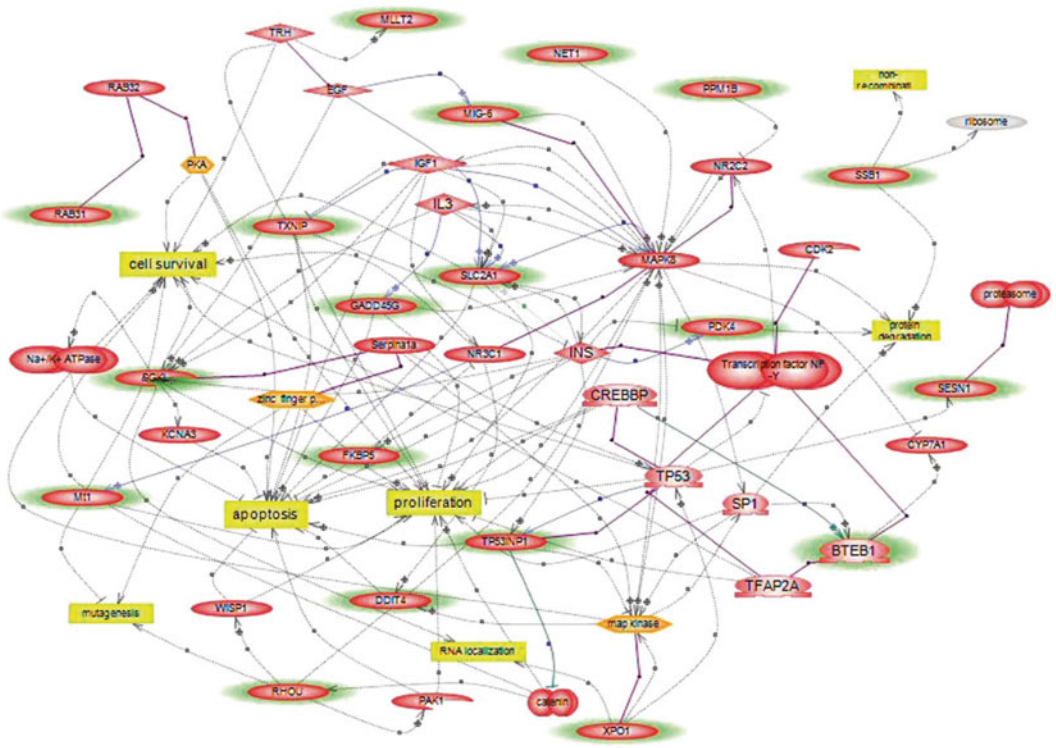

Fig. 4 Functional interactions of 24 ethanol-responsive gene products. Ethanol-responsive gene products (*orange ovals* shaded in *green*) are shown with other cellular objects such as protein (*orange ovals*), cell complex (e.g., transcription factor NFY, Na+/K+ ATPase), cell process (*yellow rectangles*), etc. These interactions could be of several different types: expression (e.g., *blue lines* connecting two cell objects), regulation (e.g., *grey lines*), binding (e.g., *purple lines*), etc. The interactions of these ethanol-responsive genes contribute directly or indirectly to a number of cell processes, specifically apoptosis, cell survival and proliferation. (Reprinted from Uddin and Singh [58] with permission from Elsevier.)

network would indicate physical interaction between transcription factors and *cis*-regulatory elements, i.e., protein-DNA interactions.

Once the initial network is developed, each interaction between two nodes (e.g., cell processes, proteins, enzymes, cell complex, treatment, etc.) should be individually verified by examining the cited curation and literature(s). Any irrelevant and indirect relationship should also be excluded from the network during final analysis. The result is also further cross-checked with other relevant database entry and can be statistically validated using appropriate algorithm. This kind of rigorous exercise helps reveal significant and fruitful information generally hidden in the network. For example, an analysis similar to the one described in Fig. 4 starting with all 60 ethanol-responsive genes was narrowed down to only 7 genes that showed direct connection to ethanol in closely interacting pathways in the brain (Fig. 5). The result shows that ethanol affects multiple cellular events that include synthesis and degradation, gene regulation, transcription, translation and expression, phosphorylation, molecular transport, biogenesis and various enzymatic activities. Through this and other subsequent downstream events, ethanol contributes both positively and negatively to a large number of biochemical pathways. Although drugs of abuse act on different receptor systems, they activate common downstream sequences of events, which underlie characteristic behavioral phenotypes such as compulsive drug-taking, craving, and relapse [42].

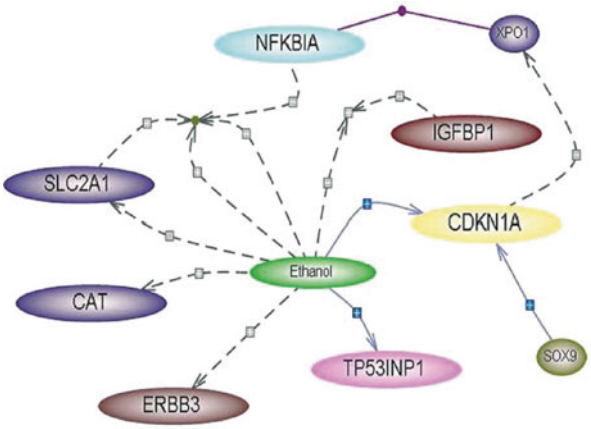

Fig. 5 An example of a final interaction network. A proposed pathway for ethanol's action on genes is shown where they directly interact with ethanol and other genes in the brain. This kind of small network showing most relevant association can be developed from an initial output of a pathway analysis software and can be used for further experimental validation. (Reprinted from Uddin et al. [60] with permission from Springer Science + Business Media.)

Transcription Regulatory Network in Drug Metabolomics

As we have learned above that ethanol and other drugs' action may be realized through the transcriptional control of gene expression, transcriptional regulators or factors and their combinatorial control on *cis*-regulatory elements play a critical role in the co-expression of these genes. This affects the interaction of genes in the metabolome and thus may affect signals that cascade through cellular pathways. There has been rapid progress in recent years in the development of a systems approach for identifying such transcriptional regulatory networks from high-throughput data generally generated from microarray experiments [3, 52, 59]. A summary of this powerful approach is outlined in Fig. 6.

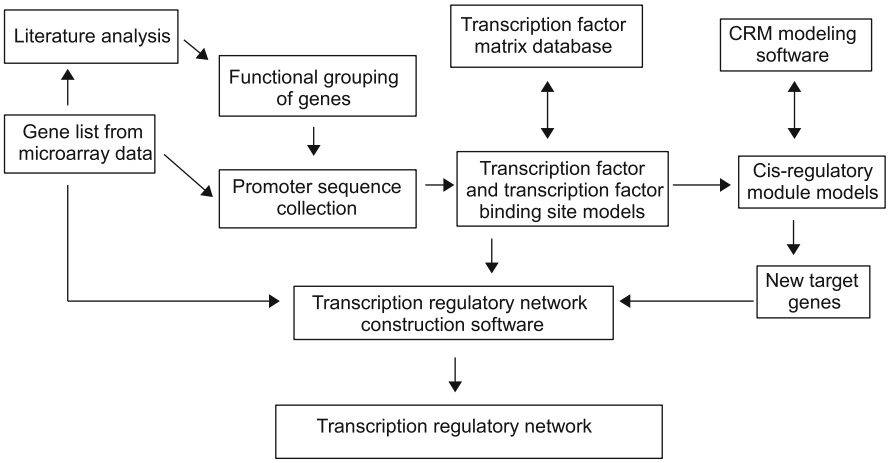

Fig. 6 Workflow of generating transcription regulatory network

Gene Selection and Literature Analysis

Since this approach can also use microarray technology, a list of genes showing significant difference between experimental and control cells or tissues can be developed using microarray experiments as described in the previous strategy or using similar comparable method. Now we need to investigate all possible physical interaction between transcription factors and between transcription factors and *cis*-regulatory elements, e.g., promoters, enhancers and other *cis*-acting regulatory elements on the promoter regions involving these genes. Various free and commercial software packages are available for this purpose (Table 1) that offer a number of modeling tools integrated with statistical algorithms and curated literature and transcription factor databases. The strategy outlined below can be performed using either free software tools such as the TOUCAN package or commercial software such as the GEMS Launcher package (Table 1).

Once the genes are selected they are used in literature analysis to identify possible transcription factors that interact with their promoter sequences either manually or by using commercially available software such as Bibliosphere (www.genomatix.de). This analysis is performed to subgroup initial gene set into overexpressed Gene Ontology groups based on the results from literature analysis. The stringency level can be set by the user, for example, for this analysis it can be set as that each transcription factor must be co-cited with at least two input genes, each transcription factor must be co-cited with one input genes at least two times and finally the co-citation should be at the sentence level in the abstract describing some function. Only subgroups that are statistically significant and bear meaningful association with the pathways potentially affected by the drug under study can be selected for further analysis.

Transcription Factor and Regulatory Elements Modeling

For modeling transcription factor and their possible binding sites it is necessary to obtain the promoter sequences of the genes. They can be retrieved from any public (e.g., NCBI and Ensembl) or commercial (e.g., Gene2Promoter www.genomatix.de) databases generally 500 bp–1 kb upstream and 100 bp–200 bp downstream of the transcription start site. The promoter sequences are then analyzed to construct common significantly conserved *cis*-regulatory modules generally consisting of two or more *cis*-regulatory elements where potential transcription factors or transcription regulator motifs bind on the promoter sequences of the input gene set [59] (Fig. 7).

Genes belonging to a Gene Ontology biological process group should be analyzed together as a subset. It is known that in eukaryotes, more than one transcription factor is required to regulate and initiate gene expression. Also, the co-regulation of mammalian genes usually depends on sets of transcription factors rather than individual factors alone, and *cis*-regulatory elements are often organized into defined modules of two or more transcription factor binding sites and clusters of such motifs [10, 13]. Therefore, the *cis*-regulatory modules identified in this way can be very useful in search for other potential new target genes that share the same framework of the known *cis*-regulatory modules. To identify possible *cis*-regulatory modules, first, the promoter sequences of the genes are scanned for matches to a transcription factor matrix library (e.g., MatInspector, www.genomatix.de or MotifScanner, http://homes.esat.kuleuven.be/~saerts/software/help/WebServices/motifscanner.htm). The transcription factor matches found are then used as basic motifs for the extraction of common *cis*-regulatory module models, for example, by FrameWorker (www.genomatix.de) or ModuleSearchers

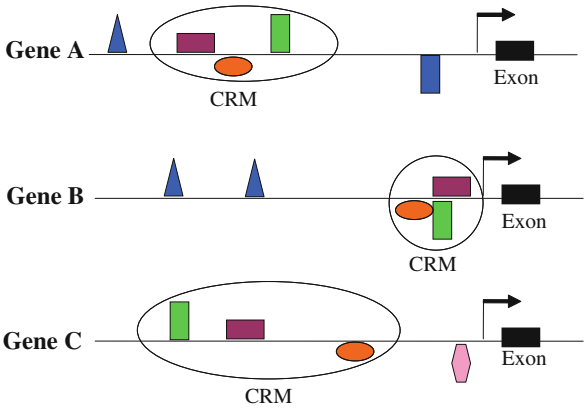

Fig. 7 Transcription factor and regulatory elements modeling. The figure shows a common *cis*-regulatory module (CRM) consisting of three common transcription factors (shown as *colored shapes*) shared by genes A, B and C

(http://homes.esat.kuleuven.be/~saerts/software/help/WebServices/modulesearcher.htm) program. The *cis*-regulatory module models with the best significant scores are selected to scan other DNA sequences (e.g., complete promoter database of organism or animal under study) for matches to these models. This would also verify the specificity of the models generated by the modeling software used. The bioinformatics tools that can be used for this search are, for example, ModelInspector (www.genomatix.de) or MotifSampler (http://homes.esat.kuleuven.be/~saerts/software/tutorial1/TOUCAN_Tutorial_MotifSampler.html). This approach also has the ability to identify other potential target genes of *cis*-regulatory module models predicted above.

The use of this strategy in research on drugs of abuse has shown promising results. For example, one research involving alcohol has shown that the alcohol-responsive metallothionein genes [31, 32], Mt1 and Mt2, are regulated by transcription factor cyclic AMP responsive element binding protein and metal-activated transcription factor 1 and primarily involved in zinc ion homeostasis [59]. Cyclic AMP responsive element binding is known to control gene expression for a variety of functions in the central nervous system and thought to be associated with both anxiety and alcohol preference. Haplodeficiency of the cyclic AMP responsive element binding gene and ethanol-induced decreases in cyclic AMP responsive element binding function have been shown to be associated with increased alcohol drinking in mice.

The search in the modeling databases for genes that share the same *cis*-regulatory module as cyclic AMP responsive element binding has revealed new target genes Synj1 (Synaptojanin 1) and Tph1 (tryptophan hydroxylase 1), potentially regulated by this module. Synj1 is known to be involved in the regulation of synaptic vesicle function and has been studied as a potential candidate gene for psychiatric disorders [43, 61]. Interestingly, the Tph1 gene product is known as a rate-limiting enzyme in the biosynthesis of serotonin and its activity is most abundant in the brain. Alteration in brain serotonin level has been implicated as an important contributing factor in many psychiatric disorders including alcoholism [20]. Altered arrangement of transcription factor binding sites in the module can direct the action of these and other target genes in intracellular signaling cascades, cell growth and/or maintenance. In addition to cyclic AMP responsive element binding, other key transcription factors identified are EVI1 (ecotropic viral integration site-1) and SP1. These modulate the contribution of the target ethanol-responsive genes in cell cycle regulation and apoptosis or programmed cell death. Multiple lines of evidence indicate that different groups of ethanol-responsive genes are involved in different biological processes and their co-regulation most likely results from different sets of regulatory modules.

Construction of Transcription Regulatory Network

The new target genes identified are added to the original list and the newly compiled list of genes is used to construct a regulatory network using the information available in the interaction databases. This way the microarray gene expression data profiles and transcription factor *cis*-regulatory module analysis data are integrated into protein–protein and protein-DNA interaction data available in the databases to obtain a broader systems view. Because gene expression and *cis*-regulatory module location data provide complementary information, integration of these data sources can emphasize the functional part of the network and thus make the inferred network more biologically relevant. There has been significant progress in the development of interaction databases (Table 1). These databases are constructed by storing curated published protein-DNA or protein–protein interaction obtained from extensive literature mining where in the literature protein-DNA interaction was validated using ChIP-chip analysis and protein–protein interaction was measured by two-hybrid system, Co-IP and mass spectrometry experiments. Results from other high-throughput technologies, such as genome-wide location analysis and cap analysis of gene expression, are also used that experimentally map many types of functional DNA elements on the genome. Though the use of different database in constructing the regulatory network may vary, however, the basic construction principle would be the same as constructing a pathway (Fig. 2).

A refined regulatory network constructed from an integrated approach can provide novel biological insight into cellular interactions in response to drugs and alcohol. This may predict new genes that are contributing in a particular pathway or indicate up or downstream effects of other pathways. Now would be time to experimentally validate these findings with rigorous testing. However, before jumping into experiment one must consider that the predicted networks are time, space and condition dependent, that is, different parts of the network will likely be active at different conditions. They have to be evaluated under specific condition of interest.

A network established this way is termed as a static network. This kind of network can be generated for a given dose of drug or alcohol for each cell, tissue or organ type for an animal system. A number of static networks can be connected and mapped together to generate a tissue- and drug-specific dynamic network (Fig. 1), which would provide significant knowledge toward our understanding of the metabolomics of drugs of abuse.

Application of Metabolomics in Solving Addiction Disorders

The strategies presented above has been successfully applied in studying tissue and disease specific regulatory networks for human diseases, including cancer [45, 53], cardiac hypoxia [11], innate immunity [18] and inflammation [6]. They were also used in the past to study the metabolomics of alcohol action [58–60]. Most recently [30], similar method was used to develop a common molecular network underlying addiction to different abusive substances. Using literature mining, a Knowledgebase of Addiction-Related Genes (KARG) was developed (http://karg.cbi.pku.edu.cn) that contains over two thousands items of evidence linking 1,500 human genes to addiction. Sequences of nearly 400 human addiction-related genes were analyzed using bioinformatics tools, e.g., KOBAS software [46] and mapped to statistically significant biologically meaningful experimentally validated pathways in the KEGG database [23]. Molecular pathways that were identified as significantly enriched for four drugs of abuse including cocaine, alcohol, opioids, and nicotine were selected as common pathways for drug addiction. This study found several pathways shared by all four addictive substances which are “long-term potentiation”, “MAPK signaling pathway”, “GnRH signaling pathway” and “Gap junction” and by connecting these

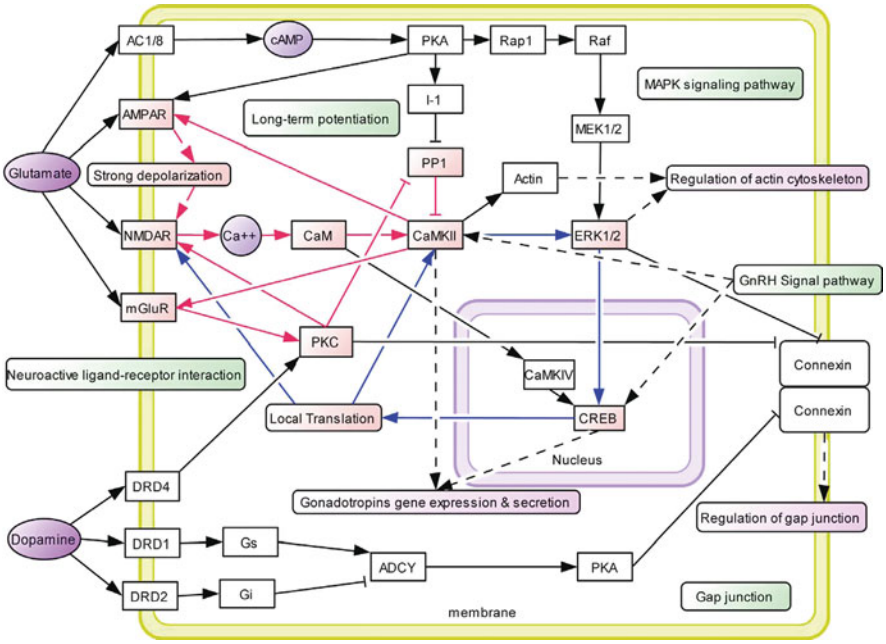

Fig. 8 Hypothetical common molecular network for drug addiction. The network was constructed manually based on the common pathways identified and protein interaction data. Addiction-related genes were represented as *white boxes* while neurotransmitters and secondary massagers were highlighted in *purple*. The common pathways are highlighted in *green boxes*. Related functional modules such as "regulation of cytoskeleton", "regulation of cell cycle", "regulation of gap junction", and "gene expression and secretion of gonadotropins" were highlighted in *carmine boxes*. Several positive feedback loops were identified in this network. Fast positive feedback loops were highlighted in *red lines* and slow ones were highlighted in *blue lines*. (Reprinted from Li et al. [30] with permission.)

pathways with additional protein–protein interaction data constructed a hypothetical common molecular network for drug addiction (Fig. 8). Interestingly, cyclic AMP responsive element binding, an important transcription factor implicated in alcohol research [59] has also been identified in this common pathway.

Integration of Systems Biology to Medication Discovery

Common human diseases are driven by complex networks of genes and a number of environmental factors. To understand this complexity in order to identify targets and develop medications against disease, a systematic approach is required to elucidate the genetic and environmental factors and interactions among and between these factors, and to establish how these factors induce changes in gene networks that in turn lead to disease.

The rapid progress in the development of large-scale high-throughput genetic screening technologies, availability of super computing power of modern specialized software and instant high-speed web access to numerous genetic data repository have enabled researchers to take a more systems biology approach to study complex traits like disease. Genotyping of hundreds of thousands of DNA markers, scanning through millions of single nucleotide polymorphisms, and profiling tens of thousands of molecular phenotypes simultaneously in thousands of individuals are now possible. This makes it possible to integrate data from all available sources and reconstruct complete genetic networks associated with disease. This can help

us identify common pathways in the intracellular signaling cascades shared by the causal factors driving disease, formulate clinical approach for prevention and develop effective treatments for a wide range of addictive disorders.

Neurobiological Basis of Drug Reward and Reinforcement

David M. Lovinger

Contents

Introduction

Drug abuse and addiction to drugs involves a number of factors including genetic and environmentally influenced predispositions, the actions of the drugs themselves, the immediate environment, and the neurobiological mechanisms that promote and support drug actions and addiction. This chapter deals mostly with the latter aspect of drug use, abuse and addiction, as we will explore the ways in which the brain is built to adapt to environmental circumstances, and how these aspects of neural function can promote the continued use and abuse of certain drugs and ultimately promote behaviors we think of as addiction. We will then consider the mechanisms through which drugs of abuse interact with the brain systems that promote maladaptive drug use and addiction.

Addiction has been defined in several different ways, most of which stress the habitual or compulsive nature of addictive behavior, the physical, psychological and social damage produced by the behavior, and the trauma associated with cessation of the behavior. Compulsive drug use is certainly one type of addiction [21], but addictions are not limited to drugs of abuse, and can center on natural biological drives (e.g., sex, food consumption), physical activities (e.g., excessive exercise), relatively benign drugs (e.g., caffeine), as well as drugs of abuse (discussed in [86]). The latter substances will be the main focus of the present discussion. In addition, excessive use of drugs may lead to health and psychological problems even in the absence of an agreed-upon definition of addiction. Thus, it is important to understand the neural mechanisms that contribute to prolonged and maladaptive drug use.

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision [3] does not refer specifically to addiction, but instead covers what we generally think of as drug addiction under the heading of "Substance-Related Disorders". Within this classification, the manual defines substance dependence in the following way: "When an individual persists in use of alcohol or other drugs despite

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_13,

problems related to use of the substance, substance dependence may be diagnosed. Compulsive and repetitive use may result in tolerance to the effect of the drug and withdrawal symptoms when use is reduced or stopped." Common features of these descriptions are behavioral change that centers on the addictive substance or action (sometimes referred to as a "habit"), continued use despite negative consequences, and the possible negative consequences of cessation of the experience. All of these aspects of drug use disorders can be seen to relate to innate brain mechanisms underlying processes referred to as reinforcement and/or reward. In this context, it is important to discuss current ideas about the neural mechanisms of reinforcement and reward before discussing the impact of drugs of abuse on these processes.

Behaviorism and the Concepts of Reward and Reinforcement

An important aspect of the use, abuse, and addiction to a wide range of drugs is their reinforcing properties. A reinforcer is defined in experimental psychology as a substance or stimulus presented following a behavior that increases the incidence of the behavior above baseline levels. As Skinner [155] wrote, "The operation of reinforcement is defined as the presentation of a certain kind of stimulus in a temporal relation with either a stimulus or a response. A reinforcing stimulus is defined as such by its power to produce the resulting change [in the response]. There is no circularity about this; some stimuli are found to produce the change, others not, and they are classified as reinforcing and non-reinforcing accordingly." It is worth highlighting the dual use of the term stimulus by Skinner to refer to both the result of the action (the reinforcer), and a stimulus within the environment that can become associated with the response and the reinforcer. One definition of reinforcement, although not Skinner's position, is that it involves a strengthening of the ability of stimuli to elicit responses (the so-called stimulus-response model [70]), while a somewhat looser definition is a strengthening of the ability of the environment in general, including some neural activity within the animal itself and the animal's past history in that environmental context, to elicit the response [40].

The concept of reinforcement is best known from the work of Konorski and Skinner on what is now called operant or instrumental conditioning [82, 155]. However, the term reinforcement has also been used in the context of Pavlovian, or classical, conditioning. One use of this term is that presentation of an unconditioned stimulus subsequent to the conditioned stimulus "reinforces" the ability of the conditioned stimulus to elicit a conditioned response. This term has also been used to refer to the effects of stimuli that predict the value of a "rewarding" stimulus presented prior to presentation of food or another naturally desirable outcome [131, 149, 150]. For example, in the paradigm used by Schultz [149, 150], responding for food (licking) as well as neuronal activity related to stimulus presentation and responding can be measured. Dayan and Balleine provided a nice discussion of the distinctions between reinforcement in the context of Pavlovian and instrumental conditioning [35].

Two forms of reinforcement, termed positive and negative have also been postulated. Positive reinforcement refers to the process in which delivery of a desirable consequence increases the incidence of the behavior. This is quite easily understood in the context of the instrumental or operant conditioning paradigm in which delivery of palatable food will increase bar pressing by a rodent or key pecking by a pigeon [155]. Negative reinforcement occurs when the performance of an action results in omission of an undesirable stimulus (e.g., footshock), and the incidence of the behavior increases as a result of this learning process [157]. The initial phases of learning some skills, such as swimming, involve what might be termed negative reinforcement as the skill helps to reduce the undesirable effects of the environment. Many investigators do not subscribe to the idea that

positive and negative reinforcement are distinct processes, as both types of reinforcement basically refer to something that increases the incidence of a given behavior. However, negative reinforcement is a useful concept when measuring stimulus-behavior relationships, as it describes a condition in which increasing behavior leads to omission of a stimulus. Learning in everyday life will often involve both positive and negative reinforcement.

Two other terms that have come to be used in the context of instrumental learning and addiction are punishment and reward. Consideration of the conditions that promote cessation of behavior led to the definition of the undesirable outcome as punishment [7, 170], although the role of punishment has been hotly debated [156]. The term reward was not so readily accepted by early behaviorists, but has come into common use as a reference to the desirable outcome in an instrumental learning paradigm. The terms reward and positive reinforcement are often used interchangeably, but as we will discuss, these terms can be used to refer to different processes that control instrumental learning of actions, including drug self-administration.

Studies conducted over the last few decades have led to the refinement of the concepts of instrumental conditioning, reward and reinforcement based on the role of the outcome produced by a particular behavior in conditioning paradigms. Dickinson, Balleine, and others have shown that responses developed under certain types of conditioning schedules will rapidly diminish if the value of the outcome is decreased or if receipt of the outcome is no longer contingent on making the response [1, 10, 28]. This learning of "action-outcome" contingencies is best achieved with training schedules where the outcome is easily predictable and the probability of obtaining the outcome is enhanced with increased rates of responding (e.g., fixed or random ratio schedules). In this case, the outcome has been termed to have a "rewarding" action, based on its intrinsic value to the organism at the time of testing and association with the instrumental action itself.

In contrast, training with schedules where predictability is poorer and increasing rates do not increase probability of successful outcomes (e.g., random interval schedules) produces responding that is insensitive to outcome devaluation or non-contingent presentation of the outcome [10, 37, 67]. This "stimulus-response" type of conditioning can also occur with extensive training using schedules with higher predictability (discussed in [191]). In the case of stimulus-response learning, the association is made between antecedent environmental stimuli and the subsequent response, with the outcome serving as a reinforcer regardless of the immediate value of this outcome to the animal. As you can see, this is closer to the classical definitions of reinforcement favored by stimulus-response theorists, Donahoe, and perhaps Skinner [40, 155]. It should also be noted that White [183] drew a similar distinction between reward and reinforcement, albeit with a more traditional behaviorist emphasis on the definitions of these terms. Other investigators have defined reward in terms of positive reinforcement in combination with positive hedonic value [86], an idea that suggests more overlap between the two processes. While the separate definitions of reward and reinforcement in this context may be debated, there is strong evidence for the two instrumental conditioning processes themselves. Thus, the differentiation of the roles of stimuli/environment and outcome in the two different learning processes is important, and separate discussion of reward and reinforcement in these contexts is useful.

Before we consider how reward and reinforcement contribute to addiction it is worth discussing the adaptive purpose of these neural systems. Behaviors that lead to enhanced survival and/or reproduction are necessary for propagation of genes and species. Innate feeding, reproductive and harm-avoidance behaviors exist in all animals, but learning about features of the environment is necessary to obtain the opportunity to express these innate behaviors. Pavlovian conditioning is one such learning process whereby performance of something approximating an innate or reflexive behavior can come

to be elicited by stimuli that were originally neutral with respect to predicting a particular outcome (e.g., obtaining food or avoiding harm). Instrumental conditioning adds another layer of sophistication to this process. Animals with this capacity can learn to perform new actions and new sets of actions to obtain a positive consequence or avoid punishment. Both types of learning have obvious adaptive utility, as the animal can now integrate complex features of the world and new behavioral strategies into maintaining safety, as well as the quest for food and mating partners. The power of the neural mechanisms involved in reward and reinforcement likely derives from this relationship to survival and reproductive success.

However, there is the possibility that reward and reinforcement mechanisms will not always be used for adaptive purposes. One such example is the phenomenon of self starvation. Animals that are trained to perform an intracranial self-stimulation task, described later, will perform this task at the expense of sufficient eating if access to food is time-restricted [141]. Similar self-starvation is observed if animals are given the opportunity to run on a wheel when on a limited food access schedule [16, 142]. This particular form of self-starvation has been considered as a model of human anorexia nervosa [16], which itself is clearly an example of maladaptive behavior involving the brain systems we will consider. Stimuli that originally signal a positive outcome can change their predictive value (a certain location may contain food at one time and a predator at another). Furthermore, stimuli or substances that interact with the neural mechanisms involved in reinforcement may come to have reinforcing value even when they are not coupled to a favorable outcome, or even when they are associated with harmful results. Most drugs of abuse can act in this manner, and can lead to reinforcement of what we might call maladaptive behaviors. In the remainder of this chapter we will consider the brain circuitry and cellular and molecular mechanisms involved in reinforcement. Consideration of this topic will also entail some discussion of the experimental techniques used to uncover these mechanisms.

Neurotransmitters and Neural Circuitry: Involvement in Different Aspects of Reward, Reinforcement, and Addiction

While the concept of instrumental learning had begun to crystallize by the early 1930s mainly due to the work of Konorski and Skinner [82, 155, 193], little was known about the neural circuits involved in this behavior. Konorski and Divac both obtained evidence from studies involving lesions of the caudate nucleus implicating this part of the striatum in instrumental conditioning [39, 82]. The discovery by Olds and Milner [114] of intracranial self-stimulation provided an important clue as to the importance of at least one pathway within the basal ganglia. In the original intracranial self-stimulation paradigm, the animal was implanted with an electrode that could stimulate fibers in the medial forebrain bundle. Investigator-initiated stimulation at this site led the animal to repeat the behaviors that were ongoing at the time when the stimulus was delivered. Thus, activation of this neural pathway was in and of itself rewarding or reinforcing. It was later discovered that a key set of axons within the medial forebrain bundle supplied dopaminergic afferents to the forebrain regions known collectively as the striatum [31, 127, 186]. This finding stimulated work on the role of dopamine in brain mechanisms of reward and addiction that has continued to this day.

The dopaminergic pathways in the brain are now well known. The somata of the majority of neurons that use dopamine as a neurotransmitter are concentrated in contiguous ventral midbrain structures called the substantia nigra pars compacta (or A-9 nucleus) and the ventral tegmental area (or A-10 nucleus) [79]. The neurons in these two regions project to different striatal subregions and other forebrain targets. Neurons from the substantia nigra pars compacta primarily innervate the dorsal striatum (the caudate and putamen nuclei in primates). In contrast, dopaminergic neurons from the ventral tegmental area project strongly to the ventral portion of the striatum, particularly

a striatal subregion called the nucleus accumbens that sits in the ventromedial region of the striatum. Neurons within the ventral tegmental area also send dopaminergic afferents to the prefrontal, orbitofrontal (insular), and cingulate cortices, with more minor projections to other cortical regions such as the limbic cortical subregions [113].

The initial data suggesting that dopaminergic neuronal activity is crucial for intracranial self-stimulation was later supplemented by the finding that intracranial self-stimulation could be produced by stimulation within the ventral midbrain regions where the dopaminergic neurons reside. Intracranial self-stimulation is supported by stimulation in the ventral tegmental area, as well as at subregions of the substantia nigra pars compacta [31, 111, 132]. These studies did not rule out the possibility that stimulation of fibers that originated elsewhere and passed through the ventral midbrain contributed to intracranial self-stimulation. Nonetheless, the combination of these findings with those findings that dopaminergic manipulations alter intracranial self-stimulation strongly implicated dopamine coming from ventral midbrain neurons in the mechanisms that underlie reward and reinforcement during this process.

The focus on dopamine in the context of reward and reinforcement often overshadows the role of other neurotransmitters. Indeed, dopamine is a modulatory neurotransmitter that in and of itself is not capable of strong excitation or inhibition of neurons within this circuitry. Furthermore, there is evidence indicating that dopaminergic transmission is not required for certain aspects of behavior that are thought to involve reward or reinforcement. For example, gene-targeted mice that lack dopamine are still able to learn the location of food, but appear to require dopamine to express the learned behavior [135]. This finding and similar data from other studies seems to indicate that dopamine is necessary for the motivational aspects of reward seeking [11, 119] or "incentive salience" [15]. In addition, there is evidence that neurochemical lesions of the dopaminergic system do not eliminate self-administration of drugs of abuse such as heroin and ethanol [124, 130], suggesting that dopaminergic transmission may not be necessary for all of the rewarding or reinforcing effects of drugs of abuse. Thus, we need to consider the role of other neurotransmitters in reward, reinforcement and addiction. An exhaustive description of all the neurotransmitters involved in these processes is beyond the scope of the present paper. Instead, the role of particular neurotransmitters with intriguing roles in the brain reward/reinforcement circuitry will be discussed.

Within the central nervous system, the neurotransmitters glutamate and gamma-aminobutyric acid are responsible for the majority of fast synaptic transmission [79]. Glutamate directly excites neurons via the activation of ligand-gated cation channel-type receptors, while gamma-aminobutyric acid activates anion-preferring channels and generally has an inhibitory action. Both of these neurotransmitters have been implicated in brain mechanisms of reward, reinforcement, and drug actions [42, 52, 78].

One approach that has been used to examine the role of glutamate and gamma-aminobutyric acid in reward, reinforcement and addiction-related behaviors is blockade of receptors with specific antagonists, usually injected into a specific brain area [33, 34, 153, 160]. These approaches have proven to be effective in altering behavior, and have implicated certain subtypes of ionotropic glutamate receptors in reward and addiction-related behaviors. However, it is sometimes difficult to discern the specific behavioral role of glutamate and its receptors using antagonist blockade, as antagonists of ionotropic glutamate receptor will almost certainly decrease neuronal activity and disrupt circuit activity. Thus, the antagonist effect may not necessarily reflect a need for activation of the receptor so much as the necessity of activity of a particular set of neurons. The opposite case often obtains for gamma-aminobutyric acid (GABA)-ergic activity, as blockade of gamma-aminobutyric acid receptors, gamma-aminobutyric acid-A receptors in particular, tends to increase neuronal activity and may stimulate circuitry. For these reasons, much

recent research on gamma-aminobutyric acid and glutamate roles in reinforcement, reward and addiction has focused on the role of particular glutamate receptor and gamma-aminobutyric acid-A receptor subunit proteins.

The ligand-gated ion channels that mediate fast excitatory and inhibitory synaptic transmission are multimeric proteins that can be formed by numerous subunits and subunit combinations. Chronic exposure to addictive drugs alters the expression of particular ionotropic gamma-aminobutyric acid and glutamate receptor subunits [22, 75, 89]. Manipulating subunit expression can subtly alter receptor function without eliminating receptor activity. This has allowed investigators to explore the roles of these receptors in drug- and addiction-related behaviors without major disruption of the activity of neurons within the reward/reinforcement circuitry. This line of research has been boosted immensely by the development of techniques for transgenic receptor expression and gene-targeted receptor modification and disruption (i.e., so-called knockin and knockout techniques). It is now common for investigators to use transgenic and gene-targeting techniques to produce mice that express higher or lower amounts of a desired receptor subunit, while production of mice that express a slightly mutated version of a receptor has become more common. Viral-based gene overexpression, often involving microinjection of constructs into specific brain regions is now also being widely used to enhance protein function in neurons within reward/reinforcement circuitry. Altering expression of the GluR1 alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor subunit in gene-targeted mice alters instrumental learning [74, 171], and reduces morphine dependence and sensitization [178]. Altered acute responses to drugs of abuse, as well as changes in ethanol tolerance and dependence have been observed in mice in which gamma-aminobutyric acid-A receptors have been altered by gene targeting of alpha2, alpha5 and delta subunits [94, 104, 174]. However, one caveat that must be added to this discussion is that neuronal activity has not been measured in vivo in the animals used in these studies, and thus, the extent to which subunit loss alters circuit activity has yet to be determined in any of the aforementioned experimental models.

The neuromodulatory transmitter serotonin (or 5-hydroxytryptamine) can influence the brain reward and reinforcement circuitry, in part through actions on dopaminergic neurons [52, 69]. Serotonin can also influence goal-directed and habitual behavior through its role in control of affect and in "impulsivity". The likelihood of choosing new actions without strong outcome control has been linked to disorders of brain serotonergic systems. Impulsivity is responsive to some treatments aimed at the serotonergic system [52, 121]. Because of the disregard for outcomes, impulsive responding may be a first step in the process leading to stimulus control of behavior and maladaptive habits. Measures of impulsivity in animal models have been suggested to predict a pattern of addiction-like drug taking in rodents [13]. Serotonin levels in several brain regions are elevated during administration of psychostimulant drugs such as amphetamine and cocaine, and there is evidence that excessive serotonergic transmission contributes to the addictive effects of these drugs, in addition to the well-characterized role of dopamine in these processes [51, 64, 69, 109, 162].

Opioid neuropeptides are widely distributed in the brain, including in the action/reinforcement/reward circuitry discussed at present [79]. These peptides, enkephalins and endorphins in particular, are perhaps best known for their roles in analgesia. However, it is now well established that opioid peptide production and release is increased in response to stressful stimuli and other environmental challenges [45, 126]. Brain opioid systems have also been implicated in mechanisms of reward, particularly in relation to food and drugs of abuse. Studies of food-related behaviors generally indicate that opioid peptides signal something about the hedonic value or desirability of the food, sometimes called "liking" [11, 14, 59]. Opiate drugs that act as agonists at mu and delta-type opiate receptors are self-administered in instrumental paradigms (reviewed in [56]),

and opiate agonists produce decreases in the threshold for intracranial self-stimulation [19, 181]. Opiate antagonists can also influence intracranial self-stimulation [182]. These findings indicate that activation of the brain opioid system has "rewarding" effects.

The brain endocannabinoid system has also begun to receive a great deal of attention as a mediator of instrumental learning and addiction. Endocannabinoids are lipid metabolites that act on the cannabinoid receptors, the receptors originally discovered as mediators of the psychoactive effects of drugs such as marijuana and hashish [112]. In the brain, endocannabinoid agonists act mainly through the cannabinoid-1 receptor to produce short- and long-lasting synaptic plasticity [93]. The role of the brain endocannabinoid systems in responses to a variety of drugs of abuse is a fascinating topic that has received a great deal of attention in recent years, and this subject will be discussed later in this chapter. Recent studies using instrumental conditioning techniques indicate that cannabinoid-1 receptors play a role in transition from action-outcome to stimulus-response (habit) learning [49, 62]. Thus, the endocannabinoid system may have an important role in reinforcement-based instrumental learning. It is not yet clear if alterations in dopaminergic transmission or effects on other neurotransmitter systems are involved in this habit-promoting effect of endocannabinoids. The cannabinoid-1 receptor is highly expressed throughout the brain circuitry thought to mediate instrumental conditioning [61, 66]. Within these circuits cannabinoid-1 receptors are expressed on axon terminals of glutamatergic and GABAergic neurons (reviewed in [93]), and may well regulate release of other neurotransmitters including catecholamines [166]. Thus, there are many possible sites where endocannabinoid-dependent synaptic plasticity may play a role in this type of learning and in addiction.

The foregoing discussion should make it clear that to better understand the neuronal mechanisms contributing to reward, reinforcement and addiction we need to understand more fully the brain circuits involved in the control of actions and the instrumental learning of actions and association of actions with stimuli. We must also gain a better understanding of the roles of particular neurotransmitters and receptors in different parts of these circuits. The forebrain, in conjunction with the ventral midbrain, can be conceptualized as a series of parallel cortex-basal ganglia-cortex circuits that can also be serially interconnected (see [191] for review). The ultimate function of these circuits is to modify cortical and brainstem output to control the selection, initiation and timing of actions to produce effective integrated behaviors. Neurons and synapses within these circuits can undergo plastic changes that are thought to contribute to learning of new actions and association of actions with conditioned stimuli.

In an admittedly simplistic scheme, this circuitry can be separated into at least 3 parallel circuits [191] (Fig. 1). (More recently, 4 such circuits have even been suggested [192], and undoubtedly further subdivisions will emerge.) Each of the circuits consists of a cortical component, a striatal component, downstream basal ganglia components, and a thalamic component. The "sensorimotor" circuit is comprised of the primary and secondary sensory and motor cortices and the substantia nigra pars compacta which project to the putamen (the dorsolateral striatum in rodents), which then projects to the motor regions of the globus pallidus, ultimately influencing the ventral thalamus and closing the loop back at the sensory and motor cortices (Fig. 1a). The "associative" circuitry involves similar connections between associative areas of the cortex (including the prefrontal and parietal regions), the substantia nigra pars compacta, the caudate nucleus (the dorsomedial striatum in rodents), associative regions of the pallidum, and the mediodorsal and ventral thalamus (Fig. 1b). The "limbic" circuitry involves the limbic cortices (including not only neocortical prefrontal and temporal areas, but also archicortical regions such as the hippocampus and basolateral amygdala), the ventral tegmental area, the ventral striatum/accumbens, the ventral pallidum, and the mediodorsal thalamus (Fig. 1c). One can even consider connections

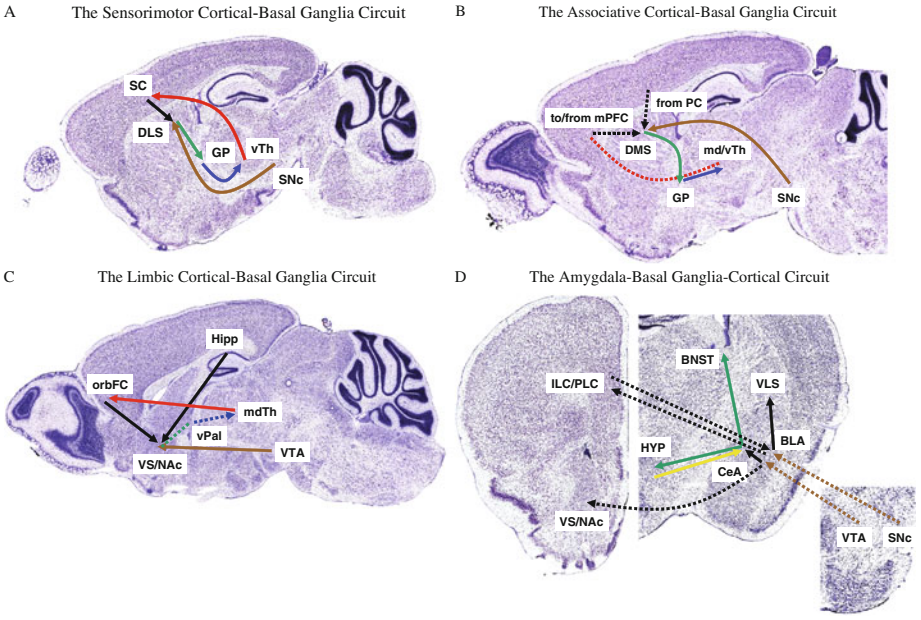

Fig. 1 Schbematic diagram of the reward/reinforcement circuits in the rodent brain. (**a**) The sensorimotor circuit (shown in a parasagittal orientation) contains glutamatergic connections from the somatosensory and motor cortices to the dorsolateral striatum (putamen equivalent in rodents), gamma-aminobutyric acid (GABA)-ergic connections from the dorsolateral striatum to the motor pallidum, GABAergic pallidal connections to the ventral thalamus, and glutamatergic thalamocortical projections back to the sensory and motor cortices. Dopaminergic inputs to the dorsolateral striatum come from the substantia nigra pars compacta. (**b**) The associative circuit contains glutamatergic connections from the medial prefrontal and parietal cortices to the dorsomedial striatum (caudate equivalent in rodents), GABAergic connections from the dorsomedial striatum to the pallidum, GABAergic pallidal connections to the mediodorsal and ventral thalamus, and glutamatergic thalamocortical projections back to the associative cortex. Dopaminergic inputs to the dorsomedial striatum come from the substantia nigra pars compacta. (**c**) The limbic circuit contains glutamatergic connections from the limbic cortical and limbic areas such as the orbitofrontal cortex, hippocampus, and basolateral amygdala to the ventral striatum/nucleus accumbens, GABAergic nucleus accumbens connections to the ventral pallidum, GABAergic pallidal connections to the mediodorsal thalamus, and glutamatergic thalamocortical connections back to the limbic cortex. Dopaminergic inputs to the nucleus accumbens come from the ventral tegmental area. (**d**) The basolateral and central amygdala connect to a variety of brain regions involved in motivation, reward, and reinforcement (shown here using separate brain sections). The basolateral amygdala receives dopaminergic input from the substantia nigra and ventral tegmental area, as well as glutamatergic input from the medial prefrontal cortex. Glutamatergic efferents from the basolateral amygdala innervate the medial prefrontal cortex, central amygdala, dorsal striatum, and nucleus accumbens. The central amygdala receives afferent input from the hypothalamus as well as glutamatergic input from the basolateral amygdala. GABAergic efferent output from the central amygdala innervates the hypothalamus and the bed nucleus of the stria terminalis. *Solid arrows* depict connections within the plain of the single brain section depicted, while *dashed lines* show connections that run out of the plain of the section. *Black arrows* = glutamatergic cortical afferents; *green arrows* = GABAergic striatal afferents; *blue arrows* = GABAergic pallidal afferents; *red arrows* = glutamatergic thalamic afferents; *brown arrows* = dopaminergic nigral and ventral tegmental afferents. Abbreviations: BLA = basolateral amygdala; BNST = bed nucleus of the stria terminalis; CeA = central amygdala; DLS = dorsolateral striatum; DMS = dorsomedial striatum; GP = globus pallidus; Hipp = hippocampus; HYP = hypothalamus; ILC = infralimbic cortex; mdTh = mediodorsal thalamus; md/vTh = mediodorsal and ventral thalamus; mPFC = medial prefrontal cortex; orbFC = orbitofrontal cortex; PC = parietal cortex; PLC = prelimbic cortex; SC = sensory cortex; SNc = substantia nigra pars compacta; VLS = ventrolateral striatum; VS/NAc = ventral striatum/nucleus accumbens; vPal = ventral pallidum; VTA = ventral tegmental area; vTh = ventral thalamus

within the amygdala to have a similar organization, with the cortical component being the basolateral amygdala, the ventral tegmental area projections providing the dopaminergic modulatory input, the striatal components being the central amygdala and bed nucleus of the stria terminals, and downstream targets leading ultimately to cortical outputs (Fig. 1d). Evidence for interconnections among the circuits at the level of striatonigralstriatal projections can help to coordinate the different systems [12, 68, 159, 191]. To fully understand reward and reinforcement-dependent learning and resultant behavioral output in the mammalian brain, it is necessary to consider all of the components in this circuitry.

Recent studies have begun to shed light on the role of these different forebrain circuits in instrumental and Pavlovian conditioning, and the ideas generated from these studies are now being applied to examination of drug actions [10, 41, 50, 191, 192]. Based on excitotoxic lesioning and local pharmacological manipulations, evidence has accumulated that the associative circuit involving the dorsomedial striatum and associated circuitry, including the basolateral amygdala [117, 118] has key roles in action-outcome learning. Afferent inputs from the prefrontal cortex to neurons in the dorsomedial striatum provide one source of input containing information relevant to action selection, and the cingulate cortex may provide input about discriminative stimuli [10]. The dopaminergic input from the substantia nigra may provide information about reward value. The contribution of action-outcome learning to drug taking is easy to conceptualize. Intrinsically rewarding effects of drugs likely control behavior even in recreational or social users seeking the euphoric effects of cocaine and amphetamine or the anxiety-reducing effects of alcohol. Indeed, studies in rat indicate that cocaine "seeking" behavior, measured as an instrumental response normally associated with drug availability is rapidly lost with devaluation under certain conditioning regimens [115]. It is not yet clear if action-outcome contingencies continue to drive drug seeking and self-administration after long-term drug use and in addicted individuals. It is tempting to speculate that addiction involves a shift in behavioral control from action-outcome/reward to stimulus-controlled/reinforcement mechanisms such as those described in the next few paragraphs. Interestingly, Pelloux et al. [122] have shown that rats given limited experience with cocaine seeking and taking will readily suppress seeking responses when intermittent punishment is given, while prolonged exposure to this paradigm reveals a subgroup of rats that will not show this punishment-suppression effect. Furthermore, rats allowed to orally self-administer cocaine continued to show instrumental responses associated with the drug even after cocaine devaluation [105]. Thus, evidence is developing that prolonged exposure to psychostimulants can lead to a shift from action-outcome to stimulus-driven behavior.

The sensorimotor circuit involving the dorsolateral striatum appears to have a prominent role in stimulus-response or habit learning. In this circuit the neocortical components and the dorsolateral striatum process information about the relationship between stimulus presentation and response performance, with the dopaminergic inputs from the substantia nigra (and the ventral tegmental area to some extent) providing a reinforcing signal to promote the stimulus-response association [10]. It has been suggested that the role of dopamine is required for the initial stages of this association, but that behaviors become engrained and resistant to dopaminergic manipulations once the stimulus-response association is formed and habitual behavior is in place [184]. Ultimately, output from the motor cortex is necessary for behavioral performance, and thus, this circuit can produce relatively straightforward throughput from sensory input to motor output. Habitual responding has been postulated to contribute to drug-taking behavior, such that when an individual is in the proper environment with the drug available, the actions involved in drug administration will be automatized and will often continue regardless of the specific outcome of drug usage. There is emerging evidence that this sort of responding may contribute to cocaine and alcohol-related behaviors in rodents

[38, 106, 122], but see also [146]. However, to date the role of stimulus-response associations in drug administration and relapse have not yet been thoroughly examined and fully dissociated from the stimulus-dependent forms of learning thought to be mediated by the limbic circuit (described below).

Among the roles of the limbic circuit is the integration of information for Pavlovian and instrumental conditioning in a type of learning called Pavlovian-instrumental transfer [32, 191, 192]. In this circuit, limbic neocortical areas such as the ventral prefrontal cortex provide information relevant to task outcomes to the nucleus accumbens. The basolateral amygdala provides input on reward and appetitive incentive value to the accumbens, where it is combined with the other cortical information. Dopaminergic inputs to the basolateral amygdala, limbic neocortex, and ventral tegmental area also provide information about reward value, while the orbitofrontal cortex may provide information important about the relationship of particular stimuli to task outcomes [116]. The role of the hippocampus and other limbic cortical regions that project to the nucleus accumbens is less clear. The net result is development of associations between environmental stimuli and task outcome (sometimes called stimulus-outcome learning), through which discrete stimuli gain control over particular instrumental responses. In this way the Pavlovian association of the stimulus transfers to the performance of the instrumental response. A role for this type of learning within the context of addiction is easy to postulate. It has long been thought that stimuli that are associated with, and predictive of, drug administration (e.g., needles, liquor bottles) can stimulate drug seeking and taking [50, 83, 139]. Indeed, there is experimental evidence that this sort of cue-induced relapse and drug craving can be induced in both humans and experimental animals [17, 25, 26, 83, 139].

The characterization of the limbic circuit as the mediator of reward and/or reinforcement is an idea that has captured the imagination of neurobiologists and addiction researchers [6, 53, 71, 80]. However, it is now becoming clear that the circuitry that includes the dorsal striatum has an equally important role in these processes (see [192] for review). In addition to the studies mentioned above that implicated the associative and sensorimotor circuits in action-outcome and stimulus-response learning, there is also evidence that dopaminergic innervation of the dorsal striatum plays important roles in instrumental learning. Stimulation of dopaminergic neurons in the substantia nigra pars compacta supports intracranial self-stimulation, as mentioned above. Furthermore, activation of substantia nigra neurons with intracranial self-stimulation-inducing patterns enhances learning and striatal synaptic plasticity [132]. An elegant series of studies by the Palmiter laboratory indicates a key role for dorsal striatal dopamine in instrumental learning and performance. Using dopamine restored in the dorsal striatum of mice that have been engineered to lack the neurotransmitter, these investigators have shown that food-seeking and instrumental learning/performance were rescued [136, 137]. Thus, full neurochemical integration within the dorsal striatum is all that is needed for proper motivational signaling and instrumental performance. This is not to say that the limbic circuitry does not have reward-related functions, but rather that an intact limbic circuit may not be necessary for proper learning and performance of a purely instrumental task.

In recent years researchers have also focused on the circuitry involved in generating undesirable effects that contribute to drug taking and relapse, and the effects of the drugs themselves on this circuitry (reviewed in [84, 86]). There is evidence for reduction in the positive hedonic effects of drugs after sustained self-administration, and negative consequences of drug use and withdrawal increase with repeated use and withdrawal [48, 81, 84, 86, 92, 102]. The amygdala and associated structures appear to have prominent roles in this scenario. The amygdala has generally been thought of as a brain region involved in the processing of information related to emotion, and the role of the amygdala in anxiety and responses to stress is widely known [90]. However, one can also view the role of the amygdala as providing a neural index of

the incentive value of a particular stimulus or event [10, 144, 176]. In this context, the amygdala plays roles in both reward and reinforcement processes as defined above. Furthermore, it is now clear that the structure we call the amygdala can be subdivided based on cytoarchitecture and afferent/efferent connections. Two well characterized amygdalar subregions are the basolateral and central nuclei. The basolateral amygdala is an archicortical structure containing mainly glutamatergic projection neurons and a small number of GABAergic interneurons. The basolateral amygdala innervates other structures within the amygdala, but also has connections with parts of the prefrontal cortex, and the dorsomedial and ventral regions of the striatum [143]. Input to the basolateral amygdala from areas such as the ventral tegmental area and the locus coeruleus provides information about arousal and motivational state [128]; thus, one possible role for this brain region is to integrate information necessary for a reward signal and relay that information to the associative circuit involved in action-outcome learning. The central amygdala is similar in cytoarchitecture to the striatum, having a large proportion of GABAergic projection neurons [143]. This structure receives excitatory input from the basolateral amygdala, neocortical and paleocortical regions, as well as information about motivational state via neuromodulatory regions such as the hypothalamus [143]. Output from the central amygdala is sent to the bed nucleus of the stria terminalis, hypothalamus, and other subcortical regions as well as to the substantia nigra and ventral tegmental area, where it can influence the circuitry involved in stimulus-response and stimulus-outcome learning [128, 143]. The amygdala has also emerged as a brain region with important roles in conditioned responses related to the rewarding effects of drugs studied using the conditioned place preference task described in the following section [20, 55]. The amygdala interconnections with the bed nucleus of the stria terminalis, a subcortical nucleus with a striatal-like organization (i.e., populated predominantly by GABAergic projection neurons) have generated a great deal of interest, as the bed nucleus of the stria terminalis has been implicated in the actions of drugs of abuse as well as in drug self-administration and relapse [5, 57, 179].

Clearly, a better understanding of the brain regions in involved in learning and control of behavior involving reward and reinforcement is emerging. In addition, methodology is emerging that will help us define the roles of brain circuitry and circuit physiology in behavior, and help us to refine our behavioral models based on neuroscientific findings. One of the challenges in addiction research in the coming years will be to determine how the function of these brain circuits contributes to responses to drugs of abuse, maladaptive use of the drugs, and addiction.

Models of Drug Use and Drug Addiction

Examination of the neural basis of drug actions, drug use, and addiction has relied to a great extent on development of laboratory animal models. A great deal of progress has been made with this approach. However, it has proven difficult to model all aspects of drug actions and addiction. For example, how does one assess "euphoria" or "craving" in an animal that is incapable of verbal self-report. Progress was slow at times for development of reasonable models of self-administration for drugs such as alcohol, cannabinoids, and nicotine [95, 147, 158]. Agreeing on a universal definition of addiction and developing an animal model thereof has also proven to be difficult. Nonetheless, several decades of research have led to the development of a variety of behavioral tests that assay various aspects of drug action, drug use, and addiction (Table 1). These techniques continue to be refined and combined with new techniques for neuroscientific investigation to provide more complete information about relevant neural mechanisms. The following discussion will describe some of these animal models with the emphasis on models of drug reward, reinforcement, and addiction.

Table 1 Models of drug reward and reinforcement: relation to phenotypes of human drug use, dependence, and addiction

Model	Human drug use phenotype
Simple operant self-administration	Hedonic value, liking/wanting
Devaluation	Goal-directed vs. habitual responding
Intracranial self-stimulation threshold changes	Hedonic value, anhedonia
Conditioned place preference/aversion	Reinforcement, craving, incentive sensitization, resistance to negative outcome
Progressive ratio breakpoint	Hedonic value, compulsivity
Behavioral "cost"	Hedonic value, compulsivity
Response persistence without drug	Compulsivity
Punished responding/pairing with undesirable tastant	Compulsivity, resistance to negative outcome
Cue-induced reinstatement	Craving, incentive sensitization
Secondary reinforcement	Craving, habitual responding
Psychomotor stimulation/sensitization	Incentive sensitization

A seemingly direct way to measure the reinforcing effects of a substance is to determine whether delivery of the drug itself will support learning or continued performance of a particular action or set of actions. This so-called self-administration paradigm has been used to examine the reinforcing actions of many drugs of abuse in a variety of animal models, and in general all of these drugs have been found to support self-administration under at least one schedule of drug administration [50]. Comparisons of self-administration in humans and laboratory animals have indicated similarities that auger well for the experimental use of these procedures [120]. The general procedure is to train the animal to press a lever or nosepoke an object in order to receive the drug either by oral, intravenous, or intracranial routes of administration. Using the basic instrumental training schedule, animals can also be tested in a final short "extinction" session in which no drug is available to see if they perform the operant behavior. This helps to assess the drug-seeking behavior without any interference from neural actions of the drug itself (e.g., depressant effects that reduce rate of responding). Variations of this basic procedure include the use of secondary reinforcers (e.g., stimuli paired with the opportunity for drug self-administration that come to elicit behavior themselves) [13, 41], and use of a progressive ratio schedule in which animals must increase their responses exponentially [133] with each trial in order to continue drug delivery. In this latter procedure, the investigator assesses the "breakpoint", which is the response requirement beyond which the subject will no longer work for the drug. This procedure can be used to determine the relative reinforcing efficacy of a particular drug. This approach has the advantage of direct measurement of the animal's willingness to use the drug. However, there are some drawbacks to self-administration techniques. For example, self-administration leading to high levels of drug in the brain that impair subsequent performance of the actions needed for further drug taking (reviewed in [60]). Oral self-administration of drugs such as ethanol brings into play factors such as taste that affect the willingness of certain animals to ingest the desired drug [54]. Use of instrumental self-administration procedures also necessitates consideration of separate neural control of drug seeking and drug taking [14, 139, 147]. Nonetheless, self-administration procedures are arguably the most direct measure of use and abuse, particularly given the variety of procedures that have been developed using instrumental paradigms. Self-administration procedures also allow investigators to examine the effects of treatments on drug use in preclinical assays.

In light of the previous discussion of reinforcement and reward, or action-outcome and habit learning, it seems important to evaluate which of these modes of behavior actually drives drug self-administration. As mentioned above investigators are just beginning to examine this

issue with interesting early results [38, 106, 122], but see also [146]. Another common variant of the drug self-administration procedure is cue-induced drug-related responding and reinstatement of this responding and/or drug taking. It has clearly been demonstrated that cues signaling the opportunity to respond instrumentally and obtain a drug can come to elicit responding in the absence of the drug, and especially robustly when the drug has been omitted for long periods of time [17, 77, 151]. This procedure involves a component of stimulus-outcome learning or Pavlovian-instrumental transfer with the cue serving as the Pavlovian conditioned stimulus. Indeed, this type of conditioning has become pretty much the standard in instrumental self-administration procedures as some explicitly paired cue, most often a light, is included in most such studies. This may be one reason for the large number of studies implicating the aforementioned limbic circuitry in drug-seeking behavior, as this circuitry appears to have important roles in stimulus-outcome learning. There is certainly some heuristic value to such studies in the context of human addiction, as it is easy to imaging how environmental stimuli that signal drug availability might trigger drug seeking and relapse.

Other surrogate measures of the rewarding effects of drugs of abuse have been developed. Drawing on the intracranial self-stimulation paradigm discussed above, investigators have examined the ability of drugs of abuse to shift the threshold stimulus intensities needed to support self-stimulation. Several abused drugs produce a leftward shift in the stimulus-response curve or increase rates of responding, indicating that they enhance the reinforcing properties of intracranial self-stimulation (see [187] for review). Drugs with this sort of action include those that are strongly self-administered such as cocaine and amphetamine, as well as other drugs of abuse, although studies of ethanol have yielded mixed results that might be explained by variables such as route of drug administration [9, 87, 107]. This technique can reveal indirectly the rewarding or reinforcing effects of drugs, but thus far the emphasis has mainly been on the effects of investigator-administered drugs and involvement of the limbic circuitry. It would be interesting to see this line of research extended to include more self-administration/intracranial self-stimulation studies and examination of different circuitry and component brain regions.

Recent studies have focused on identifying behaviors that might be indicative of an "addictive" phenotype in experimental animals. One approach has been to develop a battery of tests designed to measure continued drug seeking and taking under conditions where these behaviors become increasingly difficult and costly. Deroche-Gamonet et al. [36] have develop a three-test battery consisting of: (1) measuring the progressive ratio breakpoint mentioned above; (2) measuring the persistence of instrumental responding on a previously cocaine-associated manipulandum even when a signal indicates no drug availability, and (3) determining whether cocaine self-administration will continue even when associated with electric footshock (a paradigm also used in [122, 173]). Interestingly, Wolffgramm and Heyne [189] and Petry and Heyman [123] have used a conceptually similar approach with alcohol. Wolffgramm and Heyne [189] provided the alcohol in a solution with a normally aversive tastant, and found that this procedure decreased drinking in animals that had short-term alcohol drinking experience while drinking was maintained at much higher levels in animals that had been drinking alcohol for a long time period (at least 9 months). Petry and Heyman [123] steadily increased the behavioral "cost" necessary to obtain an alcohol-containing solution and found that rats with experience drinking alcohol maintained their drinking despite the increasing cost, while similar effects were not observed with palatable nutrient-containing solutions. These sorts of techniques are now being used to examine factors that predispose animals to uncontrolled/compulsive drug self-administration. Everitt and coworkers have determined that what appears to be impulsive responding in a 5-choice serial reaction time test is predictive of later abusive drug use in

this paradigm [13]. This paradigm has now been used by investigators to identify subgroups of rats that are especially vulnerable to what might be termed addiction. Interestingly, only a relatively modest subgroup of rats given extensive self-administration experience show maintained responding in the second and third tests and also show high breakpoints in test one [36]. It is hoped that this approach will provide a powerful tool for identifying genetic, neuronal and circuit differences that contribute to enhanced susceptibility to drug addiction.

Investigators have also taken advantage of Pavlovian conditioning to examine whether drug administration can be used to produce a conditioned place preference in an animal [172]. In this paradigm, the animal is given the drug paired with one of 2 or 3 chambers in an apparatus, and then tested later for location preference. In a final drug-free test, the animal is then free to choose a location in which to spend the trial. If more time is spent in a particular location, this is thought to indicate that the drug paired with this location has a preferred or reinforcing effect. This technique has the advantage that the animals are not subjected to drug intoxication at the time of testing, so there is little chance of impairment of the behavior by the drug itself. However, it must be stressed that the location is a conditioned stimulus and not a reward or reinforcer of any kind in this paradigm. Thus, the technique does not measure these functions per se, i.e., the animal does not have to repeat an action in order to obtain an outcome, and thus, it is at best a surrogate measure of the underlying construct and one that may be subject to influence by properties of the environment or drug that are not directly related to its reinforcing effects.

The "psychomotor" stimulant effects of drugs have also been proposed to provide a measure of drug reinforcement, reward, and addiction [188]. Administration of many drugs will produce forward locomotion and it has been theorized that this represents an operant approach response indicative of positive reinforcement by the drug [188]. The fact that forward locomotion is elicited by stimulation of the medial forebrain bundle, the site where stimulation yields intracranial self-stimulation, was also advanced as evidence that the mechanisms underlying this locomotion are linked to positive reinforcement. However, it is possible that sensitization is merely an adjunct consequence of drug taking and medial forebrain bundle stimulation. The circuitry that controls performance of voluntary actions overlaps extensively with that involved in reinforcement, reward, habit formation and addiction. Thus, it is possible that drug actions produce separate effects that both influence locomotion and drug reward or drug seeking, but that these effects are separable. Indeed, elegant recent studies showed just such a separation for regions of the ventral tegmental area and nucleus accumbens implicated in cocaine- and opiate-induced locomotor stimulation and conditioned place preference or self-administration [152, 153]. In addition, mice that lack dopamine show a nearly complete loss of morphine-stimulated locomotion, but continue to show morphine-induced conditioned place preference [63]. Locomotor stimulation and reward/reinforcement can also be separated pharmacologically. In the case of alcohol, stimulation of forward locomotion is inconsistent in rats and locomotor depressant effects are most often observed [46, 97], but rats clearly show other signs of ethanol reward and reinforcement (see [83, 84] for examples). Furthermore, Risinger et al. [134] and Sanchez et al. [148] found that genetic factors underlying ethanol-induced locomotor stimulation and conditioned place preference or ethanol drinking differ. Thus, it is not clear that forward locomotion is a good proxy for the actual reinforcing effects of the drug.

The idea of sensitization, an increase in frequency and intensity of a behavior elicited by a stimulus or treatment, has also figured prominently in models of drug abuse and addiction. Repeated administration of certain drugs of abuse, psychostimulants in particular, elicits successively larger increases in locomotor activity in rodents. It has been speculated that this locomotor sensitization is a result of the underlying neuroadaptive processes that contribute to addiction following repeated drug exposure.

However, it is still not clear that the locomotor-stimulating effects are related to reward or reinforcement per se, as discussed above. In one sense, however, drug seeking and self-administration must involve some form of sensitization, as these behaviors involve increases in responding elicited by the drug or drug-related environments or cues. One theory advanced to account for this aspect of drug-related behavior is the incentive-sensitization model [139]. This theory provides a reasonable explanation for the willingness of addicts to expend a great deal of energy and engage in new behaviors to obtain drugs, and also can explain the greater motivation of animals to work for previously used drugs in tasks such as the progressive ratio/breakpoint paradigm mentioned above. Other behavioral measures in laboratory animals provide evidence for enhanced incentive to seek and use drugs. For example, conditioned place-preference and cue-induced reinstatement of drug seeking indicate that the motivational value of previously neutral stimuli is enhanced when these stimuli are associated with drugs of abuse (reviewed in [139]). Thus, while simple locomotor sensitization may provide only limited information about drug effects on the brain reward/reinforcement system, the concept of sensitization is important within this context.

A role for negative reinforcement in addiction is also easily conceptualized, and experimental models of addiction based on this idea have been developed. Drugs such as benzodiazepines have known anxiolytic properties [21], and thus reduce an aversive state. The psychostimulants produce acute mood elevation that may provide temporary relief from negative affect (although these drugs are by no means effective antidepressants). Thus, negative reinforcement may be a strong driving force for acute drug use.

Relief of the negative symptoms encountered during drug withdrawal can also be characterized as a negative reinforcing component of addiction. Withdrawal following chronic use of different drugs of abuse produces symptoms ranging from heightened anxiety and irritability (benzodiazepines, alcohol) and dysphoria and depression (psychostimulants) to severe physiological symptoms such as abdominal cramps (heroin) [21, 102]. Withdrawal from drugs is associated with higher thresholds for intracranial self-stimulation in experimental animals, indicating dysphoria associated with this state [86, 154]. Relief from these symptoms has been postulated to drive relapse to drug use [84, 86]. Indeed, animals made dependent on drugs will increase self-administration and drug-related instrumental responding following drug withdrawal (reviewed in [86]). This sort of "reinstatement responding" has also been observed in alcohol-dependent animals and is referred to as the "alcohol deprivation effect" (reviewed in [163]). Animals that have undergone "conditioned aversion" in which withdrawal is rapidly induced and paired with previously neutral stimuli show reinstatement of heroin self-administration and elevation of intracranial self-stimulation thresholds, as if the aversive effects of withdrawal were reducing rewarding drug effects while driving relapse [81]. It is easy to imagine how this withdrawal-relief model can explain relapse after full-blown symptoms have begun. However, it is not so clear that this model can explain continuous drug use in the absence of withdrawal sufficient to produce symptoms. The ability of this model to explain relapse long after the cessation of withdrawal symptoms is also not as clear. However, lasting recruitment of drug effects on brain systems involved in stress responding has been suggested to underlie the long-term susceptibility to relapse [86].

The concept of negative reinforcement is also built into addiction theories based on Opponent-Process theories [86, 161]. These theories essentially propose that net emotional state is the result of competition between emotions (e.g., elation vs. fear), and that changes in the competitive balance over time can lead to changes in net emotion and behavior. Within the context of addiction one can easily envision that the euphoric "high" achieved just after administration of a drug like cocaine can dissipate and be replaced by depression as the neurochemical effects of the drug wear off [177]. With repeated drug use, the euphoria becomes less pronounced as the depression is

enhanced, and the user ends up taking the drug to relieve the depression, which could be termed a negative reinforcement model. This process has been modeled with cocaine and heroin self-administration, and it was found that both intracranial self-stimulation thresholds and cocaine or heroin self-administration escalated after several cycles of self-administration and withdrawal [2, 81]. Koob, LeMoal, and coworkers have extended these ideas to include the concept of "allostasis" [101, 185] in which the emotional "set-point" resulting from the new balance of opponent processes is altered toward a more depressed level with repeated drug use [84, 86]. The addict ends up using the drug to maintain this new set-point, often relieving more adverse emotional symptoms. Experimental models such as withdrawal-induced excessive self-administration have been used in conjunction with neurochemical approaches to implicate the amygdala and associated brain regions in these allostatic changes and the accompanying negative reinforcement driving drug taking and relapse (reviewed in [84, 86]). Brain systems for responding to environmental stress and internal anxiety may provide the aversive effects that interact with brain reward/ reinforcement circuitry to drive drug use in these models [85].

Actions of Addictive Drugs Within the Reinforcement and Reward Circuitry

The majority of abused substances act on specific molecular targets within the brain. These drug actions influence mechanisms thought to be involved in addiction, usually by producing a direct reinforcing or rewarding effect. Using the aforementioned addiction models combined with neurochemical and pharmacological techniques, investigators have discovered a number of molecular interactions produced by acute and chronic drug exposure that underlie the rewarding and reinforcing effects of drugs of abuse. Perhaps the mechanisms that are easiest to appreciate are those triggered by the so-called psychostimulant drugs, such as cocaine and amphetamine. These compounds act directly on the protein known as the dopamine transporter to enhance the concentration of dopamine present in the synaptic cleft following release of the neurotransmitter [88]. Cocaine is a competitive inhibitor of dopamine transporter that reduces the reuptake of dopamine into neurons, while amphetamine can also increase release of dopamine directly through the dopamine transporter [76]. It is easy to see how these molecular actions have rewarding and reinforcing consequences, given that dopamine has an important role in both of these processes, and these drugs will enhance dopamine signaling.

Given that cocaine is thought to act primarily on the dopamine transporter, it is surprising that evidence has emerged for actions of drugs of abuse that could be construed as indicating reinforcing effects of cocaine even in the absence of the transporter [140, 162]. However, it appears that blockade of serotonin reuptake indirectly mediates this effect. Even more surprising is the finding that serotonin mediates cocaine conditioned place preference in dopamine deficient mice [64]. These mice show a conditioned place preference for morphine [63]. Thus, dopamine itself may not be necessary for this drug-related learning. However, evidence that manipulations that decrease the firing of dopaminergic neurons reduces conditioned place preference in these dopamine-deficient mice suggest that another factor released by these neurons may have important roles in drug-related reward [64].

The actions of many other drugs of abuse have also been suggested to involve dopamine, but in a less direct manner. For example, opiates, nicotine and alcohol all increase dopamine levels in regions of the brain such as the ventral and dorsal striatum, and appear to do so by increasing the firing activity of the dopaminergic neurons themselves (reviewed in [125]). Hypotheses about the mechanisms underlying the reinforcing effects of these drugs of abuse have generally centered on the idea that enhancement of dopaminergic transmission leads to reward or reinforcement,

and that all drugs of abuse work through this mechanism in one way or another. However, this idea is undoubtedly too simplistic given the evidence discussed above that dopamine is not necessary for reward-related learning. Furthermore, dopamine does not appear to be necessary for self-administration and reinforcing effects of all drugs of abuse, particularly for drugs with indirect effects on the dopaminergic system. Studies of the effects of dopaminergic lesions and dopamine receptor antagonists on ethanol self-administration have yielded mixed results in a variety of self-administration and operant paradigms. D2 receptor antagonists and D1 antagonists and knockout of D1 and D2 reduce self-administration in some paradigms, but alcohol intake is not abolished after lesions of the dopaminergic system of by other dopamine receptor antagonists [125, 130, 145]. The evidence for dopamine involvement in opiate self-administration and opiate-related reward/reinforcement is likewise mixed, including evidence for lack of effect of dopaminergic lesions [124, 125]. Thus, it appears that dopaminergic transmission is not strictly necessary for alcohol and opiate intake. Dopamine is probably not the final common pathway for drug reward, reinforcement, and self-administration as was once imagined, and the focus has now shifted to the importance of the circuitry that is influenced by dopamine.

The primary targets of almost all drugs of abuse are cell surface proteins that regulate synaptic transmission. The role of neurotransmitter transporters as targets for psychostimulants has already been discussed. Drugs such as nicotine, benzodiazepines, barbiturates, and, to some extent, alcohol produce their actions by altering the neurotransmitter receptors known as ligand-gated ion channels [21]. These receptors mediated fast synaptic transmission in the brain and can directly influence the activity of neurons within the brain reward/reinforcement circuitry. An assortment of other psychoactive and addictive drugs, including opiates, cannabinoids, and hallucinogens, produce their actions via G protein-coupled receptors [21]. This class of receptors mediates the neuromodulatory actions of neurotransmitters by initiating or influencing intracellular molecular signaling pathways [21, 79]. The subtle changes in neuronal activity and gene expression produced by drug actions at these receptors can have profound acute and long-lasting effects on the brain reward and reinforcement systems.

Opiate drugs produce their intoxicating and rewarding effects through activation of mu, and to a lesser extent delta and kappa, opiate receptors [30, 98]. Opioid peptides and their receptors have also been implicated in the rewarding effects of drugs of abuse, including effects of nicotine, cannabinoids and alcohol (reviewed in [30, 47]). There is also considerable evidence that opiate receptor blockade reduces rewarding and reinforcing effects of a variety of drugs of abuse, as well as drug seeking and taking in animal models of addiction (see [18] for review). The opiate receptor antagonist naltrexone can also produce lower sensitivity to intracranial self-stimulation, but this is mainly seen with stimulation in the ventral striatum and not with ventral tegmental area stimulation [182]. Thus, there is reason to believe that opioid peptides can mediate reinforcing and rewarding effects of drugs of abuse, perhaps independent of the actions of dopamine.

As mentioned above, the cannabinoid drugs produce their intoxicating actions mainly via brain cannabinoid-1 receptors. Delta-9-tetrahydrocannabinol, the main psychoactive ingredient in cannabis-derived drugs, is a partial agonist of the cannabinoid-1 receptor. Several synthetic delta-9-tetrahydrocannabinol analogs and other cannabinoid-1 agonists also produce intoxicating effects. Emerging evidence indicates an important role for endocannabinoids and the cannabinoid-1 receptor in drug self-administration. Antagonist blockade or gene-targeted knockout of cannabinoid-1 receptors decreases self-administration of a variety of drugs of abuse in animal models [96], and the cannabinoid-1 antagonist rimonabant shows some effectiveness in reducing cigarette smoking in humans [91]. Blockade of the receptor decreases intake of ethanol and self-administration [27, 180]. Antagonists of the

cannabinoid-1 receptor also reduce increases in extracellular dopamine produced by several drugs of abuse [24], and thus, endocannabinoids may alter the rewarding *or* reinforcing actions of drugs of abuse via this mechanism.

Chronic exposure to drugs of abuse is thought to bring about neuroadaptive changes that alter the brain reinforcement/reward circuitry. Recent studies have focused on changes in the efficacy of synaptic transmission and alterations in dendritic morphology in neurons within the ventral tegmental area and nucleus accumbens. Cocaine exposure has been demonstrated to produce changes in the ratio of excitatory synaptic responses mediated by AMPA and N-methyl-D-aspartate-type glutamate receptors, a change thought to reflect long-term plasticity of glutamatergic synapses [4, 169, 175]. This sort of synaptic plasticity has been observed in recordings from both nucleus accumbens medium spiny neurons and ventral tegmental area dopaminergic neurons [169, 175]. Even a single dose of cocaine appears to produce this plastic change in excitatory transmission [175]. Other drugs of abuse, including ethanol, alter efficacy of both excitatory and inhibitory transmission in the ventral tegmental area [103, 164]. Synaptic plasticity produced by drug exposure may condition synapses within the reinforcement/reward circuits to enhance responses to subsequent exposure to drugs or drug-related stimuli. This could occur at the expense of using this circuitry to learn other, more adaptive, responses to environmental stimuli.

Chronic drug exposure also alters long-term synaptic depression mediated by endocannabinoids and the cannabinoid-1 receptor. Repeated exposure to delta-9-tetrahydrocannabinol for days eliminates this form of long-term synaptic depression in the hippocampus and nucleus accumbens [65, 100], and this adaptation appears to involve decreases in the presynaptic actions of cannabinoid-1 receptors. Even a single exposure to delta-9-tetrahydrocannabinol produces a similar action [99]. A single treatment with cocaine also eliminates endocannabinoid-dependent long-term synaptic depression [44], and chronic ethanol exposure has been reported to have a similar action in the striatum [190]. Given the role of cannabinoid-1 receptors in responses to drugs of abuse mentioned previously, it is possible that adaptations in endocannabinoid/cannabinoid-1 function underlie neuroadaptations that lead to altered reinforcing and rewarding properties of many drugs of abuse.

Repeated exposure to cocaine, amphetamine and other drugs of abuse alters the dendritic structure of neurons in the prefrontal cortex, nucleus accumbens, and dorsal striatum [73, 108, 138]. Changes in spine density and dendritic branching are seen, with differential effects in different brain regions. These morphological changes are thought to lead to alterations in the ability of neurons within this circuitry to respond to normal levels of synaptic input. Ultimately, this dendritic rearrangement could lead to less plasticity within the circuitry and help to rigidify behaviors related to the addictive drug.

There are also a host of cellular and molecular changes within the reinforcement/reward circuitry that have been related to drugs of abuse (see [110] for review), and there is simply not space within this review to cover all of these changes. However, interesting information is emerging from examination of drug-induced changes in glutamatergic synaptic transmission within the circuitry of interest. Glutamate signaling through G protein-coupled receptors called "metabotropic" glutamate receptors is one system implicated in these drug-induced changes [58, 168]. The metabotropic glutamate receptors come in a variety of subtypes [29]. The different metabotropic glutamate receptor subtypes produce diverse cellular actions including inhibition and stimulation of neurotransmitter release and activation of intracellular signaling pathways that contribute to changes in neuronal excitability and long-lasting plasticity of synaptic transmission [29]. An emerging line of research has implicated group I metabotropic glutamate receptors in neuroadaptations to abused drugs, as well as drug self-administration [58, 168]. The expression and function of metabotropic glutamate receptor-5

is down-regulated following chronic administration of cocaine and withdrawal, but up-regulated by alcohol exposure (reviewed in [168]). At the same time, expression of the Homer protein that interacts with this receptor and changes its signaling functions undergoes similar drug-related up-regulation [165, 167, 168]. The group I metabotropic glutamate receptors are implicated in forms of synaptic plasticity throughout the brain reward/reinforcement circuitry, including endocannabinoid-dependent long-term synaptic depression [58]. Thus, cocaine-induced down-regulation of metabotropic glutamate receptor-5 in brain regions such as the nucleus accumbens following chronic drug exposure enhances could underlie loss of metabotropic glutamate receptor-mediated synaptic plasticity [44, 58]. In the case of alcohol, increased metabotropic glutamate receptor/Homer expression may be part of a general increase in glutamatergic signaling after repeated drug administration and withdrawal, contributing to plastic changes in the circuitry that ultimately foster increased drug seeking and self-administration [168]. This idea is consistent with the finding that a metabotropic glutamate receptor-5 antagonist decreases alcohol seeking and relapse in animals with self-administration experience [8].

However, despite this wealth of knowledge, it is still not clear how the cellular and molecular changes brought about by drugs of abuse contribute to overall changes in circuit function that ultimately lead to addiction. Addressing this topic will require more sophisticated analysis of neuronal and circuit function in vivo, combined with continued work at the molecular, cellular and behavioral levels. Clearly, this is a key direction for future research on the neural basis of drug reinforcement and reward.

What Drives Drug Use, Abuse, and Addiction: The Direction of Future Research

Ultimately, the goals of research on drugs and addiction are to gain a better understanding of how drugs act on the brain, and to develop better approaches for minimizing and treating drug abuse and drug addiction. The neurobiological mechanisms discussed in the present paper indicate that brain mechanisms of reward and reinforcement are more complicated than most of us previously imagined in terms of both the circuitry involved and the underlying neurochemistry.

The interactions of drugs of abuse with these systems are likewise complex. It is likely that drugs engage multiple aspects of the different circuits during the initial phases of exposure. Drug actions on dopaminergic transmission and other aspects of the associative circuit will signal the positive hedonic value of the drug and establish the motivation to continue to take the drug. At the same time, drug-associated cues and environmental connections to drug availability will be signaled and learned through the limbic circuitry, likely contributing to the sensitized incentive described by Robinson and Berridge [139]. It is currently thought that the role of the sensorimotor circuitry in drug seeking and taking develops rather slowly during the course of experience with drugs [41, 50]. However, the rate of recruitment of this system may depend on the schedule and contingencies of drug availability, especially in relation to instrumental behaviors. Furthermore, engagement of the sensorimotor circuitry may develop in series or in parallel with activation of the other circuits, and there may be competition between the different circuits for control of behavior. Ultimately the involvement of the systems will likely depend on the pattern of recruitment of different circuit elements. However, there is emerging evidence that reinforcing effects of drugs ultimately lead to involvement of the sensorimotor circuitry and establishment of drug-related "habits" [12, 41, 50, 191]. One intriguing scenario is a shift from a purely stimulus-outcome based mode of responding to one that also includes stimulus-response-based actions. Thus, a drug user may initially come to associate certain cues with the rewarding effects of a drug, and this may initially drive drug seeking. With continued drug exposure, the stimulus-response circuitry becomes progressively more engaged as drugs reinforce

the stimulus/environment control of drug seeking and use. Indeed, the work of Everitt and colleagues appears to support such a transition from limbic to sensorimotor circuit control of drug-related actions [12, 41]. It remains to be seen how action-outcome-based learning plays a role in this scenario, but this form of learning will almost certainly play a role in drug use and abuse in humans. One possibility is that action-outcome learning may drive the acquisition of new behaviors that are designed to locate and obtain drugs of abuse, providing another mechanism through which incentive sensitization takes over brain function to promote drug seeking and use. Brain mechanisms involved in stress responsivity and production of aversive responses to drug withdrawal also become progressively more involved as drug use and abuse continues, and these circuits likely interact with mechanisms of reward and reinforcement to promote relapse to drug use (Fig. 1).

The effects of stress on the prefrontal cortex are of interest in this regard. Recent studies showing that exposure to acute or chronic stress and corticosterone treatment stunts the dendritic morphology of neurons in the medial prefrontal cortex [23, 72, 129] suggest that the circuitry involving this brain region is impaired during stress. These dendritic stunting effects have been postulated to impair "executive" decision-making capabilities [139]. One result of this neurotoxic stress effect may be to drive behavior away from goal-directed actions and toward habitual responding [43]. Thus, stress may act on the reward/reinforcement circuitry at a number of levels to promote inflexible drug seeking and use. Ultimately, drug use and abuse is initiated and sustained by a number of intrinsic neural mechanisms including goal-directed behavior, environmentally stimulated instrumental behavior, habitization of drug-related responses, and negative reinforcement/allostasis that promotes a return to drug usage.

Determining the relative roles of these different neural mechanisms and neural circuits in drug use, abuse, and addiction will require new avenues of research at the molecular, cellular, systems and behavioral levels. Ultimately, an integrative approach that incorporates all of these levels of analysis is needed. Behavioral models of different aspect of drug reward, reinforcement, and addiction need to be used with an eye to determining the roles of the underlying changes in circuits, cells and molecules. In using these models it will be necessary to bear in mind all of the possible processes that contribute to drug use, relapse, and addiction, including goal-directed behavior, cue-related conditioning, avoidance of aversive consequences and development of habitual actions. The development of models that allow investigators to select animals that are highly sensitive to compulsive drug use should provide the opportunity to examine genetic, epigenetic and environmental factors that have predispositional effects in these animals. However, the generality of these models to multiple drugs of abuse needs to be demonstrated, and it will be important to determine if the same factors play a role in development of compulsive use of different drugs. It is quite possible that no one model will be able to tell us all that we need to know to understand maladaptive drug use and addiction. Thus, it is important to continue to cultivate useful models and develop new ones, always with an eye to determining the underlying neurobiology.

In considering the role of neural circuitry in drug reward, reinforcement, and addiction a more inclusive approach will likely be needed. Basic neuroscientific research is now revealing multiple parallel brain systems for control of different aspects of action production and action learning. Movement beyond the monolithic concept of a single neural reward/reinforcement system is necessary. It is likely that these systems will have similar roles in behavior directed toward drugs of abuse, and this must be considered in designing experiments aimed at determining the neural basis of drug seeking and use.

At the cellular and molecular levels a number of changes brought about by drug exposure and related conditioning have been described. However, little is known about the role of most of these changes in the development of maladaptive drug use and/or addiction. Consideration of the wide variety of neurotransmitters and

receptors that participate in normal and abnormal functioning of the relevant brain circuitry is especially important. Experimental approaches designed to manipulate particular molecules within given cell types and circuits (e.g., local drug application, disconnection analyses, and the use of sophisticated genetically manipulated mice) will play an ever increasing role in our quest to determine which molecular and cellular changes are important and which are merely epiphenomena or secondary to the truly causal changes. The powerful tools for genetic manipulation, molecular analysis, examination of neurophysiology and neurochemistry at the in vitro and in vivo levels, and ever more sophisticated behavioral analysis in a variety of organisms should allow investigators to make rapid progress in this area in the coming years.

Ethanol (Alcohol)

History

Ethanol is surely the oldest known substance of abuse. The details of the original discovery of fermented beverages have been lost to time because of the unavailability of the written word. Thus, no one really knows exactly when humans started drinking fermented beverages. Animals such as birds, insects, and elephants have shown

signs of drunkenness by purposefully eating ripened fruit in which yeast produced ethanol [76]. It is known that intentionally fermented beverages existed as early as 10,000 B.C. [188]. Aristotle, the founding father of the scientific method, showed in the third century B.C. that boiled wine lost its intoxicating character, but he never took the next step of condensing the ethanol [76]. The distillation of ethanol from wine was discovered by a Muslim chemist in the eighth century A.D. There are a myriad of accounts of the incorporation of alcoholic beverages into the daily life of every society. As with all substances of abuse, ethanol was probably not used abusively at first. For example, early versions of beer were used as food. Alcoholic beverages such as beer and wine were used in ritualistic religious exercises, and evidence of the use of beer and wine as medicinal remedies exist at least 2,000 years before the birth of Christ.

A recently published book describes in detail the cultural history of alcohol [76]. The use of alcoholic beverages in most societies is certainly evident. It has produced social and health benefits as well as significant detrimental forensic and health problems. For example, light to moderate alcohol intake is probably associated with lower risk of cardiovascular mortality in hypertensive men [149, 161]. On the other hand, excessive ethanol consumption is closely associated with abnormal elevation of blood pressure in normotensive and hypertensive individuals [161]. Despite its social and possible health benefits, excessive ethanol consumption is a major medical health problem. In 1995, it was reported that about 10 million Americans were considered to be alcoholic [9].

Chemical Properties

Ethanol is a relatively simple molecule (C_2H_6O) with a molecular weight of 46 and density of 0.789 g/cm^3. At ambient temperatures, it is a clear, colorless liquid that is highly volatile, flammable, and miscible with water and many other organic solvents. Its lipid:water partition coefficient is 0.096, which indicates that the distribution of ethanol favors an aqueous versus a lipid phase [177]. In humans, this solubility ratio explains the distribution of ethanol in total body water.

Ethanol concentration is expressed in a variety of ways depending on the application. For example, a blood alcohol concentration of 0.1% (w/v) is the upper limit of the legal range while driving a car in many states. This concentration can also be expressed as 100 mg%, 100 mg/deciliter, 1 g/L, and 21.7 mM. The concentration of ethanol in commercially available forms of consumable, distilled alcoholic beverages is expressed in terms of proof, which is a number that is approximately double the percentage of ethanol (200 proof = 100% ethanol). The term proof was used in the nineteenth century by English sailors who developed a test for the minimal concentration of ethanol in rum. If the sailor could successfully ignite gun powder soaked in the rum, it was "proof" that the rum was acceptably potent and had not been diluted with water. At least 50% (v/v) of ethanol is necessary to ignite gun powder. This simple test was important because the sailors were given rum as part of their pay.

Pharmacokinetics

Routes of Administration

Alcohol is one of the drugs of abuse that can be legally purchased with age as the only restriction. Humans self-administer ethanol by the oral route exclusively. There are many forms of commercially available alcoholic beverages with widely varying percentages by volume, including beer (~5%), malt liquor (~7%), wine (~12%), sherry or port (~17%), cordials or liqueur (~24%), brandy (~40%), and distilled spirits (~40–50%).

Absorption and Distribution

After oral administration, ethanol is rapidly absorbed into the blood principally from the small intestine, but also from the stomach and

colon [46, 71, 115]. It is known that food, ethanol concentration, and liquid volume affect the gastric emptying rate and gastric absorption of ethanol, but once ethanol reaches the small intestine, its absorption is rapid and complete [251]. For example, when a non-intoxicating dose of ethanol (~0.5 g/kg) is ingested over a relatively short period of time (~30 min) on an empty stomach, ethanol reaches its maximal concentration in the blood within 15–30 min [16]. In fact, intravenous administration of ethanol combined with quantification of either breath or blood ethanol concentration has been used to estimate total body water [177].

Metabolism

The metabolism of ethanol occurs mainly in the liver by oxidation of ethanol to acetaldehyde by alcohol dehydrogenase and conversion of nicotinamide adenine dinucleotide to nicotinamide adenine dinucleotide hydrate. A secondary pathway of oxidative ethanol metabolism occurs in liver microsomal tissue in the smooth endoplasmic reticulum [139]. Chronic consumption of ethanol increases the capacity of the liver microsomal ethanol oxidizing system with a rise in several cytochromes P-450, especially a nicotinamide adenine dinucleotide phosphate-requiring enzyme (CYP2E1). This system provides a higher rate of ethanol oxidation and is important to the development of tolerance to alcohol [139]. Both of these mechanisms produce acetaldehyde which is then converted to acetate by the action of aldehyde dehydrogenase.

Elimination/Excretion

The disappearance of ethanol from the blood or breath was originally thought to be a linear, zero order function, i.e., independent of the blood ethanol concentration and probably due to saturation of alcohol dehydrogenase [155]. However, it has been shown more recently that the elimination profile is more accurately described by Michaelis–Menten kinetics [250]. Nevertheless, at higher doses of ethanol, there is an apparent linear phase (15 mg%/h) that starts at the completion of the absorption-distribution phases and extends to a blood ethanol concentration of about 20 mg%. Below this concentration, the elimination becomes curvilinear. The elimination half-life of ethanol is about 2–4 h. Between 90 and 95% of ingested ethanol is converted to acetaldehyde and acetate and then eliminated in the urine. About 3–5% of a dose of ethanol is eliminated unchanged in the urine, breath, or through the skin [250]. Less than 2% of ethanol is metabolized non-oxidatively to ethyl glucuronide, ethyl sulfate, phosphatidylethanol, and fatty acid methyl esters. Interestingly, these "direct metabolites" of ethanol are measurable as markers for ethanol consumption.

Pharmacodynamics

The small size and simplicity of ethanol's structure (Fig. 1) is in contrast to its significant and complicated pharmacodynamic effects. When compared with most other drugs, very high concentrations of ethanol, in the millimolar range, are required to produce biological effects. Because of its simple chemical structure and the concentrations required for physiological effects, ethanol binding sites with high affinity (μM or nM range) most likely do not exist. It has been proposed that an ethanol binding site exists on gamma-aminobutyric acid-A ($GABA_A$) receptors that contain a combination of α4 (or α6), β3, and δ subunits, making them sensitive to concentrations of ethanol as low as 3 mM [90, 243]. Furthermore, relatively recent reports indicate that a certain domain of the

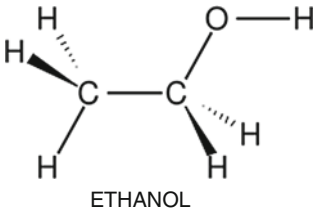

Fig. 1 Structure of ethanol

enzyme adenylyl cyclase is responsible for sensitivity to ethanol [90]. Amino acid mutations of target proteins designed to modify ethanol's effects have suggested that specific groups of amino acid residues in transmembrane regions of proteins may be binding sites for ethanol [159]. The results of these relatively recent studies suggest that ethanol situates itself into tiny pockets in protein structures to produce significant changes in biochemical, physiological, and behavioral functions.

Neuropharmacological Effects

The neuropharmacological effects of ethanol have been identified and measured at biological levels from the molecular to the behavioral.

At the cellular/molecular level, it has been shown that acute, physiologically relevant concentrations of ethanol (5–50 mM) affect the function of numerous different receptor types [236]. Ethanol inhibits *N*-methyl-*D*-aspartate receptors [100, 145] and L-type Ca^{2+} channels [244], and enhances the function of gamma-aminobutyric acid-A receptors [8], glycine receptors [159], serotonin-3 receptors [144], and neuronal nicotinic acetylcholine receptors [5, 172].

Effects of ethanol on the aforementioned receptor systems (e.g., a neurotransmitter receptor or ion channel) can often be demonstrated using electrophysiological techniques, thereby showing effects on neurons or neuronal systems. If ethanol affects the rate of neuronal firing, membrane potential, or other cellular parameters, then the effects of ethanol on receptor systems and perhaps specific brain areas can sometimes be linked to certain behaviors [53]. Electrophysiological studies have shown that ethanol affects the firing rate of neurons in several brain areas, including the cerebellum, inferior olivary nucleus, locus coeruleus, ventral tegmental area, substantia nigra, hippocampus, and septal area [53]. Furthermore, these effects of ethanol on single cells are thought to mediate neurotransmission in the mammalian central nervous system, especially in the hippocampus, locus coeruleus, cerebellum, spinal cord, and cortex via pre- and post-synaptic effects [53].

From the behavioral perspective, acute low doses of ethanol are anxiolytic and can enhance mood and produce euphoric feelings in humans. In fact, the use of ethanol as a disinhibitor in social settings is well known and widespread throughout recorded history [76]. For those who have the ability to limit ethanol intake, there appear to be social and health benefits. On the other hand, higher acute doses cause intoxication, sedation, sleep, and "hangover," and very high acute doses can induce coma and possibly death as a result of respiratory depression. Studies with laboratory rodents showed effects of ethanol to produce hypothermia, analgesia, motor activation, and, at higher doses, motor incoordination. Chronic, heavy alcohol consumption produces a myriad of problems as discussed below.

The behavioral consequences of acutely administered, lower doses (<30 mM) of ethanol may be linked to certain receptor systems. For example, intoxication, sedation, and motor incoordination are probably mediated via certain subunit configurations of the gamma-aminobutyric acid-A receptor [53, 243]. Also, there is thought to be differential sensitivity among presynaptic, postsynaptic, and extrasynaptic gamma-aminobutyric acid-A receptors with the extrasynaptic types being the most sensitive [67]. Ethanol-induced hypothermia and analgesia are not thought to be mediated by gamma-aminobutyric acid-A receptors, but by inwardly rectifying G protein-gated K^+ channels [18, 108, 123]. The concentration of ethanol required to affect other receptors is very high (>50 mM), so the involvement of these receptors at physiological concentrations is not clear.

A discussion of the neuropharmacology of ethanol would not be complete without comments about acetaldehyde. Acetaldehyde is the first metabolic product of ethanol in vivo and is produced by the action of alcohol dehydrogenase. Acetaldehyde may be responsible for some of the effects of ethanol, probably mostly the unpleasant and chronic side effects [53, 243]. The mechanism whereby these effects of

acetaldehyde occur may be due to aldehyde-amine condensation products of amino acid side chains on proteins [53]. Humans who carry a certain inactive form of mitochondrial aldehyde dehydrogenase do not metabolize acetaldehyde and have an uncomfortable facial flushing reaction after drinking alcohol [162]. Also, the hangover that occurs after a bout of heavy drinking is probably caused by high concentrations of acetaldehyde [243].

Toxicology

Whether ethanol produces an acute, satisfying, possibly beneficial effect versus an acute or chronic, unhealthy toxic effect is related to the concentration of ethanol, the dose of ethanol, and the length of exposure to ethanol. From a medical perspective, ethanol consumption of less than two standard drinks per day ($\leq\sim$30 g) by humans appears to decrease mortality [11] and the mechanism is probably related to a reduction of coronary heart disease [47]. Thus, low or moderate levels of ethanol consumption are thought to be healthful. On the other hand, chronic heavy ethanol consumption of 5 standard drinks per day ($\sim$75 g) or more for men and 4 standard drinks per day ($\sim$60 g) or more for women or frequent binging can cause severe, detrimental health problems [138]. These health problems result from direct toxic effects of ethanol on the liver, heart, brain, kidneys, and stomach. Indirectly, the replacement of calories from food by calories from ethanol (malnutrition) can cause additional negative effects on these organ systems [138]. These serious effects of ethanol abuse can eventually result in alcoholism, a pathology that includes very serious medical and behavioral difficulties.

Cocaine

History

Cocaine is a derivative of the coca plant *Erythroxylon coca* native to the mountains of South America. Traditionally, South American natives have chewed coca leaves as a stimulant to fend off fatigue, especially at relatively hypoxic elevations of the Andes Mountains. In 1574, the Spanish physician Nicolas Bautista Alfaro (1493–1588) published a description of the plant, its use and its effects [32]. In 1862, the German chemist Albert Neiman (Gottingen, Germany, 1834–1861) isolated the active component of the coca plant and called it cocaine. He was also the first to report the local anesthetic properties of cocaine, noting its numbing effects on his own tongue. In 1880, pharmacologist Basil Von Anrep of the University of Leipzig proposed use of cocaine as a surgical anesthetic in humans [240]. Canadian surgeon William S. Halsted became the first physician to use cocaine for a nerve block during surgery and subsequently became the first known physician to develop a cocaine addiction. In 1884, psychiatrist Sigmund Freud published a cocaine monograph entitled "Uber Coca" in which he advocated for the use of cocaine to treat a variety of conditions including asthma, wasting diseases and syphilis [74]. Freud also eventually became addicted to cocaine. In the late 1800s, cocaine was added to a number of beverages including the "medicinal" wine Vin Mariani in France. In 1895, The Lancet published a report of six cocaine associated deaths underscoring the significant potential toxicity of this drug. Cocaine was an ingredient in the original version of John Pemberton's Coca Cola; cocaine was removed from the popular soft drink in 1906. With passage of the Harrison Narcotic Act in 1914, nonprescription use of cocaine was made illegal. In 1970 cocaine was classified as a Schedule II drug (Comprehensive Drug Abuse Prevention and Control Act).

Pharmacodynamics

The cocaine is a tropane (aminoester) alkaloid with a $p\mathrm{K}_a$ of 8.6. "Crack" cocaine (free-base) is produced by combining cocaine HCl with an alkali. Crack cocaine is more heat-stable than is cocaine HCl and therefore can be smoked [63].

Cocaine interacts primarily with these central nervous system biogenic amine systems. Cocaine blocks the in vitro reuptake of norepinephrine, dopamine, and serotonin [111]. Saturable, high-affinity Na^+-independent and Na^+-dependent [^{3}H]-cocaine binding has been associated with sites for serotonin and for dopamine reuptake, respectively, in the central nervous system [200]. With acute or low-dose administration of cocaine, this reuptake inhibition leads to increased aminergic concentrations within aminergic synapses and increased binding both to pre- and postsynaptic aminergic receptors. Chronic cocaine administration is generally believed to result in aminergic depletion for the duration of drug exposure [111]. However, unlike high doses of methamphetamine [107], chronic cocaine does not produce dopamine nerve terminal degeneration, at least in the prefrontal and frontal cortex or dorsal raphe [50].

Various addictive drugs such as cocaine that act as positive reinforcers increase synaptic dopaminergic concentrations in selected areas such as the nucleus accumbens. Homologous recombination targeting the dopamine transporter results in an absence of cocaine- or amphetamine-induced behavioral activation [84]. The ventral tegmental area, nucleus accumbens, and caudate nucleus, areas rich in the neurotransmitter dopamine, are collectively considered the "reward pathway" [126, 127]. Cocaine antagonism of presynaptic dopamine transport results in elevated dopamine levels in mesolimbic synapses with resultant drug reinforcement. Maintenance of higher dopamine levels in "reward pathway" synapses leads to feelings of euphoria and a "cocaine high". The increased availability of synaptic dopamine is thought to act on D1-like (D1 and D5) and D2-like (D2, D3, and D4) receptors in the mesocorticolimbic synapses. The effects of cocaine acting on the dopamine D1 receptor in the nucleus accumbens and ventral tegmental area are thought to be responsible, at least in part, for the reinforcing properties associated with long-term exposure to this drug [218].

Long-term cocaine use is associated with a selective decrease in D1 receptors in striatal reward areas both in rodents [29, 30, 33] and in non-human primates [167]. Dopamine depletion using the neurotoxin 6-hydroxydopamine infused into either the nucleus accumbens or the ventral tegmental area results in an attenuation of the reinforcing effects of cocaine self-administration. Similarly, dopamine D1 receptor knockout mice demonstrated a lack of reinforcing effect of cocaine in contrast to wild-type controls [31]. D1 and D2 receptors have opposing intracellular and behavioral effects and thus may differentially affect drug-reinforcing behaviors. David Self and colleagues [218] demonstrated that cocaine self-administration behavior was mediated by dopamine D1 and not by dopamine D2 receptors and that this behavior progressively diminished in rats when cocaine was replaced with saline ("extinction behavior").

Cocaine also blocks voltage-gated sodium channels and thus reversibly attenuates conduction of nerve impulses, which accounts for the local anesthetic properties of the drug [200]. Depending on the relative distribution of the drug, a relatively selective depression of inhibitory neurons can produce cerebral excitation at lower concentrations of the drug, and this in turn can lead to generalized convulsions. At high concentrations, cocaine could produce more profound depression of brain function and ultimately coma, cardiorespiratory arrest, and death.

Pharmacokinetics

Distribution

Cocaine is rapidly absorbed across nasal, trachea and laryngeal epithelial membranes within minutes of its administration. Peak plasma concentrations of 120–474 ng/ml are reached within 30–60 min of intranasal administration and remain detectable up to 6 h after administration [15, 234]. Cocaine may limit its own absorption due to its activity as a potent vasoconstrictor [250]. Bioavailability of intranasal cocaine (i.e., area under the plasma concentration-time curve) is approximately 5

times less than that for equivalent intravenous dosing (0.19–2.0 mg/kg). The biological half-life for cocaine is 0.5–1.5 h with a volume of distribution of 2.0 L/kg and a systemic clearance of 2.0 L/min [111].

Metabolism/Elimination

Cocaine metabolism is catalyzed by esterase activity, principally within plasma and liver. Liver esterase activity accounts for 30–50% of the metabolism of cocaine to ecgonine methyl ester. Another 30–40% of cocaine is non-enzymatically hydrolyzed into benzoylecgonine (Fig. 2). The elimination half-lives of these major metabolites of cocaine are 6 and 4 h, respectively. These metabolites can be detected in urine samples up to 60 h after cocaine administration. A small amount (1–5%) of cocaine is excreted unchanged in urine within 8 h of administration [111]. Individuals with liver dysfunction or malnutrition, or who are being treated with plasmapheresis, who are pregnant or who have taken anticholinesterase medication (e.g., echothiophate eye drops, neostigmine) are relatively esterase-deficient, resulting in reduced capacity to degrade cocaine and thus elevated circulating levels of the drug with the potential for increased toxicity.

Cocaine metabolism demonstrates first-order kinetics over a wide range of doses. Within 4–5 h, almost all of a dose of cocaine has been metabolized, with metabolites present in urine for 4–8 h following intranasal dosing [111]. Measurable levels of the metabolite benzoylecgonine may be detected in urine as long as 60 h after a single dose of cocaine and for up to 3 weeks after heavy use of cocaine.

Less than 10% of cocaine is *N*-methylated into the active metabolite norcocaine. Liver *N*-methylation activity is increased by progesterone. *N*-methylation of cocaine into norcocaine is thus enhanced under conditions of elevated progesterone, e.g., during pregnancy. This may account for the reported increased cocaine-associated cardiotoxicity during pregnancy.

Concurrent use of cocaine and alcohol results in the production of the active metabolite cocaethylene (ethylbenzoylecgonine) (Fig. 3) [220]. Cocaethylene has a significantly longer elimination half-life than cocaine and may be more cardiotoxic than cocaine [209].

Toxicology

Cocaine-induced antagonism of nigrostriatal dopamine activity may result in extrapyramidal motor dysfunction including bradykinesia,

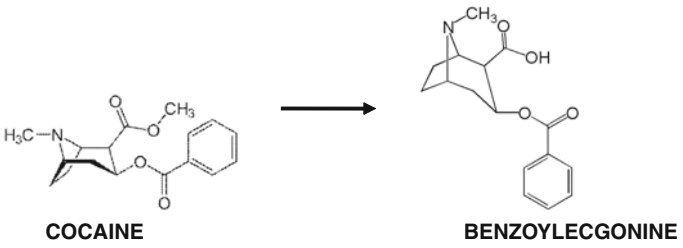

Fig. 2 Structures of cocaine and its metabolite benzoylecgonine

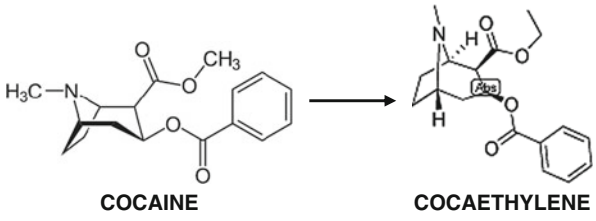

Fig. 3 Structures of cocaine and cocaethylene

akinesia, akathisia, catalepsy and dystonic reactions [72]. In a study conducted between 1979 and 1990 by the Medical Examiner's Office for Dade County, Florida, excited delirium was associated with approximately 1 in every 6 cocaine-related deaths. These victims were described as having experienced an immediate onset of bizarre and sometimes violent behavior, including extreme paranoia, ending in cardiorespiratory collapse and death.

Cocaine abuse is also associated with both acute and long-term cardiotoxicity [207, 232, 237]. Acutely, cocaine acts as a vasoconstrictor reducing blood flow to myocardium with an increased risk for cardiac ischemia and infarction. Cocaine-inhibited reuptake of norepinephrine also leads to increased intracellular concentrations of calcium within cardiocytes which through membrane depolarization can trigger sustained action potentials, extra systolic contractions and tachycardia. Long-term effects of cocaine on cardiac function can include a depression in contractility, in part related to the activity of cocaine as a local anesthetic. Cardiomyopathy associated with long-term cocaine abuse may be a result of oxidative stress to the myocardium [109]. Systemic effects include peripheral vascular constriction with resultant ischemic compromise of various organs.

Long-term use of cocaine is also associated with elevated circulating levels of muscle enzymes such as creatine kinase, suggesting muscle degradation or rhabdomyolysis [210]. Thirty-three percent of the participants in a study of cocaine-induced rhabdomyolysis experienced acute renal failure, severe liver dysfunction, and disseminated intravascular coagulation; six of them died.

Cocaine has been shown repeatedly to affect adversely reproductive function in female rats [118, 119], male and female non-human primates [156] and male [41] and female [24] humans. In the rat, cocaine administration produces loss of estrous cyclicity which at higher doses of cocaine may become permanent [119]. Maternal cocaine use during gestation has also been associated with numerous adverse effects on the developing fetus, including growth retardation, dysmorphic features, seizures and strokes and numerous postnatal behavioral abnormalities [239]. Because such fetuses are typically exposed to various confounding variables, such as a lack of prenatal care, poor maternal nutrition and polydrug exposures, the idea of a specific cocaine teratophilia (or "cocaine baby") syndrome has been called into question [125].

Amphetamine and Amphetamine-Analogs

History

The Chinese plant ma hung (*Ephedra vulgaris*) has been used traditionally to treat asthma. In the 1920s the active ingredient in extracts of this plant was identified as ephedrine. In 1887, the Romanian chemist Lazar Edeleanu (1861–1941) first synthesized alpha-methylphenethylamine [62], now more commonly known as amphetamine (**a**lpha-**m**ethyl**ph**en**e**thyl**amine**). Originally named phenylisopropylamine, amphetamine was largely forgotten for the next four decades. In the late 1930s, amphetamine was prescribed for narcolepsy as well as hyperactivity syndromes. In 1932, the pharmaceutical company Smith, Kline and French marketed the racemic amphetamine (dl-amphetamine) mixture benzedrine as an over-the-counter medication for treating congestion by inhalation of the drug. Benzedrine was typically administered via inhalers. From its introduction in the 1930s until 1954, ephedrine was available without prescription (i.e., "over-the-counter"). By the 1940s and 1950s, reported abuse of these inhalers began to emerge. Benzedrine inhalers as well as other preparations of the drug could be used to produce a stimulant effect and were sometimes abused as "bennies". With passage of the Comprehensive Drug Abuse Prevention and Control Act in 1970, amphetamine was classified as a Schedule III drug. The following

year, the classification of amphetamine was changed to Schedule II.

The term "amphetamines" also refers to a class of drugs derived from amphetamine, the substituted amphetamines. In recent years, the easily synthesized *N*-methylated form of amphetamine, methamphetamine, has become readily available and one of the most commonly abused stimulants in the United States. However, methamphetamine is not a recent addition to the list of amphetamine-related drugs. In 1885, the Japanese physician-chemist Nagayoshi Nagai (1844–1929) isolated ephedrine from the plant Ephedra vulgaris and, in 1893, synthesized methamphetamine by reduction of ephedrine using red phosphorus and iodine [141]. In 1929, he was the first to synthesize and elucidate the structure of ephedrine. In 1919, the Japanese chemist Akira Ogata (1887–1978) synthesized crystallized methamphetamine. In the 1980s, methamphetamine became increasingly more popular as a street drug. In 1996, the Methamphetamine Control Act was enacted to regulate the key ingredients (e.g., ephedrine, pseudoephedrine, phenylpropanolamine) in manufacturing methamphetamine and to increase criminal penalties for possession, distribution and manufacturing of the drug. The price of methamphetamine is largely determined by the availability of ephedrine, a key ingredient. Regulation of ephedrine, and its resulting unavailability, has increased its wholesale price. As a result, drug traffickers have switched to a less regulated and more economic substitute, pseudoephedrine. However, the Combat Methamphetamine Epidemic Act of 2005, a part of HR 3199 bill was enacted regulating over-the-counter sales of cold medicines containing pseudoephedrine. Methamphetamine can be smoked, snorted or injected, has significantly longer lasting stimulant effects than cocaine, and is generally much less expensive to purchase than cocaine [157]. Methamphetamine is considered highly addictive. Methamphetamine users typically develop tolerance to the drug that leads to higher and more frequent use.

Amphetamine is a homologue of phenethylamine and a weak base with a chemical structure very similar to dopamine and norepinephrine. Amphetamine is the parent compound for a class of similar psychoactive drugs including the *N*-methylated form of amphetamine, methamphetamine and the methylenedioxy analog of methamphetamine, 3,4-methylenedioxy-N-methylamphetamine ("Ecstacy;" MDMA; Fig. 4). Typically, formulated as a racemic mixture (D- and L-amphetamine), D-amphetamine is thought to act primarily on the dopaminergic systems, while L-amphetamine is comparatively norepinephrinergic (noradrenergic). Amphetamine and related drugs are lipid soluble in non-ionized form and as such are readily absorbed across the gastrointestinal tract lining as well as across the blood-brain barrier. Amphetamines can thus be taken effectively either by oral or parenteral routes of administration.

Pharmacologist David E. Nichols formulated the term "enactogen" to describe a class of synthetic drugs similar in structure to the stimulant 3,4-methylenedioxy-*N*-methylamphetamine (Ecstasy) but which exibit hallucinogenic properties [174, 176]. The term "entactogen" is a combination of the roots "en" (Greek: *within*), "tactus" (Latin: *touch*) and "gen" (Greek: *produce*) [176]. Enactogens are characterized by a substituted amphetamine core thus belonging to the phenethylamine class of psychoactive drugs. Enactogens include 3,4-

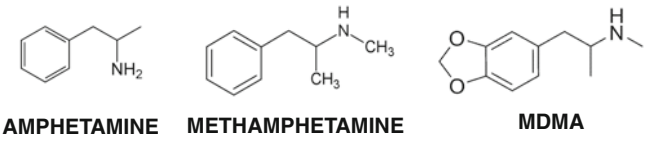

Fig. 4 Structures of amphetamine and structurally related drugs. MDMA = 3,4-methylenedioxy-*N*-methylamphetamine

methylenedioxyamphetamine (Tenamfetamine), 4-methylenedioxy-*N*-ethylamphetamine, 3,4-methylenedioxy-alpha-ethyl-*N*-methylphenethylamine ("EDEN" or "Methyl-J"), α-ethyltryptamine ("etryptamine"), and 4-bromo-2,5-dimethyphenethylamine. 3,4-Methyle-nedioxy-*N*-methylamphetamine is also often considered a member of the entactogen family.

4-Bromo-2,5-dimethyphenethylamine was first synthesized from 2,5-dimethoxybenzaldehyde by Russian-American pharmacologist Alexander Shulgin in 1974. In the late 1970s, the German pharmaceutical company Drittewelle began manufacturing and marketing the drug as an aphrodisiac called Eros. Shortly after its introduction to clinical psychiatry, 4-bromo-2,5-dimethyphenethylamine made its way into the recreational drug scene. 4-Bromo-2,5-dimethyphenethylamine remains popular within the rave subculture but is often confused with 3,4-methylenedioxy-*N*-methylamphetamine (Ecstasy). 4-Bromo-2,5-dimethyphenethylamine and related entactogens are now classified as Schedule I drugs in the United States.

Based on the known mechanisms of action of 3,4-methylenedioxy-*N*-methylamphetamine, entactogens are thought to act by increasing synaptic levels of dopamine, norepinephrine, and serotonin. However, there have been very few research studies to examine the pharmacology of entactogens in humans or experimental animal models.

Pharmacodynamics

Amphetamines are central nervous system and sympathetic nervous system stimulants, acting on biogenic amine pathways [157]. Physical effects include reduced appetite, hyperactivity, restlessness and insomnia, tachycardia and increased blood pressure and constipation. Behavioral effects include anxiety and generalized excitability, a perception of increased energy, repetitive actions, increased alertness, emotional liability and, with higher or long-term dosing, occasional psychosis. These effects are similar to those of other stimulants such as cocaine. The amount of releasable as well as previously released dopamine at dopaminergic nerve terminals is closely regulated by two selective membrane-bound transporters [114, 166, 205, 211]. Dopamine is moved via vesicular monoamine transporter-2 into synaptic vesicles for storage and eventual release. Without vesicular transport, dopamine remains within the cytoplasm where it is subject to degradation including oxidation and reactive free radicals which are potentially neurotoxic. Extracellular dopamine is moved back into the presynapse via the dopamine transporter. Dopamine transporter inhibition or blockade results in increased levels of extracellular dopamine. Amphetamines induce presynaptic dopamine release, block dopamine reuptake, inhibit dopamine storage within presynaptic vesicles and block enzyme-catalyzed dopamine metabolism. Shortly after amphetamine administration, reversal of the dopamine transporter results in non-vesicular dopamine efflux [128, 227]. In addition, the movement of dopamine into synaptic vesicles is blocked by amphetamine, resulting in increased dopamine release into the synapse and the potential for dopamine oxidation and damaging free radical formation within the presynapse. Although also acting through similar mechanisms on norepinephrine and, to a lesser extent, serotonin terminals, amphetamine's reinforcing and behavioral-stimulant effects are associated with enhanced dopaminergic activity, primarily within the mesolimbic dopamine system [54, 166]. The targeted effects of amphetamine on dopaminergic activity in caudate nucleus, nucleus accumbens and ventral striatum correlate well with stereotypic onset of euphoria associated with this drug [61, 113]. Amphetamine also acts to increase glutamate release in selected brain areas such as the nucleus accumbens, striatum and prefrontal cortex [54]. These areas are implicated in reward pathways.

Similar to its effects on the dopamine transporter, amphetamine can also reverse the direction of serotonin movement via the serotonin transporter [228]. Amphetamine

interacts with the serotoninergic system in selected brain regions such as the mesocorticolimbic pathway [97]. Similar to amphetamine, methamphetamine induces release of serotonin, dopamine, and norepinephrine as well as blockade of serotonin, dopamine, and norepinephrine transporters within the central nervous system, leading to increased synaptic activities of these biogenic amines.

Formation of free radicals including oxygen and nitrogen species is particularly characteristic of methamphetamine administration [83, 133, 258]. An amphetamine analog, methamphetamine, induces selective degeneration of dopamine neuron terminals without cell body loss. Methamphetamine-induced terminal degeneration may be mediated in part by excitatory amino acid (e.g., glutamate) activity [49]. Methamphetamine also induces rapid and reversible decreases in the rate-limiting enzyme for serotonin (5-hydroxytryptamine) synthesis, leading to reduced levels of this biogenic amine within various central nervous system areas [12, 104, 191].

Amphetamine, 3,4-methylenedioxy-*N*-methylamphetamine, and other psychotropic agents may also interact with a relatively new class of receptors called the trace amine-associated receptors [21]. Trace amine-associated receptors represent a class of G protein-coupled binding sites for endogenous trace amines, metabolic products of the better know biogenic amines such as norepinephrine, dopamine, serotonin, and histamine. Trace amines are normally present in very low (nanomolar) concentrations and include ρ-tyramine, octomaine, tryptamine and β-phenylethylamine. Trace amines such as β-phenylethylamine may function to modulate biogenic amine synaptic activities in selected brain areas related to affective states and thus in maintaining levels of excitement and alertness [227]. Branchek and Blackburn [25] have hypothesized a role for trace amines in substance abuse, depression, attention deficit hyperactivity disorder, eating disorders, schizophrenia, and other neuropsychiatric diseases.

Pharmacokinetics

Metabolism/Elimination

Metabolism of amphetamine is almost exclusively hepatic. In the liver, amphetamine can be hydroxylated (phenyl ring), deaminated or conjugated [254]. Methamphetamine is N-demethylated. In a study of human subjects given measured doses of amphetamine orally, 34% of the drug was excreted unchanged in urine [189]. Metabolites of the drug included benzoic acid and parahydroxy-amphetamine. These metabolites were themselves further converted into hippuric acid and parahydroxynorefedron, respectively.

Toxicity

The toxic effects of amphetamine and related drugs can be very serious and potentially fatal [56]. Short-term effects of amphetamine include increased heart rate and blood pressure, decreased appetite, feelings of elation and self-assuredness, and reduced fatigue. Long-term, repetitive amphetamine use has been associated with insomnia and restlessness, significant weight loss, hallucinations and paranoid psychosis. Amphetamine use can also include psychic dependence and tolerance, as well as psychotic episodes in some individuals [45]. Continuous high dose amphetamine use has been associated with a state of paranoid (“amphetamine”) psychosis closely resembling the symptoms of paranoid schizophrenia. Symptoms include hyperactivity, anxiety, paranoid delusions and auditory-tactile hallucinations in a setting of clear consciousness with little if any disorientation.

Use of amphetamines and related stimulants is particularly dangerous in individuals with a history of heart disease or underlying hypertension as well as those with glaucoma [56]. Amphetamines and stimulants should also be avoided by anorexic individuals because of the appetite suppressing properties of these drugs.

Amphetamines can cause life-threatening hypertensive crisis and possibly neurotoxic reactions when taken with monoamine oxidase inhibitors for clinical depression. Amphetamine-associated death is considered to be a direct consequence of excessive sympathomimetic activity. Amphetamine toxicity includes hypertension, hyperpyrexia, delirium, convulsions and severe tachycardia leading to cardiovascular collapse. Amphetamine also increases sympathetic tone regulating smooth muscle contraction and thus can affect adversely the functions of the gastrointestinal tract, uterus, urinary bladder and other organs dependent on smooth muscle activity.

3,4-Methylenedioxy-*N*-methylamphetamine has been associated with serotoninergic depletion and neuronal degeneration in rodent and non-human primate models [93, 201, 202, 222]. These neurotoxic effects were more pronounced in non-human primates than in rodents [222]. Within 3 weeks of 3,4-methylenedioxy-*N*-methylamphetamine administration, profound serotoninergic neurodegeneration was seen in non-human primates in most brain areas [203]. Some central nervous system areas showed evidence of partial recovery, i.e., hippocampus, caudate nucleus and frontal cortex; however, the partial recoveries appeared to be short-term, with a return to the dramatic patterns of serotoninergic losses seen 2 weeks after drug exposure.

Colado and colleagues [42] reported that 3,4-methylenedioxy-*N*-methylamphetamine administration to pregnant rats does not produce damage to serotonin nerve terminals in the brains of the fetuses, in contrast to the serotoninergic neurodegeneration seen in the central nervous system of the mothers. They hypothesized that this contrast in maternal versus fetal effects may be due to 3,4-methylenedioxy-*N*-methylamphetamine converted into free radical associated metabolites in the adult brain but not in the immature brain. Alternatively, the developing central nervous system may have more effective or more active free radical scavenging mechanisms than the mature adult central nervous system.

Therapeutic administration of amphetamines is usually by oral route. When used recreationally, amphetamines are taken orally, snorted, smoked, or injected intravenously [65]. Methamphetamine's methyl group is lipid soluble and easily transported across the blood-brain barrier as well as relatively resistant to enzymatic degradation catalyzed by monoamine oxidase. After oral administration (4 × 10 mg), methamphetamine is initially detected in plasma samples within 15 min–2 h. Maximal plasma concentrations (14.5–33.8 μg/L) are achieved within 2–12 h and the drug remains measurable for 36–72 h after administration [215]. Methamphetamine has an elimination half-life of 9–15 h primarily via urinary excretion. Methamphetamine elimination half-life varies with differences in urinary pH. One of the metabolites of methamphetamine is amphetamine.

Amphetamine and amphetamine-like derivatives are potent central nervous system stimulants affecting regulatory centers for heart rate, body temperature, blood pressure, appetite, attention, mood and responses associated with alertness or alarm responses [56]. Physiological and psychological responses to amphetamines closely resemble the sympathetic nervous system induced fight-or-flight responses, including increased heart rate and blood pressure, vasoconstriction, bronchodilation, and hyperglycemia. Users report increased ability to focus on tasks, an overall increase in mental alertness, avoidance of fatigue and decrease in appetite.

Drug tolerance develops rapidly in amphetamine abuse [135]. Tolerance to the drug's effects results in increasing amounts of the drug needed to obtain similar rewarding effects. However, chronic amphetamine use can produce so-called "reverse tolerance", or sensitization to some of the psychological effects of the drug. Amphetamine users will often take more of the drug during withdrawal periods and may use other drugs such as benzodiazepines or less commonly barbiturates to lessen the effects of withdrawal [38, 135].

Methamphetamine administration is associated with both dopaminergic and serotoninergic neurodegeneration. The generation of free radicals as a by-product of increased dopamine and serotonin metabolism is postulated to play a key role in this neurodegeneration [83, 258]. Blocking increases in methamphetamine-induced release of dopamine or serotonin reduce the neurodegeneration seen with administration of this drug. Additionally, pretreating with multiple injections of escalating doses of methamphetamine produces tolerance to the long-term neurotoxic effects of methamphetamine on striatal dopamine neurons [225]. Though not yet well defined, the mechanism for this tolerance may be related to aberrant vesicular monoamine transporter-2 and dopamine transporter function in these neurons.

Opiates

History

Crude opium is a component of the opaque, milky-white sap obtained from the seedpods of the poppy plant (*Papaver somniferum*) [27]. This plant and its product opium was likely cultivated in the Mediterranean region as early as 5000 B.C. by ancient Egyptians and Greeks and later by the ancient Romans. Opium was introduced into China around 800 A.D. and, with the arrival of European explorers to China, to Europe by the seventeenth century. In 1680, a famous English physician named Thomas Syndenham introduced opium to the medical field. In the seventeenth century, many people in Europe were treated for a variety of health problems with opium. In 1729, opium smoking was made illegal in China and soon the importation of opium was banned. This ban upset the British who were in charge of trading this valuable product. Opium was still smuggled into China and is considered the underlying cause of the so-called "Opium Wars" (1839–1842 and 1856–1860) between the British and the Chinese. In the United States, opium was used to treat soldiers during the Civil War (1861–1865). During the late 1800s, doctors prescribed "tonics" containing opiates for many conditions. Typically, these medicines failed to list opiates as one of the ingredients.

Opium represents a complex of sugars, proteins, fats, water, meconic acid, plant wax, latex, gums, ammonia, sulphuric and lactic acids, and numerous alkaloids. Alkaloids present in opium include morphine (10–15%), codeine (1–3%), noscapine (4–8%), papaverine (1–3%), and thebaine (1–2%). Narceine and approximately 25 other alkaloids are also present but have little to no effect on the central nervous system, and are not usually considered to be opiates. Thebaine is considered highly toxic and thus not used therapeutically [3]. Thebaine acts as a potent stimulant rather than as a depressant, at higher concentrations causing strychnine-like convulsions. Thebaine can be used to produce the semi-synthetic morphine analogues oxycodone, dihydromorphenone, hydrocodone, and etorphine.

In 1805 the German pharmacist Frederick Serturner isolated morphine from opium. He named this new-found compound after Morpheus, the Greek god of dreams. Morphine-related analogues include the diphenylpropylamines (e.g., methadone), the 4-phenylpiperidines (e.g., meperidine), the morphinans (e.g., levorphanol) and 6,7-benzomorphans (e.g., metazocine), each of which has in common a piperidine ring or a key component of that ring structure. Heroin was first synthesized in 1874 by the British chemist C. Adler Wright. Heroin is synthesized from morphine. Heroin is the 3, 6-diacetyl ester of morphine, i.e., diacetylmorphine (Fig. 5). Heroin became widely accepted within the medical community in the early 1900s. The high risk for addiction was not initially recognized by physicians at that time. With a better understanding for its abuse potential, heroin was later regulated with passage of the Harrison Narcotic Act of 1914. The drug is now classified as a Schedule I substance with significant abuse potential but no accepted medical use.

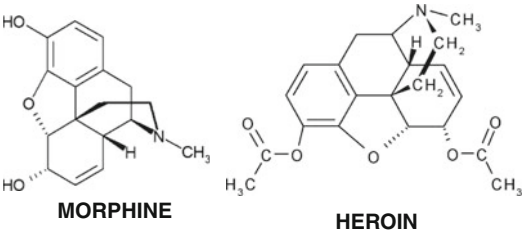

Fig. 5 Structures of morphine and heroin

The term "opiate" refers to morphine-like alkaloids (e.g., morphine itself, heroin, codeine, thebane and papaverine) derived from opium as well as a number of semisynthetic and synthetic opiates. "Opioid" refers to endogenous substances with morphine-like activity. Endogenous opioids include dynorphins, enkephalins, endorphins, endomorphins and nociceptin/orphanin FQ. The term "endorphin" was first used in the mid-1970s to describe any endogenous morphine-like substance, now classified as endogenous opioidergic peptides. We now recognize several classes of endogenous opioidergic peptides including enkephalins, endorphins, dynorphins and endomorphins. Opiates like morphine and heroin bind to and activate the same receptors used by endogenous opioidergic peptides, namely mu, kappa, and delta receptors. Opioidergic receptors are expressed only in the central nervous system, gastrointestinal tract and vas deferens. Most opioid receptors are linked to an inhibitory G protein (G_i). Thus endogenous opioidergic peptide receptor binding is associated with inhibition of adenylate/cyclic AMP second messenger systems and inhibition of the target neuron.

Endogenous opioidergic peptides are generally involved with homeostasis or regulation of basic physiologic functions including respiration, endocrine functions and nociception (pain). Endogenous opioidergic peptides may also play important roles in mood and affect. The greatest density of opioidergic receptors is found in the limbic system (emotions and affect) and in the dorsal horn of the spinal cord (nociception). Thus, it should not be surprising that endogenous opioidergic peptides are thought to integrate euphoric and emotional components of pain relief.

According to the 2006 National Survey on Drug Use and Health, heroin accounts for nearly 90% of opiate abuse in the United States though some opiates with medicinal use such as morphine, oxycodone, meperidine, and codeine are also subject to abuse. Reflecting greater worldwide availability as well as an interest among drug dealers to reach a wider market with an aversion to the risks associated with use of hypodermic needles, heroin purity has risen from 10% as recently as the 1980s to current purity of 50–60% and greater. Heroin is rarely sold in pure form on the street but rather is routinely diluted with cutting agents such as sugar, starch, baking soda, quinine, or other substances. A typical street unit or "bag" of heroin contains 30–50 mg of cut drug.

Pharmacodynamics

Opiate agonists and antagonists bind to stereospecific, saturable receptors in the brain and other tissues. Central nervous system opioidergic receptors are widely but unevenly distributed. These receptors were originally classified according to their affinity for binding agonists: mu receptors preferentially bind morphine, kappa receptors preferentially bind ketocyclazocine, and delta receptors bind deltorphin II. Morphine also binds to both kappa and delta receptors though with lesser affinity than to mu receptors. In 2000, these receptors were reclassified as OP_1 (delta), OP_2 (kappa), and OP_3 (mu) by a subcommittee of the International Union of Basic and Clinical Pharmacology (IUPHAR Compendium of Receptor Characterization and Classification, 2nd Edition, London: IUPHAR Media, pp. 321–333, 2000). Mu receptors are located widely throughout the central nervous system, especially in the limbic system (frontal and temporal cortex, amygdala, and hippocampus), thalamus, striatum, hypothalamus, and midbrain. Kappa receptors are located primarily

in the spinal cord, periaqueductal grey area and cerebral cortex. Delta receptors are located primarily in pontine nuclei, amygdala, olfactory bulbs and deep cerebral cortex. Opiate receptors are G protein coupled and function as modulators, both positive and negative, of synaptic transmission. Most known opiates exhibit no ceiling effect for analgesia with the exception of codeine for which a ceiling effect is estimated as 7 mg/kg. Mu-receptor activation can result in analgesia, euphoria, respiratory depression, miosis, decreased gastrointestinal motility, and physical dependence. Kappa-receptor stimulation also produces analgesia, miosis, respiratory depression, as well as, dysphoria and some psychomimetic effects (i.e., disorientation and/or depersonalization). Delta-receptor activation produces dysphoria, respiratory depression at high doses and cardiac stimulation. Opiates working primarily through mu receptors also suppress cough reflex. The antitussive effects of codeine are mediated through direct action on receptors in the cough center of the medulla.

Heroin is rapidly transported across the blood-brain barrier and metabolized into morphine and related compounds. It is generally assumed that heroin itself has only minor pharmacological effects. Most of the pharmacological effects associated with heroin are actually caused by morphine as well as, to some degree, the other two major metabolites 6-acetylmorphine and morphine-6-glucuronide [246]. Morphine-6-glucuronide possesses analgesic properties though morphine-3-glucuronide does not seem to have any agonistic effect either in vivo or in cell cultures [95].

Most opiates such as heroin and morphine produces a profound sense of euphoria in most users though this effect diminishes with development of tolerance to the drug. Heroin and morphine share in common the ability to induce euphoria and relaxation as well as, with time, drowsiness and sleepiness. Short-term studies among users suggest that heroin tolerance develops no more rapidly than tolerance to morphine [233]. This is perhaps not surprising given the physiochemical properties of heroin and morphine and the metabolism of heroin metabolism of heroin to morphine.

Pharmacokinetics

Routes of Administration/Metabolism

Heroin represents the diacetyl derivative of morphine. The usual route of administration is intravenous though other routes of administration include intramuscular, subcutaneous, rectal and intranasal. After absorption, it is rapidly converted into either morphine or monoacetylmorphine which is highly lipid soluble and thus easily crosses the blood-brain barrier with rapid induction of euphoria (NIDA Research Report—Heroin Abuse and Addiction: NIH Publication No. 05-4165, Printed October 1997, Reprinted September, 2000, Revised May 2005). When taken orally, heroin undergoes extensive first-pass metabolism via deacetylation into morphine in the liver. Thus heroin can be considered a prodrug [214]. In contrast, intravenous injection of the drug essentially bypasses first pass metabolism with rapid distribution across the blood-brain barrier due to the presence of acetyl groups which make the drug more lipid soluble than morphine [122]. Within the brain, heroin is deacetylated into 3- and 6-monoacetylmorphine and morphine, which bind to μ-opioid receptors. Most of the morphine is further converted to morphine-3-glucuronide (approximately 50%) and morphine-6-glucuronide (approximately 10%) [4]. Recent studies have demonstrated that the brain, pancreas, and myocardium can also produce morphine [19].

Morphine is metabolized primarily into morphine-3-glucuronide and morphine-6-glucuronide via glucuronidation catalyzed by the liver enzyme UDP glucuronosyl transferase 2B7 (UGT2B7) [117]. Morphine is similarly metabolized in brain and kidneys. At least in studies using rodent models, morphine-6-glucuronide is far more potent an analgesic than morphine itself. However, this morphine metabolite crosses the blood-brain barrier poorly in contrast to morphine.

Toxicology

The psychological dependence associated with opioidergic addiction is both protracted and complex. Well beyond the recovery from the physical need for the drug, the opiate addict may obsess about use of the drug and feel an inability to deal with daily activities without use of the drug. These individuals are at high risk for relapse assuming that neither the physical environment nor the behavioral motivators associated with the abuse have been altered.

Opiate withdrawal symptoms in opiate users can be seen as early as 2–3 h after last dose of drug (National Institute on Drug Abuse, InfoFacts: Heroin, May 2006). Major withdrawal signs peak between 48 and 72 h after last dose and subside within 9–12 days. Initial signs of withdrawal include dilated pupils, profuse sweating and anxiety. These individuals also experience progressively stronger drug craving, severe abdominal distress, diarrhea, nausea and vomiting, restlessness, muscle and bone pain, insomnia, cold flashes with goose bumps ("cold turkey") alternating with high temperature spiking ("hot flashes"), and kicking movements ("kicking the habit"). Severe depression is a common manifestation. Opiate withdrawal is rarely fatal though sudden withdrawal by heavily dependent users in poor health may be fatal. Opiate withdrawal is considered less risky than alcohol, benzodiazepine, or barbiturate withdrawal.

Following intravenous infusion of heroin, the user experiences a surge of euphoria ("rush") along with dry mouth, a warm flushing of the skin and a heaviness of the extremities [151]. The user then becomes alternately somnolent and alert ("on the nod"), shifting between wakeful and drowsy states. Mental functioning declines. Tolerance to the effects of the drug develops over time and regular usage. In effect, the user must use more heroin to achieve the same intensity of effect. Eventually, drug-induced neural plasticity within reward pathways of the brain results in addiction to the drug.

It is very difficult to establish a median lethal dose for heroin among regular users. Individuals have overdosed on as little as 1 mg/kg of heroin. A median lethal dose for non-addicts has been suggested as 1–5 mg/kg. However, there may be no easily identifiable upper limit to the amount of heroin a heavily addicted individual can take. Research studies conducted in the 1920s among opiate addicts described administering heroin in doses of 1,600–1,800 mg with no obvious adverse side effects. These results are supported by studies in rats showing that 14 days of pretreatment with morphine or heroin reduced mortalities associated with subsequent morphine administration [226]. Thus, long-term opiate abuse is typically associated with development of highly significant drug tolerance.

Neurologic complications associated with heroin use include peripheral neuropathies, nerve pressure palsies, hypoxic encephalopathy, seizures, rhabdomyolysis and transverse myelopathies. Spongiform leukoencephalopathy is a relatively rare complication of heroin use with only 70 reported cases from the first reported case in 1984 through 2004 [89]. This complication is typically seen among users who inhale fumes generated by heating heroin, a practice called "chasing the dragon" [98]. The typical lesions include abnormal white matter with patchy spongiform change and prominent reactive fibrous gliosis consisting of glial fibrillary acidic protein-positive fibrous astrocytes. Symptoms vary according to the brain regions involved but often include cognitive dysfunction, cerebellar ataxia, dysarthria, and motor restlessness, with an estimated mortality rate of approximately 25%.

Heroin-related death has been associated with the phenomenon of place tolerance and overdose as a result of using the drug in an unaccustomed environment [79]. The mechanism for fatal overdosing in this situation was described as an overriding of conditioned or place tolerance. Because heroin use is such a highly ritualized behavior, longtime users exhibit increased tolerance to the drug in locations in which they have

repeatedly administered heroin. When the drug is used in a different location, this environment-conditioned tolerance does not occur, which produces enhanced effects of the drug. In response to this decrease in tolerance, the user increases the typical dose of the drug. If extreme in self-dosing, the result can be a fatal overdose.

Morphine also affects immune system function via interactions with dendritic cells [158]. Dendritic cells, a type of antigen presenting cell, express opiate receptors. Dendritic cells exposed to morphine during their maturation produce increased levels of interleukin-12, a cytokine responsible for promoting the proliferation, growth, and differentiation of T lymphocytes which are active in adaptive immune responses, and less so, interleukin-10, a cytokine responsible for promoting B lymphocyte responsiveness.

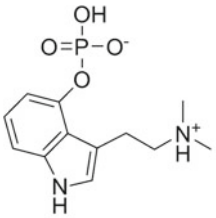
LSD

Fig. 7 Structure of psilocybin



PSILOCYBIN

Hallucinogens: Lysergic Acid Diethylamide, Psilocybin, Mescaline

History

Hallucinogens comprise a class of drugs defined by their ability to induce changes in the user's perception of reality. Users describe seemingly real images, sounds and sensations which do not in fact exist (National Institute on Drug Abuse, Research Report: Hallucinogens and Dissociative Drugs, March 2001). Traditionally, these drugs were derived from plant sources but are now synthetic with resultant greater purity of product (Drug Enforcement Administration, Drug Descriptions: Hallucinogens). Commonly used hallucinogens include lysergic acid diethylamide (Fig. 6) and psilocybin (Fig. 7).

Lysergic acid is a component of ergot alkaloids found in the ergot fungus (*Claviceps purpurea*) which infects cereal grains including rye (National Institute on Drug Abuse, InfoFacts: LSD, May 2006). Ergot alkaloids are very potent compounds responsible for ergotism (also known as ergotoxicosis, ergot poisoning and St. Anthony's Fire) characterized by convulsive and vasoconstrictive symptoms including gangrene and hallucinations, mania, and psychoses.

Lysergic acid diethylamide was first synthesized in 1938 by Swiss chemist Albert Hofmann (1905–2008) [101]. The hallucinogenic effects of lysergic acid diethylamide were not immediately recognized and the drug was ignored over the next several years. But in 1943, Hofmann accidentally absorbed a very small amount of lysergic acid diethylamide and experienced firsthand the psychogenic effects of the drug. He then followed up with an additional self-administration of lysergic acid diethylamide, later reporting the intensely psychedelic effects associated with the drug. The abbreviation "LSD" is derived from its early codename *LSD-25* (German "lysergsäure-diethylamid" followed by a sequential development number). Lysergic acid diethylamide was initially marketed by Sandoz Laboratories as a therapeutic drug with numerous potentially useful psychiatric applications. However, the drug's entry into

the illicit, recreational environment with ensuing political repercussions eventually precluded further interest in the drug among pharmaceutical companies and physicians. The substance was eventually banned for any use other than research as a Drug Enforcement Administration schedule I substance.

For a time during the 1950s and early 1960s, intelligence agencies in the United States and other countries had an interest in the use of lysergic acid diethylamide to facilitate interrogations and mind control (U.S. Congress: The Select Committee to Study Governmental Operations with Respect to Intelligence Activities, Foreign and Military Intelligence [Church Committee report], Report no. 94–755, 94th Congress, 2nd Session, Washington, D.C.: GPO, 1976). The Central Intelligence Agency conducted such studies through the Office of Scientific Intelligence largely in response to similar studies employed by the Soviet Union and China in the early 1950s. One such study involved the use of United States soldiers dosed with lysergic acid diethylamide to study the effects of panic. By the late 1960s, the Central Intelligence Agency had ended these lysergic acid diethylamide studies, the results of which were considered too unpredictable.

The principal psychoactive component of so-called "magic mushrooms" is an indole related to tryptamine, psilocybin. Use of hallucinogenic mushrooms (*Psilocybe cubensis* and *Psilocybe semilanceata*) may go back as far as prehistoric humans though conclusive evidence for this is lacking. Their early use was probably associated with religious communing, divination and healing just as they are among some present-day Native Americans. Bernardino de Sahagún (1499–1590), a Franciscan missionary, described the ritualistic use of teonanácatl or "flesh of the gods" among the Central American Aztecs. In the 1960s, recreational use of hallucinogenic mushrooms was promoted by R. Gordon and Valentina Wasson, Timothy Leary, and others which led to the popularization of a number of psychoactive *Psilocybe* species found in North America, Europe, and Asia.

In 1958, Hofmann had identified psilocin and psilocybin as the active compounds in psychoactive mushrooms. By the early 1970s, a number of psychoactive *Psilocybe* species were described, these variants being found in North America, Europe and Asia. These mushrooms may also contain small amounts of other psychoactive tryptamines. Psilocybin and psilocin are listed as Schedule I drugs in the United States and many other countries.

Mushroom concentrations of psilocybin and psilocin vary significantly among varieties of psychoactive mushrooms but averages 0.5–2.0% of the dry weight of the average mushroom. The more common species *Psilocybe cubensis* contains approximately 10–25 mg psilocybin and psilocin. When psilocybin is ingested, it is broken down to produce psilocin, which is responsible for the hallucinogenic effects. About 25–50 mg of psilocybin and/or psilocin is generally thought to be a heavy psychoactive dose of these drugs.

Pharmacodynamics

The hallucinogenic effects of lysergic acid diethylamide and phenethylamine hallucinogens are thought to be mediated by the binding of these drugs to the serotonin-2A receptor [150]. Lysergic acid diethylamide administered in so-called "recreational doses" has been shown to interact with serotonin-1A, serotonin-2A, serotonin-2C, serotonin-5A, serotonin-5B, and serotonin-6 receptors. More specifically, the hallucinogenic effects of lysergic acid diethylamide have been attributed to the drug's strong partial agonist effects at serotonin-2A receptors [150]; selective serotonin-2A specific antagonists block the psychotropic activity of lysergic acid diethylamide [175]. With the exception of the ligand-gated ion channel serotonin-3 receptor, serotonin receptors are G protein coupled, seven-transmembrane receptors that activate intracellular second messenger pathways. The exact sites and mechanisms of action are not yet known.

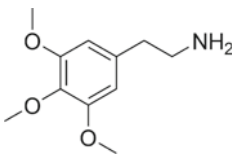
In addition to the drug's effects on serotonin-2A receptors, lysergic acid diethylamide has also been shown to affect glutaminergic systems within the central nervous system. Systemic lysergic acid diethylamide (0.1 mg/kg, intraperitoneally) or direct lysergic acid diethylamide infusion (10 μM) into prefrontal cortex has been associated with elevated levels of glutamate release in this brain region, an effect blocked by administration of the serotonin-2A antagonist M100907 (0.05 mg/kg, intraperitoneally) [171]. Chronically, lysergic acid diethylamide may activate dopamine- and cyclic AMP-regulated phosphoprotein with molecular weight 32 kDa (DARPP-32)-related pathways—a mechanism of action shared by numerous other psychoactive drugs, including cocaine, amphetamine, methamphetamine, nicotine, caffeine, phencyclidine, ethanol, and morphine [229].

Typical doses of lysergic acid diethylamide are measured in microgram amounts rather than the more typical milligram amounts associated with other drugs of abuse. Hofmann determined that an active dose of mescaline, roughly 0.2–0.5 g, has effects comparable to 100 μg or less of lysergic acid diethylamide [101]. A single dose of lysergic acid diethylamide is typically 100–500 μg; threshold psychotropic effects of the drug are experienced with as little as 25 μg [87]. The median lethal dose for lysergic acid diethylamide has been estimated to range from 200 μg/kg to >1 mg/kg though there are no known deaths attributed directly to the use of lysergic acid diethylamide. Lysergic acid diethylamide users do not exhibit the typical features of drug addiction and dependence though tolerance to the drug can develop rapidly. Users demonstrate cross-tolerance between lysergic acid diethylamide and psilocybin [110]. Attenuation of tolerance to lysergic acid diethylamide is thought to be related to drug-induced down-regulation of serotonin-2A receptors in as yet undefined central nervous system areas.

Adverse reactions to lysergic acid diethylamide have been treated using fast-acting benzodiazepines such as diazepam or triazolam. These serve as anxiolytics, calming the individual but without directly blocking lysergic acid diethylamide binding at serotonin-2A sites. Theoretically, specific serotonin-2A receptor antagonists, e.g., the atypical antipsychotic quetiapine fumarate, would act to block lysergic acid diethylamide binding at these receptors, thus attenuating the psychoactive effects of lysergic acid diethylamide.

Mescaline (3,4,5-trimethoxyphenethylamine) (Fig. 8) is a naturally occurring hallucinogenic phenethylamine. Mescaline is one of several psychoactive alkaloids produced by several species of cactus including the peyote cactus (*Lophophora williamsii*), the San Pedro cactus (*Echinopsis pachanoi*), and the Peruvian Torch cactus (*Echinopsis peruviana*) [129]. The peyote cacti are primarily subterranean, with underground roots and a relatively small above-ground crown consisting of several disk-shaped "buttons". These buttons are cut from the cactus and dried. Peyote includes a number of alkaloids including mescaline. Peyote has been used as a part of religious rites by Native American Indians of the arid northern Mexico and southwest United States for thousands of years. Peyote buttons with measurable levels of mescaline were found within prehistoric native Indian ruins and traced back to 3780–3660 B.C. by radiocarbon dating [64]. Mescaline was first isolated and identified in 1897 by German chemist Arthur Heffter and first synthesized in 1919 by Ernst Späth.

Fig. 8 Structure of mescaline



Mescaline is rapidly absorbed after oral ingestion by rats [184]. The hallucinogenic effects of associated with ingestion of mescaline are seen in doses of 300–600 mg, the equivalent of 9–20 small peyote cactus tops. Mescaline is 1,000 to 3,000 times less potent than lysergic acid diethylamide, and 30 times less potent than psilocybin. The median lethal dose has been estimated as 212 mg/kg intraperitoneally for mice, 132 mg/kg intraperitoneally for rats

and 328 mg/kg intraperitoneally for guinea pigs. About half the initial dosage is excreted by 6 h, but the effects of mescaline can last up to 12 h. Tolerance to mescaline increases with repeated administration. Mescaline may exhibit cross-tolerance with either lysergic acid diethylamide or psilocin. Equipotent doses of mescaline and lysergic acid diethylamide have been described as all but indistinguishable in psychoactivity [216]. A significant amount (20–50%) of an ingested dose of mescaline is excreted in the urine unchanged in canine experimental models [40]. Lesser amounts (7%) are excreted in urine by humans [55]. Mescaline is primarily metabolized via oxidative deamination. Excreted metabolites include 3,4,5-trimethoxyphenylacetic acid and 3,4,5-trimethoxybezoic acid.

In contrast to lysergic acid diethylamide-induced hallucinations, those associated with mescaline use are described as being consistent with actual experiences but are typically intensified through visual and auditory inputs [58, 192]. Mescaline elicits a pattern of sympathetic arousal, with the peripheral nervous system being a major target for this drug. Similar to lysergic acid diethylamide, mescaline binds to and activates brain serotonin serotonin-2A receptors with a high nanomolar affinity [164].

Pharmacokinetics

Routes of Administration

Lysergic acid diethylamide is typically administered orally. Often absorbent paper, sugar cubes or gelatin cubes are used as vehicles to deliver very small amounts of the drug. Unlike most other medicinal or illicit drugs which are dosed in milligram concentrations, psychoactive doses are measured in microgram concentrations. Liquid forms of the drug can be administered either intramuscularly or intravenously. About 20–30 μg is thought to be a threshold dose to experience psychoactive effects [87]. The psychoactive effects of a threshold dose (20–30 μg) of lysergic acid diethylamide typically last from 6 to 12 h depending on tolerance, body weight and age. These effects do not last longer than measurable blood levels of lysergic acid diethylamide as was once thought. Aghajanian and Bing [80] reported that lysergic acid diethylamide had an elimination half-life of 175 min. In a case study involving a single adult male, a 1 μg/kg dose of lysergic acid diethylamide orally had a plasma half-life of 5.1 h, with a peak plasma concentration of 5 ng/mL 3 h after drug administration [185]. These investigators also reported a close correlation between measurable blood concentrations of lysergic acid diethylamide and the time course of the subject's difficulties with simple arithmetic problems.

Following ingestion, psilocybin is rapidly absorbed and dephosphorylated to psilocin [91]. Similar to lysergic acid diethylamide, psilocin is a highly potent serotonin-1A, serotonin-2A, and serotonin-2C receptor agonist. The receptor binding potency of psilocin correlates strongly with its potency as a hallucinogen [186]. The psychoactive effects of psilocin can be highly variable among individuals. Effects reported by many individuals include strong visual and auditory components. Ingestion of psilocybin and/or psilocin is associated with an increase in the ability to concentrate on memories, feelings of time expansion, abstract and distractive thought patterns as well as indecisiveness, phonetic experimentation (glossolalia) and epiphanies about life [186, 256].

Psilocybin has a reported onset of action of 15–30 min following ingestion, with psychoactive effects lasting 5–8 h [208]. The duration of psychoactive effects correlate with dosage, which is a function of mushroom preparation and storage, and with variations in metabolism among users.

Toxicology

Lysergic acid diethylamide has been shown to bind to and induce conformational changes in

the structure of the DNA helix [59], and though reported to be mutagenic at higher doses in animal models, no detectable DNA damage or increased incidence of cancers has been seen with lysergic acid diethylamide use in humans. In fact, most hallucinogens are not known to have long-term toxicities. However, an important caveat is the potential for 3,4-methylenedioxy-*N*-methylamphetamine to produce free radicals as a side reaction to the effects of this drug on biogenic amine systems in the central nervous system. These free radicals may induce neurodegeneration within various brain areas with resultant disease states. Hallucinogen persisting perception disorder (*Diagnostic and Statistical Manual of Mental Disorders*, 4th edition diagnosis: diagnostic code 292.89) represents a condition in which the vision system-related effects of this drug persist over a long period of time [68]. Hallucinogen persisting perception disorder is distinctly different from so-called "flashbacks" in being persistent. The mechanism for this disorder has not been defined.

To date no significant toxicities have been associated with ingestion of psilocybin mushrooms, and a lethal dose in humans has not been established. The oral median lethal dose in rats is 280 mg/kg [186]. Psilocybin represents approximately 1% of the dried weight of the *Psilocybe cubensis* mushroom. An adult weighing 60 kg would have to ingest 1.7 kg of dried mushrooms to reach a dosage equivalent to the oral median lethal dose in rats. Psilocybin and psilocin are not considered addictive although both can induce short-term increases in tolerance of users.

Cannabis

History

In 1378, the Emir of the Joneima in Arabia, Soudoun Sheikouni, issued the first recorded edict prohibiting cannabis use [137]. He ordered all cannabis plants in the region destroyed and that those convicted of ingesting the plant have all of their teeth removed. Less than 20 years later, in 1393, use of cannabis in Arabia had increased [137]. And so it goes even today with the allure of this unique plant. Despite centuries of government edicts from all corners of the globe, cannabis remains the most popular psychoactive substance on the planet with the exception of caffeine, tobacco, and ethanol.

Cannabis has been used in China for over 5,000 years [152]. Its use in the Middle East is probably similarly ancient. The translation of the ingredients of the holy oil used by Aaron and his sons to anoint the tabernacle of Moses consisted of myrrh, cinnamon, cassia (commonly used as cinnamon in North America) and calamus extracted into olive oil. However, in the original Hebrew text, the last ingredient is "kanah bosm" which some contend is actually the Scythian etymological root of cannabis [152]. Indeed, the Greek historian Herodatus describes recreational use of cannabis among the Scythians 2,500–3,000 years ago [152].

Cannabis is the genus name given to several strains of the plant commonly called hemp [241]. As early as 1855, it was recognized that hemp carefully cultivated in the gardens of the near and far east had vastly different properties when consumed than the hemp grown as a large scale crop in Europe which was used in the production of fibers for rope, paper, and fabric [241]. For thousands of years in the near and far East, preparations of cannabis were smoked, eaten, or prepared in beverages [137]. Thus, while improvements in refining and distilling capabilities over the past 200 years have led to drastic increases in the potency and portability of drugs such as cocaine, morphine, and even ethanol, cannabis users continue to employ the same methods practiced by prehistoric peoples.

Chemical Properties

Raw cannabis contains 483 distinct chemical constituants, most of which are common to other plants [66]. However, the genus *Cannabis* alone produces the 66 known chemicals that constitude the cannabinoids [66]. Cannabinoids are

terpenes joined to an alkyl-substituted resorcinol [194]. Several of the cannabinoids are psychoactive, most notably Δ^9-tetrahydrocannabinol (Fig. 9). Δ^9-Tetrahydrocannabinol is regarded as the principal psychoactive constituent of cannabis and can produce discriminative stimulus effects in experienced cannabis users [35]. Other constituents of cannabis are also psychoactive, or may be metabolized into psychoactive or may be metabolized into psychoactive chemicals after ingestion; however, most of the research on psychoactive effects of cannabis focus on properties of Δ^9-tetrahydrocannabinol.

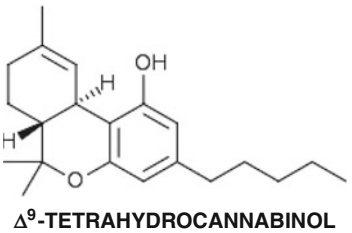


Fig. 9 Structure of Δ^9-tetrahydrocannabinol

Δ^9-Tetrahydrocannabinol has a molecular weight of 314. It is insoluble in water, and experimental preparations commonly employ the use of an emulsifier such as vegetable oil to allow an injectable solution. The concentration of Δ^9-tetrahydrocannabinol in cannabis depends upon the source, with levels ranging from 0.007% to almost 4.0% [194]. Although official reports released by the United States Department of Justice assert that the concentration of Δ^9-tetrahydrocannabinol in cannabis is increasing both in the United States and abroad (http://www.usdoj.gov/ndic/pubs11/18862/marijuan.htm; http://www.whitehousedrugpolicy.gov/news/press07/042507_2.html), others, including the director of the University of Mississippi Marijuana Potency Monitoring Project, Mohammed ElSohly, dispute this claim (http://www.slate.com/?id=2074151). While selective breeding techniques have undoubtedly resulted in enriched Δ^9-tetrahydrocannabinol-containing strains, notably in Canada and the Netherlands, after several generations in the United States, the Δ^9-tetrahydrocannabinol content of these strains recedes to levels common to American plants [194]. Climate, light, soil, humidity, and stress during the growing season all affect Δ^9-tetrahydrocannabinol content [194].

Pharmacokinetics

Routes of Administration

Marijuana is most commonly smoked. The plant material is macerated and rolled into cigarettes or loaded into a pipe. Some people utilize a water pipe in which the smoke is drawn through water with the intent of removing toxic compounds resulting from pyrolosis. This method does appear to effectively reduce the ingestion of pyrolytic toxins [213]. However, a study funded by the Multidisciplinary Association for Psychedelic Studies and the California chapter of the National Organization to Reform Marijuana Laws showed that while water pipes filter out tar, the water also traps substantial amounts of Δ^9-tetrahydrocannabinol, which leads the user to ingest more smoke, offsetting the benefits of water filtration [81]. An alternative to smoking that is growing in popularity is vaporization. This technique requires specialized equipment that heats the plant material up to 200°C, the vaporization temperature of Δ^9-tetrahydrocannabinol (MSDS, 2008; CRC Handbook) and related compounds, but not hot enough to result in combustion. This method has been shown to result in similar subjective effects (almost 90% of the vaporized substance is Δ^9-tetrahydrocannabinol), yet almost completely eliminates combustion byproducts in the inhaled product [2, 82, 94].

Δ^9-Tetrahydrocannabinol can also be eaten. Typically, fat-soluble cannabinoids are extracted into butter or some other oil which is filtered and used to make foods. Although this method eliminates any byproducts of combustion, the onset of psychoactive effects is slower and more difficult for the user to titrate [26, 194]. Alternatively, cannabinoids can be extracted from the plant

material with ethanol. The ethanol can then be consumed or used as a tincture. Again, this method eliminates harmful byproducts resulting from combustion, but makes dose titration more difficult. Further, impairment due to cannabis is enhanced by ethanol, possibly due to pharmacokinetic or pharmacodynamic interactions [103, 154]. Oral and topical preparations were the most commonly used medicinal applications in the late nineteenth and early twenieth centuries [69].

Distribution/Bioavailability

Inhalation of Δ^9-tetrahydrocannabinol results in rapid absorption, similar to other inhaled drugs. Further, smoking and vaporization produce very similar pharmacokinetic profiles in plasma of human volunteers [236]. Depending on the experience of the individual, 15–50% of the Δ^9-tetrahydrocannabinol in the raw plant matter reaches systemic circulation [181]. Oral consumption of cannabis leads to much slower and more variable absorption of Δ^9-tetrahydrocannabinol, which may depend in part on the vehicle.

The volume of distribution for Δ^9-tetrahydrocannabinol is about 10 L and is primarily distributed to body fat, and internal organs with fatty compositions such as the liver, heart, mammary tissue, and brain. Δ^9-Tetrahydrocannabinol in plasma is almost entirely bound to lipoproteins, albumin, and red blood cells. Only about 3% of free Δ^9-tetrahydrocannabinol is found in plasma [181].

Metabolism/Elimination

Metabolism of Δ^9-tetrahydrocannabinol is primarily achieved by the liver, though other organs are also able to metabolize Δ^9-tetrahydrocannabinol. Δ^9-Tetrahydrocannabinol is hydroxylated into 11-OH-Δ^9-tetrahydrocannabinol by mitochondrial cytochrome P-450, which maintains pharmacological activity [181]. Further metabolism by the same enzyme results in the inactive 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol [181]. One recent report determined the half-life of Δ^9-tetrahydrocannabinol to be 1.4 h, though this period is shorter than the results previously reported by others [9]. Determination of the half-life of Δ^9-tetrahydrocannabinol can be difficult, due to the slow development of equilibrium between plasma and fat-bound Δ^9-tetrahydrocannabinol.

Pharmacodynamics

Pharmacology

There are two types of cannabinoid receptors that have been definitively identified. Cannabinoid-1 receptors are widely expressed in the central nervous system, particularly in the hippocampus, cortex, cerebellum, and mesolimbic dopamine system. Cannabinoid-2 receptors were first identified on immune cells and thought to exist only in the periphery, but have recently been shown to be expressed by neurons and glial cells in the brain. http://www.ncbi.nlm.nih.gov.libproxy.uthscsa.edu/pubmed/18654765.

Cellular Effects

Both cannabinoid-1 and cannabinoid-2 receptors are G protein-linked receptors with a homologous structure to other, similar receptor proteins. These receptors contain seven transmembrane spanning domains with an extracellular head and intracellular tail [196]. Cannabinoid receptors are thought to associate primarily with the G_i/G_o family of G proteins, resulting in inhibition of adenylate cyclase and inhibition of calcium channels upon receptor activation [180]. However, more recent evidence suggests that at least the cannabinoid-1 receptor may associate with alternative second messenger systems depending on the agonist or tissue preparation [78].

Tissue Effects

Due to the activated receptor complex coupling with inhibitory G proteins, cannabinoid agonists tend to have inhibitory effects. Cannabinoid-1 receptors are enriched in brain and are generally thought to function as inhibitory feedback modulators of pre-synaptic neurons [235]. Stimulation of post-synaptic neurons results in liberation of membrane-bound endogenous cannabinoid agonists which migrate back across the synapse to the pre-synaptic membrane. Stimulation of cannabinoid-1 receptors then inhibits further production or release of neurotransmitter [235].

Both cannabinoid-1 and cannabinoid-2 receptors appear to promote neurogenesis, particularly in the hippocampus [112, 183]. However, the progenitor cells that result from the application of cannabinoid agonists remain undifferentiated, awaiting further signaling by other molecules. It remains unclear whether the levels of Δ^9-tetrahydrocannabinol and other cannabinoid agonists ingested by cannabis users are able to produce these effects.

Immune Effects

Generally, cannabinoids consumed during moderate marijuana use have little effect on immune system function; however, immune function can be suppressed in cells directly exposed to smoke [121]. Consequences of heavy use on immune function remain unclear. Immune cells express cannabinoid-2 receptors, with expression levels in B cells > natural killer cells > monocytes > neutrophils > T cells. Cannabinoid signaling is involved in migration of immune cells. Immune cells migrate up the concentration gradient toward the endogenous cannabinoid 2-arachidonoylglycerol. Agonists (including the partial agonist Δ^9-tetrahydrocannabinol) interfere with this chemotaxis, and this inhibition of cell migration is antagonized by cannabinoid-2 receptor antagonists [160]. Studies leading to this conclusion were performed in vitro with levels of cannabinoids unlikely to be found in recreational cannabis users. Indeed, recreational use of cannabis by immunocompromised individuals does not appear to result in increased HIV viral load or reduce the circulating T lymphoctes [1, 37].

Systemic Effects

Cannabinoid-1 receptors are highly enriched in the central nervous system, particularly in the hippocampus, cerebellum, cortex, and mesolimbic dopmaine system [196]. Cannabinoid-1- specific agonists produce characteristic effects associated with cannabinoids, including hypothermia, antinociception, locomotor depression, and ataxia [44]. Cannabis intoxication in humans produces sedation, euphoria, time dilation, dry mouth, and perceptual disturbances [173].

Therapeutic Effects

Recently, Western medicine has rediscovered potential therapeutic uses for cannabis. Because Δ^9-tetrahydrocannabinol simulates appetite and inhibits emesis, it has been used as a treatment for wasting due to chemotherapy in cancer patients as well as in HIV patients [1, 124]. Because Δ^9-tetrahydrocannabinol produces antinociception, it has been used as an adjunct to treat peripheral neuropathic pain in HIV and other patients [193]. The anti-spastic properties of cannabis have led to its use in individuals with multiple sclerosis, and its intraoptic pressure-lowering properties have led to its use in glaucoma [43, 124]. Clearly, the endogenous cannabinoid system is a rich target for therapeutic agents; however, promoting smoking as a delivery system is generally frowned upon. Thus, other delivery systems have gained traction in recent years [82, 94, 193].

Toxicology

Apoptosis

Application of Δ^9-tetrahydrocannabinol to cultured hippocampal neurons can result in cell death due to apoptosis. Chan et al. [36] treated

hippocampal slices from adult female rats with Δ^9-tetrahydrocannabinol (0.2, 0.38, 0.5, 1, and 2 μM) daily and assessed cell viability over 10 days. Δ^9-Tetrahydrocannabinol concentrations of ≥0.5 μM resulted in dose- and time-dependent decreases in cell viability over the first 6 days. The apoptotic effect of Δ^9-tetrahydrocannabinol appears to be mediated by cannabinoid-1 receptor mediated activation of c-Jun N-terminal kinase, initiating the caspase-3 programmed cell death pathway. However, in aggregating brain cell cultures consisting primarily of neurons, glia, or a mixture of the two, repeated treatment with 1 and 2 μM did not result in cell death, though GABAergic, cholinergic, and astrocytic markers were reduced following treatment [163].

It is important to note that these concentrations of Δ^9-tetrahydrocannabinol are likely higher than those achieved in vivo. Postmortem brain samples in cannabis users revealed Δ^9-tetrahydrocannabinol levels ranging from 3 nM to 0.1 μM, well below concentrations used in in vitro studies [169]. Blood levels were lower than brain levels in every subject. Consumption of a marijuana cigarette (3.55% Δ^9-tetrahydrocannabinol) resulted in Δ^9-tetrahydrocannabinol levels up to 0.85 μM; however, peak levels were rapid in onset and dissipated rapidly [105]. Thus, the relevance of apoptosis due to concentrations of Δ^9-tetrahydrocannabinol at or above 0.5 μM remains unclear. Further studies designed to examine apoptosis following systemic Δ^9-tetrahydrocannabinol administration would help clarify the impact of Δ^9-tetrahydrocannabinol on neuronal cell death.

Lung Cancer

Because smoked cannabis delivers comparable or even higher levels of tar than tobacco cigarettes, there is some interest in the relative risk of developing cancer due to chronic use [204, 231, 257]. Such studies are difficult to undertake as many cannabis users also use other recreational substances, especially tobacco [6]. To date, studies have reported mixed results [212, 238]. Recently, a case-control study was reported using adults identified by the New Zealand Cancer Registry [6]. Age-matched controls were randomly selected from the electoral roll. In this study, cannabis use, broadly defined, did not increase the relative risk for the development of lung cancer. However, heavy cannabis use (>10.5 cigarettes/day/year) did significantly increase the risk for developing lung cancer after adjusting for age, ethnicity, tobacco use, and family history of lung cancer. Thus, smoking cannabis does appear to pose a risk for subsequent development of lung cancer, but only if used at extremely high levels.

Head and Neck Cancer

While heavy cannabis use may lead to the development of lung cancer, cannabis use is not linked to increased incidence of head and neck cancer [6]. Although heavy use of cannabis (>8.3 cigarettes/day/year) resulted in a slight increase in the prevalence of head and neck cancers, this increase was non-significant. In contrast, alcohol or tobacco use significantly increased the risk of developing head and neck cancer in this study.

Mental Disorders-Psychosis

Perhaps the most controversial, potentially toxic effect of cannabis at present is a link between cannabis use in adolescence and subsequent development of psychosis. Cannabis use can result in acute psychotic episodes [140]. More recent studies have suggested that prolonged cannabis use during adolescence can increase the likelihood of psychotic symptoms at age 26.

Depression

Few studies have investigated links between cannabis use and major depressive disorder. Wilcox et al. [248] and Lynskey et al. [148]

found that initiation of cannabis use during adolescence increased the risk of subsequent depressive disorder. However, these studies were not conclusive. Further, basic research has demonstrated an anti-depressive effect of indirect cannabinoid agonists [22, 86]. Thus, a causal link between cannabis use and depression has not been decisively established.

Drug Addiction

Perhaps the most contentious debate over possible psychiatric sequelae of cannabis use relates to the "gateway" theory. That is, that use of cannabis leads to an increased likelihood of subsequent addiction to other illicit substances [170]. Currently, the most widely held opinion is the correlated vulnerabilities theory which posits a predisposition toward illicit substance use. Thus those who use cannabis could have a more permissive attitude toward illicit substances in general and may be more willing to try other illicit substances. Further, because cannabis is only available on the black market, it is often purchased from sellers who also deal in other illicit substances.

The alternative theory is that cannabis use changes the neurobiology of the initiate in ways that promote subsequent addictions. Lynskey et al. [148] report that cannabis use increases the risk of subsequent drug use in twins independent of early-onset alcohol and tobacco use or other behavioral or environmental factors. Cannabis is often the first illicit drug used by those who proceed on to addictions to other illicit substances (although it should be noted that alcohol and tobacco, which are typically used prior to cannabis, are technically illegal for adolescents in the United States). Indeed, tobacco use appears to precede and predict cannabis use [116]. However, more recently, Patton et al. [190] reported that cannabis use precedes and predicts tobacco use. Thus, it does not appear that the "gateway" phenomenon is specific to cannabis, and these results support the correlated vulnerabilities theory.

Treatment of Cannabis Addiction

No pharmacotherapy is presently approved for use in cannabis dependence. The development of cannabinoid-1 receptor antagonists such as rimonabant has provided a potential candidate, though approval for clinical use of rimonabant in the United States was recently denied due to safety concerns [134]. At present, the only treatments shown to be effective for cannabis addiction or dependence are behavioral therapies, including cognitive behavioral therapy, motivational enhancement therapy, and contingency management or some combination of these three [28]. Due to the controversy surrounding the clinical relevance of cannabis dependence and addiction, potential treatments for the disorder have not been as widely researched as for other substance use disorders such as alcohol or cocaine.

Nicotine

History

Tobacco is a plant native to the Americas. Prior to domestication, only one strain was probably existant; however, propagation of tobacco use across the world under widely varying conditions has produced up to 40 unique species [242]. Likely for thousands of years, tobacco was used by pre-Columbian Americans in religious ceremonies. Shamans used tobacco in combination with other substances to simulate near-death experiences [242].

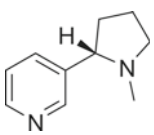
Tobacco was introduced to Europe by Christopher Columbus's crew in the late 1400s from the Bahamas. The natives they encountered smoked cigars which they called *tabacos*. Tobacco was rolled into maize leaves and smoked. Natives of Hispanola burned tobacco over open coals and inhaled the smoke through the nose. The Aztecs smoked tobacco mixed with fragrant herbs and resins from clay pipes, but also insufflated dried, crushed leaves (snuff), and chewed leaves mixed with lime. However,

pre-Colombian tobacco use appears to have been confined to North and Central America as the people of South America (with the notable exception of Peru) did not produce pipes or other smoking devices, nor was tobacco part of their folklore or culture before the arrival of Spaniards [242]. In 1559, Jean Nicot visited a pharmacy in Lisbon and brought tobacco products back to France [195]. Very soon afterward, the use of snuff (kept in sufficiently impressive boxes) was widespread among the nobility of France. For introducing this plant to greater Europe, the genus of tobacco (*Nicotiana*) and its primary psychoactive constituent (nicotine) bear the name of Nicot [195].

The United States was established, in part, to produce tobacco to meet the growing demand in Europe. From the 1600s on, tobacco use spread widely and quickly around the world. Only within the past 40 years, as the serious health concerns arising from tobacco use have become generally accepted have smoking rates begun to decline. From 1965 to 2006, smoking prevalence among adults in the United States has declined from between 40 and 50% to between 20 and 30% (Centers for Disease Control and Prevention's Office on Smoking and Health).

Chemical Properties

The primary active ingredient in tobacco is nicotine. The structure of nicotine is shown in Fig. 10. Nicotine has a molecular weight of 162.26 g/mol and is soluble in water. Nicotine extracted from tobacco in water has been used as an insecticide since 1746 [195].



NICOTINE

Fig. 10 Structure of nicotine

Pharmacokinetics

Routes of Administration

Tobacco is most commonly rolled into cigarettes and smoked. This hasn't always been the case. Until the twentieth century, tobacco was most commonly chewed, insufflated as snuff, or smoked in pipes [178, 242]. The advent of cigarette rolling machines led to increased production capacity and ultimately increased consumption of cigarettes. During the 1900s, cigarette manufacturers expended enormous resources on developing improvements in the paper, filters, flavorings, and even the tobacco blends used in cigarettes in order to produce brand-specific cigarette qualities and to increase consumer desire and demand [178].

Inhalation of cigarette smoke results in a rapid transfer of nicotine from the lungs into the blood and then into the brain. Nicotine migration from inhaled smoke to lung to brain within 10 s has been linked to its high abuse and addiction liability [96], though this has recently been questioned [52]. Because nicotine is a polar compound (weak base with pKa = 8), the use of ammonia during the production process results in a free-base form of the compound which speeds the transfer from lung to blood. Tobacco manufacturers insist that ammonia is used in the production of cigarettes to enhance the flavor of the product, rather than to enhance the psychopharmacological effects of nicotine. However, industry documents show that tobacco companies have known that the use of ammonia enhances nicotine delivery for several decades [252].

Tobacco can also be smoked loose in a pipe, or rolled into tobacco leaves as a cigar. Many users perceive that such use is less harmful that smoking tobacco in cigarettes. Reasons for these beliefs include the notion that nicotine is an additive in cigarettes but is not present in cigar or pipe tobacco, that cigar or pipe tobacco is less processed or "more organic", and that cigar or pipe smoking behavior is typically more moderate than cigarette smoking [230]. In fact,

smoking tobacco in any formulation presents a similar health risk of developing lung, larnyngeal, or oral cancers as well as other diseases that increase morbidity and mortality [230].

Smokeless tobacco includes snuff, which is insufflated, dip or chew which is kept in the mouth in contact with the buccal lining, as well as several newer formulations including snus, a Scandinavian snuff product which is held in the mouth inside a pouch. While these forms do not expose the user or bystanders to harmful smoke, smokeless tobacco contains known carcinogens. Exposure to nitrosoamines is extremely high in users of smokeless tobacco, and over a 20-year period of use, exposure levels can reach those known to produce tumors in rodents [20]. Although results are mixed and at times difficult to interpret due to differences in socioeconomic status, diet, and genetic background, use of smokeless tobacco generally increases the risk developing cancer (especially oral, esophageal, and pancreatic cancers), though not as much as use of smoked tobacco.

More recently, electronic cigarettes and other novel nicotine delivery devices have been manufactured [245]. These cigarettes contain no tobacco and do not burn. Rather, a battery powered atomizer heats a nicotine formulation contained in a disposable filter pack. Users puff on the device just as they would puff on a tobacco cigarette and the tip glows red to simulate the smoking experience. Because the user and bystanders are not exposed to smoke or tobacco, these products are touted as safer than other tobacco formulations. However, the cost is more prohibitive than tobacco products, and no long-term data on the potential health consequences or maintenance of use are yet available on these devices.

Distribution/Bioavailability

A dose of 60 mg of free-base nicotine is considered lethal in humans [195]. Even a dose as low as 4 mg can produce symptoms consistent with acetylcholinesterase inhibitor poisoning, including salivation, vomiting, muscle weakness, convulsions, and fibrillation. Smoke from modern cigarettes yields between 1 and 2 mg of nicotine per cigarette. Nicotine replacement gum is sold in 2 and 4 mg formulations, with the higher dose recommended for heavy (>25 cigarettes/day) smokers who presumably have developed tolerance to nicotine (Nicorette web site).

Metabolism/Elimination

In animals, only a small portion of administered nicotine is eliminated unchanged. Nicotine and its metabolic products are largely excreted in urine, with a single dose requiring 16 h for complete elimination [253]. Nicotine is metabolized to cotinine primarily by the liver, specifically by CYP2A6, CYP2B6, and CYP2E1 [17]. Cotinine has a longer half-life than nicotine (16 h vs. 2 h, respectively) and thus is increasingly used as a clinical biomarker of recent (2–3 days) nicotine use [17].

Pharmacodynamics

Generally, nicotine has a biphasic dose-effect curve, with low doses producing tachycardia, hypertension, and general arousal and higher doses producing bradycardia, hypotension and sedation [17]. Still higher doses can produce salivation, emesis, and convulsions. All of these effects of nicotine are subject to rapid and dramatic tolerance upon continued use. Tolerance to central nervous system and cardiovascular effects can occur within a day of use (with a return to morning levels due to abstinence imposed by sleep).

Pharmacological Effects

Nicotine binds to nicotinic acetylcholine receptors. These receptors are located in the central nervous system and distributed pre-synaptically, post-synaptically, and on the cell soma [197].

The nicotinic receptors consist of pentomers composed of either five alpha (α2–α10) subunits or a combinations of alpha and beta (β2–β4) subunits [17, 197]. The most abundant subunits are the α4 and β2, and receptors comprised of these subunits may account for 90% of all nicotine binding sites in the brain [17]. When acetylcholine or nicotine binds to the recognition site at the interface between an alpha subunit and an adjacent (alpha or beta) subunit, the conformation of the receptor changes which opens a channel to allow sodium and calcium to enter the cell [197]. This, in turn, facilitates the release of neurotransmitters—particularly dopamine in the midbrain region but also norepinephrine, gamma-aminobutyric acid, glutamate, and endorphins [17]. Because midbrain dopamine appears to be a common pathway activated by drugs of abuse and other pleasurable events, it is this action that is believed to be central to the addictive nature of tobacco [17].

Tissue Effects

In brain, acute administration of nicotine leads to a complex pattern of effects. As noted above, nicotine has a direct effect on neurons, facilitating release of neurotransmitters including norepiniephrine. The release of norepinephrine from the adrenal cortex as well as stimulation of the reticular formation results in increased arousal reflected by a decrease in alpha activity of an electroencephalagram [153]. Respiration is increased due to direct stimulation of the medulla [153]. Nicotine also stimulates the brain region responsible for emesis, leading to vomiting following high doses or in inexperienced users [153].

In the periphery, nicotine receptors are found primarily in the neuromuscular junction of voluntary muscles [153]. Nicotinic stimulation of these receptors can lead to tremor. In the cardiovascular system, nicotine increases heart rate and constricts capillaries in the skin, which lead to increased blood pressure [153]. Nicotine also inhibits stomach secretion and stimulates bowel activity [153].

Systemic Effects

Because nicotine produces rapid and profound tolerance, systemic effects of nicotine differ between smokers and non-smokers. In smokers, nicotine improves motor performance (in simulated driving tasks) and learning but impairs fine motor control due to the voluntary muscle tremor it produces [153]. While nicotine administration results in heightened arousal, most smokers report that nicotine is relaxing. This paradoxical effect on mood has been widely studied and may owe more to the other trappings of smoking (holding the cigarette, lighting it, and stopping other activities to focus on the act of smoking) rather than to a direct effect of nicotine [153]. Clearly, nicotine is reinforcing and promotes subsequent seeking and consumption of the substance, as evidenced by the high rates of addiction to nicotine [153].

Toxicology

Acute

High doses of nicotine can lead to respiratory depression and increased secretion of saliva and mucus similar to the effects of a cholinesterase inhibitor. As previously noted, nicotine can increase blood pressure and induce vomiting.

Withdrawal

Tobacco use leads to profound tolerance [17]. Abrupt cessation of nicotine leads to a wide array of withdrawal signs and symptoms including anxiety, dizziness, nausea, constipation, inability to concentrate, weight gain, and sleep disturbances [153]. The use of nicotine replacement or varenicline can minimize these problems [136].

Cardiopulmonary System

Toxic effects of tobacco use on the lungs are due to the inhalation of smoke rather than to direct

effects of nicotine. Ash and tar are deposited in the lungs and pyrolytic compounds in the smoke, particularly benzo[a]pyrine, which is metabolized into a carcinogenic compound by P-450 enzymes in lung tissue [195, 219]. Nicotine inhibits the action of cilia in the lungs which normally would move the tar up and out of the lungs and into the esophagus, leading to increased exposure to these toxic chemicals [120, 153]. Ultimately, this repeated insult to the lining of the lungs can lead to emphysema and lung cancer [187, 245].

Tobacco use is clearly linked to an increased risk of heart disease. Direct effects of nicotine on the heart and vasculature are compounded by effects of carbon monoxide and other pyrolytic compounds derived from the accompanying smoke [153]. Reduced systemic oxygen perfusion further taxes the heart and brain. Additionally, smoking contributes to the deposition of cholesterol on the vascular walls causing atherosclerosis [153]. This also reduces blood perfusion and increases the circulatory pressure.

Stroke

Because smoking is clearly linked to vascular disease, one might assume that smoking could be causally linked to acute cerebral ischemic events (stroke). However, such a relationship has been difficult to demonstrate. In a literature review, Giroud and Dumas [85] concluded that smoking increases the risk of stroke by a factor of 1.7–5.7. Despite the relative lack of data demonstrating a causal link, tobacco use is contraindicated in those at risk or recovering from stroke primarily due to its hypertensive effects [51, 73].

Cancer

While the link between some cancers and smoking is debated [153], the link between smoking and lung cancer is clear. By one estimate, 90% of all lung cancer is attributable to exposure to tobacco smoke [245]. A major constituent of smoke produced by burning tobacco is benzo[a]pyrene, which is oxidized by a P-450 enzyme to trans-7, 8-diol-9, 10-epoxide, a potent carcinogen [195]. While the use of smokeless tobacco can certainly reduce the risk of lung cancer, smokeless tobacco may lead to an increase in oral, esophageal, and pancreatic cancer [20]. Nitrosoamines that naturally occur in tobacco at extremely high levels are likely the causative element in these cancers, though carcinogenic effects of nicotine itself may also play a role by promoting the growth of cancer cells [20, 34].

Therapeutic Effects

Nicotine can improve cognitive function, especially in those afflicted with neurodegenerative disorders such as Alzheimer's and Parkinson's diseases. The use of nicotinic agonists in such individuals has recently been suggested [39]. However, due to the known perils of smoking and even smokeless nicotine delivery, such therapeutic use awaits the development of novel nicotinic agonists as well as improved delivery methods.

Treatment for Cessation of Smoking

A vast array of drugs have been tested as pharmacotherapeutics for smoking cessation [136], yet, few of these treatments have proven success over placebo. Presently, the best candidates for pharmacotherapy of smoking include bupropion and nicotine (delivered via gum or a transdermal patch formulation). Varenicline is an exciting new development currently approved as a smoking cessation therapy. Additionally, recent studies suggest that contingency management may be an effective means to reduce smoking in those who wish to stop as well as those who do not.

Bupropion appears to be effective in some individuals [249]. It works by blocking reuptake of synaptic dopamine and norepinephrine, which are thought to be important in the reinforcing and conditioned aspects of nicotine effects, respectively [136]. Nicotine replacement therapy has

been shown to be effective in some individuals. Nicotine is provided in chewing gum or on a transdermal patch. Smokers can use the gum as desired while the patch is applied and remains continuously affixed. Nicotine replacement reduces the urge to smoke by providing an alternative means of administration. However, due to potential teratogenic effects of nicotine, its use in pregnant and nursing mothers has been debated [223]. Varenicline is a nicotinic receptor partial agonist. By occupying nicotine binding sites, it can blunt or block receptor activation by nicotine yet, due to its low efficacy agonist effects, provides a low level of nicotinic signalling on its own. This compound is approved for use, yet some questions remain over its long-term safety, particularly regarding potential for development of depression, especially during smoking cessation [106, 198]. Taken together, several promising pharmacotherapies (including bupropion, nicotine replacement and varenicline) exist for treatment of tobacco addiction, each of which is more effective than placebo [63].

In addition to pharmacotherapies, behavioral therapies for smoking have been shown to be effective [131]. Most promising is contingency management. In this procedure, reducing tobacco use is reinforced, usually with a monetary payout contingent on reduced carbon monoxide or salivary cotinine levels. Even those not wishing to stop smoking reduce their consumption of cigarettes when subjected to contingency management [132]. Combining pharmacotherapy with behavioral therapy may be more effective than either alone, though this has yet to be definitively confirmed [165].

Inhalants

History

Probably the first wave of inhalant abuse was launched by the discovery of the euphoric properties of ether. During a short-lived prohibition on alcohol in Ireland during the late nineteenth century, the ethanol-like properties of ether made it an attractive alternative [194]. Volatile substance abuse was first described in 1951, and reports of "sudden sniffing deaths" began appearing in the 1960s [142]. It was at this time that amyl nitrate became widely available [14]. After over-the-counter sales of amyl nitrate were curtailed, other related nitrates were substituted, as was nitrous oxide in the form of small canisters used as whipped cream propellant and solvents such as those found in fuels, paints, and other industrial products. The median age of first inhalant use is 13 years [142]. The lifetime prevalence of use is similar in girls and boys [142]. Sniffing is inhalation directly from a container, huffing is pouring the volatile liquid directly on fabric and placing the fabric over the nose or mouth, and bagging is when the solvent is sprayed into a bag and rebreathed [142].

Mechanism of Action

Inhalants are generally grouped into three categories. The most commonly used are volatile hydrocarbons, which includes fuels such as gasoline and solvents such as toluene [142]. Volatile alkyl nitrites have distinct pharmacologic and behavioral effects and are considered a unique class of inhalant [142]. Finally, nitrous oxide is not a hydrocarbon but is widely abused as an inhalant [142].

Historically, the Meyer-Overton hypothesis was invoked to explain inhalant action. Inhalants are highly lipophilic, and the Meyer-Overton hypothesis posits that anesthetic action is related to the disruption of the orientation of membrane-bound proteins by perturbing the lipid membrane, especially in the central nervous system. This hypothesis was also used for many years to explain the actions of ethanol. However, as with ethanol, more recent evidence suggests that specific alterations in proteins responsible for neurotransmission, particularly glutamatergic, GABAergic and opioidergic pathways.

Smooth Muscle Relaxation

Although other volatile hydrocarbon effects are apparent at specific proteins in the central nervous system, the alkyl nitrites have not been shown to specifically alter proteins involved in neurotransmission. Rather, these compounds are thought to produce smooth muscle relaxation, perhaps by liberating nitrous oxide [142]. Alternatively, effects due to these drugs could be indirect, resulting from biotransformation into other pharmacologically active chemicals, such as isobutyl alcohol [142].

N-Methyl-D-Aspartate

The first evidence that inhalants could alter ion channel function specifically, rather than non-specifically by inserting in the lipid bilayer, came from Cruz et al. [48]. In that study, toluene dose-dependently inhibited inward cationic currents through recombinant Xenopus *N*-methyl-*D*-aspartate receptors. The site of action appeared to be in the NR1/NR2B subunit combination, though other combinations were also affected to a lesser extent. Addition of glycine or *N*-methyl-*D*-aspartate did not alter the inhibitory effect of toluene, which would be expected if toluene was acting as an antagonist at the *N*-methyl-*D*-aspartate or glycine site. It is important to note that *N*-methyl-*D*-aspartate function was inhibited at concentrations well below those that altered the conductance of the membrane, indicating that the effects were not due to general disruption of the membrane. α-Amino-3-hydroxy-5-methylisoxazole-4-propionic acid and kainate receptors were not similarly affected. Subsequently, Bale [13] replicated these findings in primary neuronal cultures. Additional evidence for specific action of inhalants at *N*-methyl-*D*-aspartate receptors is the upregulation of *N*-methyl-*D*-aspartate receptors following chronic exposure [23]. Like the volatile hydrocarbons, nitrous oxide also inhibits *N*-methyl-*D*-aspartate receptors [142].

Gamma-Aminobutyric Acid

Volatile hydrocarbons increase gamma-aminobutyric acid-A receptor function [142]. The site of action on gamma-aminobutyric acid-A receptors appears to be the α1β1 subunit [23]. One volatile convulsant solvent, flurothyl, inhibits recombinant gamma-aminobutyric acid-A receptor. Nitrous oxide does not influence GABAergic signalling [142]. Taken together, volatile hydrocarbon inhalants (excepting alkyl nitrites) share similar pharmacological effects with ethanol; namely inhibition of *N*-methyl-*D*-aspartate receptors and enhancement of GABAergic signalling.

Dopamine

Based on the widespread abuse of inhalants, and the involvement of the dopaminergic system in reinforcing actions of many abused drugs, one might expect inhalants to enhance dopaminergic signalling. Indeed, brief exposure to toluene increases dopaminergic firing from the ventral tegmental area and increases extracellular dopamine in the nucleus accumbens [23]. Although this evidence is consistent with dopaminergic effects of other abused drugs, it is likely that these effects are due to indirect actions of solvents at gamma-aminobutyric acid receptors, rather than to a direct effect on dopamine receptors [23].

Other Receptors and Ion Channels

There is some evidence of opioidergic involvement in the effects of inhalants. The antinociceptive effects of nitrous oxide are antagonized by naloxone, though the anesthetic effects are not [142]. Acute toluene exposure increases μ-opiod receptor protein levels in the brainstem [146]. There is also evidence of volatile organic solvents affecting serotonin-3 receptors, P2X receptors, and voltage-gated ion channels, though the relationship between these effects and behavioral effects remains murky [23].

Pharmocokinetics

Generally, inhalants are highly lipophilic, and are rapidly absorbed and eliminated. Inhalants are eliminated unchanged by respiration, are metabolized in the liver, or both [142]. Nitrous oxide is eliminated unchanged by respiration while aromatic hydrocarbons are largely metabolized by hepatic mechanisms. Alkyl nitrites may be converted to alcohols as well as nitric oxide donors. Metabolism of aromatic hydrocarbons in the liver occurs via the cytochrome P450 system. The CYP2E1 enzyme appears to be the primary enzyme recruited [142]. Extrahepatic metabolism of aromatic hydrocarbons occurs to a lesser extent and may result in organ-specific toxicity [142].

Pharmacodynamics

Toluene produces a biphasic effect on locomotion, similar to ethanol. Low doses result in hyperlocomotion, with higher doses progressing from sedation to motor impairment to anesthesia [23]. Inhalants can protect against seizures in animals, though convulsions have also been seen. In humans, inhalants rarely produce convulsions [23]. Toluene exerts anxiolytic effects in animal models, which might be expected due to activity at gamma-aminobutyric acid-A receptors [23]. Rats exposed to toluene chronically show deficits in learning and memory as assessed by the Morris-water maze [23]. This finding is mirrored by clinical evidence of learning and memory deficits in habitual inhalant abusers [142].

Operant work with inhalants is sparse. One major impediment is producing consistent exposure conditions inside of the chamber typically used for such studies. However, operant responding for food is diminished by acute exposure to inhalants, regardless of the schedule of reinforcement employed [23]. Toluene and other solvents share discriminative stimulus effects with other classic central nervous system depressants such as ethanol. This is not surprising considering the effects on gamma-aminobutyric acid-A and *N*-methyl-*D*-aspartate receptors common to these drug classes. While some have reported success at training rodents to self-administer solvents intravenously, establishing inhalant self-administration has yet to be reported [23]. Proper containment of the volatilized solvent and consistent delivery contingent upon an appropriate response will be required to perform such procedures.

Toxicology

Each class of inhalants presents its own unique toxicology. Chronic use of any inhalant can lead to neuropathy. Volatile organic solvents present the most overt and widespread toxicological effects, including cardio, renal, and hepatic toxicities. Amyl nitrites also produce direct toxic effects, while toxic effects of nitrous oxide are indirect.

Volatile organic solvent abuse leads to an array of toxic effects. Most common are neuropathies. Neurological damage is generally not dose-related. However, there may be a relationship between neurological damage and duration of use [146]. Chronic abuse of n-hexane (found in glues and fuel) is associated with peripheral neuropathy, while toluene is associated with cerebellar disease [146]. Neuropathy related to volatile organic solvent use can present as euphoria, hallucinations, headache, and dizziness progressing to slurred speech, confusion, tremor, and weakness [142]. Transient cranial nerve palsy can also occur [142]. Heavy use of these agents leads to white matter degeneration and demyelination evidenced by perivascular macrophages containing coarse or laminar myelin debris [142].

Pulmonary effects are due to either direct damage to lung tissue or by asphyxiation [146]. Hypoxia causes pulmonary toxicity that is usually due to the method of administration (mask/rebreathing) rather than overabundance of hydrocarbons [142]. Also inadvertent aspiration of liquid hydrocarbon can injure tissue [142].

Acute cardiotoxicity is usually the cause of "sudden sniffing death." It is thought that the inhalant sensitizes the myocardium by blocking the potassium current, prolonging repolarization [142]. Chronic use can result in chronic myocarditis with fibrosis and present as palpitations, shortness of breath, syncope and electrocardiographic abnormalities [142]. Renal disorders are especially associated with toluene abuse. In particular, chronic toluene exposure is considered causal for tubular acidosis, urinary calculi, glomerulonephritis, and renal failure [146]. Distal renal tubular acidosis can result in hypokalemia and muscle weakness [142]. Hepatic failure has also been observed, primarily following halogenated hydrocarbon use, such as carbon tetrachloride or refrigerants, probably due to a reactive metabolite [142]. Use during pregnancy increases the risk of premature labor or spontaneous abortion, and neonates can exhibit withdrawal symptoms [146]. Further, use of inhalants during pregnancy is associated with premature, low birth weight and length, small head, developmental delay and reduced neuronal density in rodent studies [142].

Volatile alkyl nitrite use is associated with methemoglobinemia [142]. This may be a result of the ability of these strong oxidants to change the charge on the ferrous ion from $Fe^{2+}$to Fe^{3+}[142]. The most prominent toxic effects of nitrous oxide are due to asphyxiation and auto accidents, rather than to a direct effect of the agent [142]. Chronic abuse can lead to irreversible oxidation of cobalamin (vitamin B12), which leads to aberrations in the myelin sheath [142].

Barbiturates

History

Among classes of abused drugs, barbiturates are relative newcomers with a history of just over 100 years of use and abuse. The primary reason for this rather short history is that, unlike drugs from other pharmacological classes, barbiturates have not been found in nature and had to be developed in the laboratory. In 1864, Adolf von Baeyer synthesized the first barbiturate, malonylurea, which was later named barbituric acid [143]. With the perfection of the synthetic process by Edouard Grimaux in 1879, derivatives of barbituric acid could be widely developed, including diethyl-barbituric acid or barbital, which became the first barbiturate on the market in 1904 [143]. The clinical success of barbiturates led to the synthesis of more than 2,500 different compounds with 50 of them available clinically.

Barbiturates were initially introduced as hypnotics, although other effects became evident with their continued development and clinical use. For example, the anticonvulsant effects were discovered in 1912, the same year that phenobarbital was first available commercially [102, 143]. Systematic use of barbiturates in intravenous anesthesia did not occur until 1927, with pentobarbital introduced in anesthesia in 1930, and thiopental and methohexital introduced later (1936 and 1956, respectively). These therapeutic effects led to the huge popularity and widespread use of the barbiturates, which peaked during the 1930s and 1940s [102]. In addition to the therapeutic effects of barbiturates, adverse effects were also increasing evident. One effect that took very little time to emerge was the development of dependence. Evidence that dependence developed with repeated barbiturate administration appeared in the literature in 1905, 1 year after the introduction of barbital [143]. Another problem associated with the use of barbiturates was fatal overdose. In fact, the two scientists who were responsible for the introduction of barbital in 1904, Josef von Mering and Emil Fischer, are thought to have been dependent on barbiturates and to have died of a possible overdose [143]. The abuse potential of these drugs was not reliably documented until the 1950s [102]. Together, these adverse effects led to the decline of the clinical use of barbiturates, which was further exacerbated by the introduction of the benzodiazepines in the 1960s. This new class of drugs produced similar therapeutic effects with a greater margin of safety. Today, barbiturates

are used clinically for some indications, mostly for certain types of seizures and for induction of anesthesia.

Chemical Properties

Barbituric acid is 2,4,6-trioxohexahydropyrimidine (Fig. 11). Clinically useful barbiturates are formed by the addition of alkyl or aryl groups at position 5 [99]. Salts can result when the carbonyl group on position 2 takes on an acidic character, thereby improving solubility in water and increasing absorption [99]. Thus, sodium salts are more amenable to intravenous administration and are the form of barbiturates used in anesthesia. Although barbiturates are highly lipid soluble, replacing the oxygen at C2 with sulfur decreases partition coefficients, resulting in drugs with shorter onsets and durations of action [99]. These barbiturates, which include thiopental, have been used extensively to induce anesthesia.

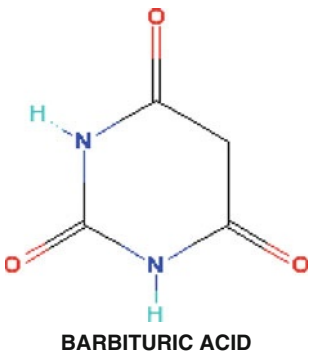


Fig. 11 Structure of barbituric acid. From http://pubchem.ncbi.nlm.nih.gov

Pharmacokinetics

Routes of Administration

Because mechanism of action does not vary among barbiturates, these drugs are generally classified according to their pharmacokinetics, specifically by their duration of action [57]. Differences in formulations, therapeutic use and abuse of barbiturates are due to differences in their duration of action. For example, ultrashort-acting barbiturates, such as methohexital and thiopental, are only available for intravenous use and are used exclusively for induction of anesthesia. Short- to intermediate-acting barbiturates, such as pentobarbital, are available in capsules, suppositories or in solution for intravenous or intramuscular administration. Long-acting barbiturates, such as phenobarbital, are only available for oral use.

Absorption and Distribution

After oral administration, barbiturates are rapidly and completely absorbed from the upper part of the small intestine. Long-acting barbiturates are absorbed more slowly than shorter-acting drugs [255]. Barbiturates are widely distributed, beginning with highly vascularized areas like the brain. For the highly lipid-soluble, ultra-short-acting drugs, these initially high concentrations of barbiturates in the central nervous system decline as the drug distributes to less vascularized areas like muscle and fat [99]. This redistribution of barbiturates from the brain to other tissues contributes to the very short duration of action of these drugs.

Metabolism/Excretion

Barbiturates are almost completely metabolized in the liver before renal excretion, and unchanged barbiturates infrequently appear in urine [255]. Microsomal enzymes oxidate the larger of the two substituent groups at position 5, forming alcohols, phenols, ketones or carboxylic acids [99]. Repeated administration of barbiturates results in the induction of the hepatic enzymes responsible for their inactivation. This metabolic tolerance shortens the half-life of barbiturates as well as that of any other drugs metabolized through the same enzymes.

Pharmacodynamics

Mechanism of Action

Barbiturates act at gamma-aminobutyric acid-A receptors. The gamma-aminobutyric acid-A receptor complex is a transmembrane protein complex that is formed by five subunits with multiple binding sites on each gamma-aminobutyric acid-A receptor. When gamma-aminobutyric acid binds to its distinct sites on this protein complex, channels open and Cl^- enters the cell. Other sites on the gamma-aminobutyric acid-A receptor complex are modulatory sites, and drugs acting at these sites can alter the effects of gamma-aminobutyric acid. Barbiturates act at distinct modulatory sites to facilitate the actions of gamma-aminobutyric acid, thereby increasing Cl^- flux [7]. At large concentrations, barbiturates can activate channels even in the absence of gamma-aminobutyric acid [7, 70, 206].

Pharmacological Effects

The primary pharmacological effect of barbiturates is to decrease activity of the central nervous system. The most prominent effects of barbiturates are their sedative effects, which vary with dose from mild sedation to general anesthesia. These drugs decrease sleep latency and the number of awakenings and can also affect the stages of sleep by decreasing time spent in rapid-eye-movement and slow-wave sleep [99]. Barbiturates can also reduce anxiety, although sometimes this effect is difficult to dissociate from sedative effects. The ability of barbiturates to prevent and reverse convulsions continues to be exploited clinically.

Toxicology

In addition to these therapeutic effects, depression of the central nervous system also accounts for the most serious acute toxicological effect of barbiturates. When central nervous system activity is reduced, there is a concomitant decrease in ventilation. Barbiturates affect both respiratory drive and its rhythmic characteristics, and at large doses, these effects can be severe enough to eliminate respiration. Thus, acute barbiturate overdose can be fatal. The respiratory-depressant effects of barbiturates can also be exacerbated by other drugs, particularly those with actions at gamma-aminobutyric acid-A receptors. Combinations of sublethal doses of barbiturates with drugs like ethanol or benzodiazepines can result in life-threatening decreases in ventilation.

In addition to their respiratory-depressant effects, barbiturates produce several other adverse effects that ultimately led to the decline of their clinical use. Perhaps the most serious problems occur when the drugs are administered repeatedly. Chronic use or abuse of sedative doses of barbiturates can result in the development of tolerance or dependence. In addition to pharmacokinetic tolerance that occurs when hepatic microsomal enzymes are induced, pharmacodynamic tolerance can also develop, which likely involves changes in gamma-aminobutyric acid-A receptor structure or function. One change that occurs in gamma-aminobutyric acid-A receptors during chronic barbiturate treatment is a functional uncoupling of binding sites [259]. Regardless of the mechanism, the development of tolerance has multiple consequences. First, a larger dose or more frequent administration is needed to maintain the desired effect. Because pharmacokinetic tolerance shortens the duration of action of a drug without altering the amount of drug needed to produce an effect, use of larger doses could lead to overdose [255]. Even if overdose is avoided by increasing frequency rather than dose, the escalating intake is more likely to result in the development of dependence and the emergence of a more robust withdrawal syndrome.

A second important consequence of chronic barbiturate treatment is the development of dependence, which is evident when withdrawal signs emerge following abrupt discontinuation of treatment. Signs begin to appear 24 h after the last dose of the barbiturate, peak within 2–3 days

and subside slowly over the next 10–14 days [75, 247]. The withdrawal syndrome has been classified based on the severity of signs and symptoms. For example, mild signs include apprehension, muscle weakness, tremors, twitches, orthostatic hypotension, anorexia, insomnia, anxiety and profuse sweating whereas severe withdrawal includes clonic-tonic seizures and psychosis which usually resembles delirium tremens that are observed when alcohol use is discontinued [247]. Increasing the dose, frequency or duration of chronic barbiturate treatment will increase the severity of the withdrawal syndrome that emerges when treatment is terminated. Because the most serious signs of barbiturate withdrawal can be life threatening, one approach that has been used to decrease barbiturate use while avoiding severe withdrawal signs has been to substitute an equivalent dose of a longer-acting barbiturate, such as phenobarbital, for the drug administered chronically [224]. The slow offset of the longer-acting drug results in the maintenance of more constant blood levels of the barbiturate, thereby preventing the emergence of severe withdrawal; the dose of phenobarbital can be slowly decreased over time until the individual can safely stop taking barbiturates altogether.

Although barbiturate abuse has declined over the last 40 years along with the decline of their clinical use, they have been abused more frequently than other central nervous system depressants except for alcohol. Some people abuse barbiturates exclusively. Often, use of barbiturates began when they were prescribed for the treatment of some disorder. With continued use and possibly escalating intake due to the development of tolerance, dependence also developed leading to the emergence of withdrawal when treatment was discontinued. These abusers continue to take barbiturates to avoid withdrawal, as opposed to taking the drug to treat the condition that prompted the initial use of barbiturates [57]. In contrast, other abusers take barbiturates in small doses, infrequently or for short periods so that dependence does not develop. These abusers often use barbiturates in combination with other drugs of abuse, including ethanol, opioids, and psychoactive stimulants.

Benzodiazepines

History

The history of the benzodiazepines is even shorter than that of the barbiturates. In the 1930s, Dr. Leo Sternbach was working on a chemical group called heptoxdiazines, which did not seem to have biological activity [130]. He moved from Poland to the United States to work for Hoffmann-LaRoche where he resumed his study of these compounds. In 1957, pharmacological effects, including sedative effects, were observed for one of his compounds (Ro#5-0690); the chemists later found that the compound had undergone a molecular rearrangement to become a 1,4-benzodiazepine [130]. Initially, the compound was called methaminodiazepoxide, although the name was later changed to chlordiazepoxide. The clinical effectiveness of chlordiazepoxide was not immediately evident. In fact, chlordiazepoxide was nearly discarded because a large dose was given to geriatric patients, resulting in ataxia [130]. Eventually, more appropriate doses were used and its clinical utility and safety were established. It was introduced in 1960 with the more successful benzodiazepine diazepam introduced in 1963. More than 3000 benzodiazepines have been synthesized, with as many as 35 in clinical use around the world. Because benzodiazepines have a larger margin of safety, as compared with the barbiturates, they quickly became the drugs of choice to reduce anxiety, promote sleep and reverse convulsions. They are still widely used today.

Chemical Properties

Benzodiazepine refers to the chemical structure of the drug, which has a benzene ring fused to a seven-member diazepine ring; benzodiazepines

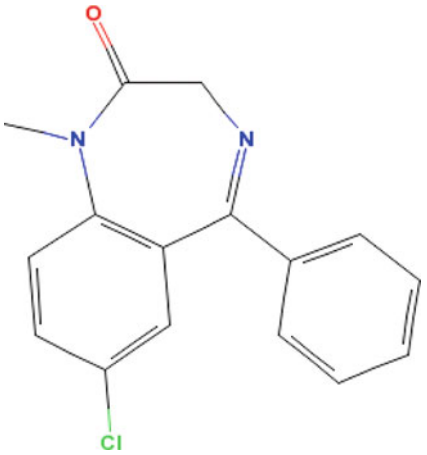

Fig. 12 Structure of diazepam. From http://pubchem.ncbi.nlm.nih.gov

that are used clinically have 1,4-diazepine rings [99]. Substituent groups at positions 1 and 3 can vary widely. Unlike diazepam (see Fig. 12), some benzodiazepines have triazolo (e.g., triazolam, alprazolam) or imidazolo (e.g., midazolam) rings fused at positions 1 and 2 [99]. Another drug with a fused imidazolo ring at positions 1 and 2 also has a methyl group at position 4 and a keto group replacing the ring at position 5; these structural variations dramatically change the pharmacology, resulting in the benzodiazepine antagonist flumazenil [99]. Like barbiturates, benzodiazepines have high lipid:water distribution coefficients; unfortunately, benzodiazepines do not form salts as readily as barbiturates. With exception of midazolam and chlordiazepoxide, which can form hydrochloride salts, benzodiazepines are insoluble in water.

Pharmacokinetics

Routes of Administration

Another similarity between barbiturates and benzodiazepines is that, within each class of compounds, the mechanism of action does not vary. Consequently, benzodiazepines are also generally classified according to their pharmacokinetics, specifically by their duration of action. Short-acting benzodiazepines generally have a half-life of minutes to a few hours; these drugs, which include midazolam, are primarily used for conscious sedation or the induction of anesthesia and are, therefore, available in commercially prepared solutions for intravenous administration. Intermediate-acting benzodiazepines, such as alprazolam or lorazepam, are used orally for anxiety and insomnia, although lorazepam is also available for parenteral administration primarily to reverse convulsions. Long-acting drugs, such as diazepam, are generally used orally.

Absorption and Distribution

The benzodiazepines that are currently used clinically are completely absorbed after oral administration. Once in the systemic circulation, they bind to plasma proteins with the extent of binding varying with lipid solubility from 70% for alprazolam to 99% for diazepam [99]. Redistribution can occur for drugs with the highest lipid solubility.

Metabolism/Excretion

Benzodiazepines are extensively metabolized by several hepatic microsomal systems. The most important aspect of the pharmacokinetics of benzodiazepines is the formation of active metabolites. Although a few benzodiazepines (e.g., lorazepam) are inactivated by the initial metabolic reaction, most are converted to metabolites that have the same mechanism of action as the parent compound. For some drugs, more than one biotransformation reaction is needed to inactivate the drug and often the subsequent reactions occur more slowly than the initial reaction. Consequently, the duration of action of most benzodiazepines has little to do with its half-life in plasma. The hepatic enzymes responsible for metabolism of benzodiazepines are not induced by chronic benzodiazepine treatment.

Pharmacodynamics

Mechanism of Action

Like barbiturates, benzodiazepines act at their own distinct sites on gamma-aminobutyric acid-A receptors where they facilitate the actions of gamma-aminobutyric acid [179]. One distinct difference between benzodiazepines and barbiturates is that benzodiazepines do not activate the channel directly and their actions are dependent on the presence of gamma-aminobutyric acid [92, 221]. Gamma-aminobutyric acid-A receptors are formed by 5 protein subunits which form the ion channel. Based on their amino acid sequence, several classes of subunits have been identified with multiple variants within each class [147]. The large number of subunits that can be combined to form gamma-aminobutyric acid-A receptor complexes indicates that many variations of this complex are possible. The subunit composition of gamma-aminobutyric acid-A receptors is clearly important in forming modulatory sites, particularly benzodiazepine sites. The gamma-aminobutyric acid-A receptor complex often includes 2α, 1β, and 2γ subunits. Benzodiazepine binding sites are formed when a γ_2 subunit is coexpressed with any α and any β [147] with the subtype of the α subunit conferring selectivity to benzodiazepine ligands [60]. Generally, 1,4-benzodiazepines bind with high affinity to benzodiazepine receptors containing an α_1, α_2, α_3, or α_5 subunit and do not bind, or bind with very low affinity, to receptors containing an α_4 subunits [147]. Three non-benzodiazepine drugs (zolpidem, zaleplon, and eszopiclone) have been introduced clinically in the last 15 years that are selective benzodiazepine receptors containing α_1 subunits and they have been used extensively in place of benzodiazepines for the treatment of insomnia.

Pharmacological Effects

The pharmacological effects of benzodiazepines are similar to those of the barbiturates; the primary effect is central nervous system depression. The most prominent effects of benzodiazepines are their anxiolytic, sedative, and anticonvulsant effects, although other therapeutic uses include their use as muscle relaxants or to induce anesthesia. In terms of clinical utility, benzodiazepines are similar to barbiturates in many ways. For example, drugs from these pharmacological classes promote sleep by decreasing sleep latency, the number of awakenings and the time spent in rapid-eye-movement and slow-wave sleep while increasing the time spent in stage 2 sleep [99]. One way in which drugs from these classes differ is their ability to relieve anxiety; the anxiolytic effects of benzodiazepines are evident at doses that do not produce sedation whereas doses of barbiturates that produce anxiolytic effects also produce sedation.

Toxicology

Benzodiazepines are relatively safe drugs. Although central nervous system depression by benzodiazepines results in decreased ventilation, these respiratory-depressant effects are mild. Even when the dose of benzodiazepines is increased, the effects on respiration are not severe enough to be life-threatening. From a clinical perspective, benzodiazepines are much safer than barbiturates because of differences in the severity of respiratory-depressant effects; this larger margin of safety of benzodiazepines has resulted in their widespread use and contributed to the decline of the clinical use of barbiturates. When administered alone, benzodiazepine overdose does not result in life-threatening respiratory depression; however, these effects can be exacerbated by other drugs. Ventilation can be dramatically decreased when benzodiazepines are administered in combination with ethanol, other positive gamma-aminobutyric acid-A modulators or drugs with primary mechanisms of action at receptors other than gamma-aminobutyric acid-A receptors, such as opioids.

Although overdose of benzodiazepines does not result in severe acute effects, their use is limited by other adverse effects, particularly by

effects that occur during chronic treatment. For example, the use of sedative doses of benzodiazepines for 2 weeks can result in the development of tolerance. Escalating intake to maintain the therapeutic effect can exacerbate the development of dependence. In order to avoid both phenomena, physicians generally limit the duration of benzodiazepine use to less than 2 weeks. Because drugs selective for benzodiazepine receptors containing α_1 subunits have sedative effects and are less likely to produce tolerance, the introduction of these drugs has led to a decline in the use of benzodiazepines for insomnia. Tolerance is less problematic when benzodiazepines are used for other indications, such as anxiety, because smaller doses are needed to produce the therapeutic effect and tolerance is less likely to develop under those treatment conditions.

Another consequence of long-term use of benzodiazepines is the development of dependence, and the signs and symptoms that emerge when benzodiazepine treatment is discontinued are similar to those that are evident following termination of barbiturate treatment. Like barbiturate withdrawal, signs and symptoms of benzodiazepine withdrawal can be separated into categories based on their severity. Minor withdrawal symptoms include increased anxiety, involuntary muscle twitches, tremor, progressive weakness, dizziness, visual illusions, nausea, insomnia, weight loss and orthostatic hypotension; major withdrawal symptoms include tonic-clonic seizures and psychosis resembling delirium tremens that occurs when alcohol use is discontinued [182]. More recently, the importance of other withdrawal symptoms, such as sleep disturbances, has been recognized [168, 199]. Although the signs and symptoms of withdrawal are similar for benzodiazepines and barbiturates, the time course for the development of dependence and the emergence of withdrawal varies slightly between these classes of drugs. Benzodiazepine dependence only becomes evident after long periods of treatment, often requiring 3 months or longer [255]. Moreover, because of the long duration of action of benzodiazepines and the formation of active metabolites, withdrawal might not emerge until 3–7 days after discontinuation of treatment. The availability of benzodiazepines with long durations of action increases the feasibility of using a drug with a slow offset to maintain more constant blood levels of a benzodiazepine while slowly reducing the dose. In this manner, benzodiazepine use can be decreased while avoiding the emergence of robust withdrawal.

Like other drugs that act at gamma-aminobutyric acid-A receptors, benzodiazepines are abused, and benzodiazepine abuse appears to be increasing. From 1992 to 2002, admissions for treatment of primary abuse of benzodiazepines increased 79%; during the same period, overall admissions for substance abuse treatment increased 22% (The Drug and Alcohol Services Information System Report, Substance Abuse and Mental Health Services Administration; available at http://www.oas.samhsa.gov/2k5/tranquilizerTX/tranquilizerTX.htm, 2005). Despite these recent increases, the incidence of primary benzodiazepine abuse remains low among the general population; however, benzodiazepine abuse is high in some groups, particularly among people who abuse other drugs. For example, the incidence of benzodiazepine use is high among opioid abusers [77, 88]. Dependence can develop during chronic benzodiazepine abuse, and the emergence of withdrawal can impact treatment outcome. Individuals sometimes prolong their drug use or abuse in order to avoid withdrawal, and relapse is common as they try to alleviate withdrawal symptoms [10]. For example, when treatment is discontinued in those using benzodiazepines for insomnia, the relapse rate is 43% [168]. Similarly, 50% of polydrug abusers experiencing withdrawal from large doses of benzodiazepines resume drug use within 2–3 days, with individuals describing extreme measures taken to avoid withdrawal [217]. Thus, emergence of benzodiazepine withdrawal could have severe consequences in drug abusers, possibly leading to increased abuse of benzodiazepines and other drugs.

Definitions Relevant to Animal Models

Drug addiction, also known as substance Dependence [6], is a chronically relapsing disorder characterized by (i) compulsion to seek and take the drug, (ii) loss of control in limiting intake, and as defined by the present author and others, (iii) emergence of a negative emotional state (e.g., dysphoria, anxiety, irritability) when access to the drug is prevented (defined here as dependence with a lowercase "d") [63, 107].

Drug addiction has been conceptualized as a disorder that involves elements of both impulsivity and compulsivity, in which impulsivity can be defined behaviorally as "a predisposition toward rapid, unplanned reactions to internal and external stimuli without regard for the negative consequences of these reactions to themselves or others" [81]. Compulsivity can be defined as elements of behavior that result in perseveration in responding in the face of adverse consequences or perseveration in the face of incorrect responses in choice situations. The compulsivity element is analogous to the symptoms of Substance Dependence outlined by the American Psychiatric Association (i.e., continued substance use despite knowledge of having had a persistent or recurrent physical or psychological problem and a great deal of time spent in activities necessary to obtain the substance) [6].

Collapsing the cycles of impulsivity and compulsivity yields a composite addiction cycle comprising three stages—preoccupation/

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_15,

anticipation (craving), binge/intoxication, and withdrawal/negative affect. Impulsivity often dominates at the early stages, and compulsivity dominates at terminal stages. As an individual moves from impulsivity to compulsivity, a shift occurs from positive reinforcement driving the motivated behavior to negative reinforcement driving the motivated behavior [57] (Fig. 1). Negative reinforcement can be defined as the process by which removal of an aversive stimulus (e.g., negative emotional state of drug withdrawal) increases the probability of a response (e.g., dependence-induced drug intake). These three stages are conceptualized as interacting with each other, becoming more intense, and ultimately leading to the pathological state known as addiction [63]. The present review will focus on the role of animal models of dependence associated with the negative emotional state of the withdrawal/negative affect stage of the addiction cycle (Fig. 1).

The diagnostic criteria for addiction described by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition [6] have evolved over the past 30 years, with a shift from the emphasis and necessary criteria of tolerance and withdrawal to other criteria directed more at compulsive use. In the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, tolerance and withdrawal form two of seven potential criteria. The criteria for substance Dependence closely resemble those outlined by the *International Statistical Classification of Diseases and Related Health Problems* [147]. The number of criteria met by individuals meeting the criteria for addiction vary with the severity of addiction, the stage of the addiction process, and the drug in question, but the criteria are well represented by symptoms that coalesce around the withdrawal/negative affect and preoccupation/anticipation stages [22, 24] (Fig. 1).

Unfortunately, the word "dependence" can have multiple meanings. Any drug, including non-abused drugs, can produce dependence if it is defined as the manifestation of a withdrawal syndrome upon cessation of drug use. However, meeting the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, criteria for substance Dependence is much more than a manifestation of a withdrawal syndrome; it is equivalent to addiction. For the purposes

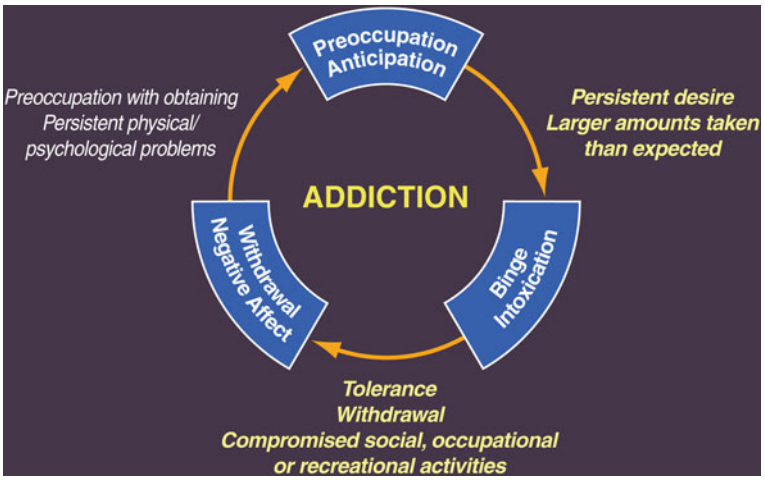

Fig. 1 Diagram describing the three stages of the addiction cycle—preoccupation/anticipation, binge/intoxication, and withdrawal/negative affect—from a psychiatric perspective with the different criteria for substance dependence incorporated from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. Bolded symptoms from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, reflect changes during the withdrawal/negative affect (tolerance, withdrawal, and compromised social, occupational, or recreational activities) stage and the increased motivation to take the drug as a result (persistent desire, larger amounts taken than expected). Reprinted with permission from [59] (American Psychiatric Publishing Inc.)

of this chapter, "dependence" with a lowercase "d" will refer to the manifestation of a withdrawal syndrome, whereas "Dependence" with a capital "D" will refer to substance dependence defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, or addiction. The terms "substance Dependence" (defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition), "addiction", and "alcoholism" will be held equivalent for this chapter.

Important for the present chapter is the distinction between physical or somatic signs of withdrawal and the motivational signs of withdrawal. Both reflect dependence with a lowercase "d," but only the motivational signs of withdrawal will be argued to be relevant to the syndrome of addiction (see discussion of somatic vs. motivational withdrawal below). Thus, although historically the diagnostic criteria have focused on physical (somatic) signs of withdrawal, more motivational signs have been neglected, and the argument of the present treatise is that motivational signs of withdrawal remain a critical aspect of the addiction process.

Different drugs produce different patterns of addiction with emphasis on different components of the addiction cycle. Probably the classic drugs of addiction are opioids. A pattern of intravenous or smoked drug taking evolves, including intense intoxication, the development of tolerance, escalation in intake, and profound dysphoria, physical discomfort, and somatic withdrawal signs during abstinence. Intense preoccupation with obtaining opioids (craving) develops that often precedes the somatic signs of withdrawal and is linked not only to stimuli associated with obtaining the drug but also to stimuli associated with withdrawal and internal and external states of stress. A pattern develops in which the drug must be obtained to avoid the severe dysphoria and discomfort of abstinence. Other drugs of abuse follow a similar pattern but may involve more the binge/intoxication stage (e.g., psychostimulants and alcohol) or less binge/intoxication and more withdrawal/negative affect and preoccupation/anticipation stages (e.g., nicotine and cannabinoids).

Animal Models of Withdrawal

Somatic Signs

Two drugs, opioids and alcohol, provide classic examples of the somatic signs of withdrawal and have served as models for measures of withdrawal per se. Indeed, as discussed above, these somatic measures are basically a "red herring" for the more motivational measures of withdrawal from the perspective of negative reinforcement, drug seeking, and craving associated with acute and protracted abstinence. However, the somatic signs of withdrawal are an index of dependence with a lowercase "d" and provide a quantifiable measure by which to assess the level of dependence and to relate to more motivational measures.

For opioids, somatic withdrawal signs in humans are dramatic, dose- and duration-of-abstinence-dependent, and include a number of overt measurable signs such as yawning, lacrimation, rhinorrhea, perspiration, gooseflesh, tremor, dilated pupils, anorexia, nausea, emesis, diarrhea, weight loss, and elevations in temperature and blood pressure [49]. In animals (rodents), opioid withdrawal signs are well characterized when precipitated with administration of a competitive opioid antagonist such as naloxone [36, 76]. A weighted scale was developed and widely adopted that included graded signs of weight loss, diarrhea, escape attempts, wet dog shakes, abdominal constrictions, facial fasciculations/teeth chattering, salivation, ptosis, abnormal posture, penile grooming/erection/ejaculation, and irritability [36] (Table 1). When the somatic signs of opioid withdrawal are directly compared with more motivational measures, the motivational measures are more sensitive and show more efficacy in defining the withdrawal state [112]. Spontaneous withdrawal shows many of the same signs, but they are significantly less intense [92].

For alcohol, the somatic signs of withdrawal in humans are equally dramatic but also life threatening and are characterized by tremor,

increases in heart rate, increases in blood pressure, increases in body temperature, anorexia, and convulsions. In its severest form, alcohol withdrawal can result in pronounced hyperthermia that can evolve into delirium tremens, a state of marked sympathetic hyperactivity, hyperthermia (which can be fatal), and hallucinations [40]. In animals (rodents), alcohol withdrawal signs are characterized by hyperactivity, tail tremors, tail stiffness, head tremors, general tremors, ventromedio-distal flexion, wet shakes, teeth chattering, akinesia, spastic rigidity, and induced and spontaneous convulsions [71] (Table 1). With alcohol, the withdrawal is only spontaneous because no known competitive antagonist can precipitate withdrawal. Similar to opioids, withdrawal from alcohol is dose- and duration-of-abstinence-dependent, with peak withdrawal ranging from 10 to 16 h with high-dose blood alcohol levels at the time of withdrawal (300–400 mg/dl) [71].

Table 1 Somatic withdrawal signs

Opioid withdrawal	
Rats	*Humans*
Weight loss	Weight loss
Diarrhea	Diarrhea
Escape attempts	Yawning
Wet dog shakes	Lacrimation
Abdominal constrictions	Rhinorrhea
Facial fasciculations	Perspiration
Teeth chattering	Gooseflesh
Salivation	Tremor
Ptosis	Dilated pupils
Abnormal posture	Anorexia
Penile grooming	Nausea
Erection/ejaculation	Emesis
Irritability	Hyperthermia
	Increased blood pressure

Alcohol withdrawal	
Rats	*Humans*
Hyperactivity	Tremor
Tail tremors	Increased heart rate
Tail stiffness	Increased blood pressure
Akinesia	Increased body temperature
Spastic rigidity	Anorexia
Convulsions	Convulsions
	Hyperthermia
	Delirium tremens

Motivational Signs

Animal models of the withdrawal/negative affect stage include increases in anxiety-like responses, measures of conditioned place aversion (rather than preference), and increases in reward thresholds using brain stimulation reward to precipitated withdrawal or spontaneous withdrawal from chronic administration of a drug [30, 34, 73, 94, 111, 112] (Table 2).

Anxiety-Like Symptoms

A common response to acute withdrawal and protracted abstinence from all major drugs of abuse is the manifestation of anxiety-like responses. Animal models have revealed anxiety-like responses to all major drugs of abuse during acute withdrawal, with the dependent variable often a passive response to a novel and/or aversive stimulus, such as the open field or elevated plus maze, or an active response to an aversive stimulus, such as defensive burying of an electrified metal probe. Withdrawal from repeated administration of cocaine produces an

Table 2 Animal models of the different stages of the addiction cycle

Stage of addiction cycle	Animal models
Binge/intoxication	• Drug/alcohol self-administration • Conditioned place preference • Brain stimulation reward thresholds • Increased motivation for self-administration in dependent animals
Withdrawal/negative affect	• Anxiety-like responses • Conditioned place aversion • Withdrawal-induced drug self-administration
Preoccupation/anticipation	• Drug-induced reinstatement • Cue-inducedreinstatement • Stress-induced reinstatement

anxiogenic-like response in the elevated plus maze and defensive burying test, both of which are reversed by administration of corticotropin-releasing factor antagonists [13, 109] (Fig. 2). Precipitated withdrawal in opioid dependence and nicotine dependence also produces anxiety-like effects [37, 44, 113]. Spontaneous ethanol withdrawal produces anxiety-like behavior [11, 19, 55, 91, 96, 127, 129].

Dysphoria-Like Symptoms

Place aversion has been used to measure the aversive stimulus effects of withdrawal, mostly in the context of opioids [43, 123] (Fig. 3). In contrast to conditioned place preference, rats exposed to a particular environment while undergoing precipitated withdrawal from opioids spend less time in the withdrawal-paired environment when subsequently presented with a choice between that environment and an unpaired environment. Such an association continues to be manifested weeks after animals are "detoxified" (e.g., after the morphine pellets are removed [10, 122]) and can be measured from 24 h to 16 weeks later [43, 122, 123]. Additionally, a place aversion in opioid-dependent rats can be observed with doses of naloxone below which somatic signs of withdrawal are observed [112]. Although naloxone itself will produce a place aversion in non-dependent rats, the threshold dose required to produce a place aversion decreases significantly in dependent rats [43].

The place aversion to opioids does not require maintenance of opioid dependence for its manifestation, and a variation of this approach is to explore the place aversion produced following naloxone injection after a single acute injection of morphine. Acute opioid dependence has been defined as the precipitation of withdrawal-like signs by opioid antagonists following a single opioid dose or short-term administration of an opioid agonist [75]. Rats show a reliable conditioned place aversion precipitated by a low dose of naloxone after a single morphine injection

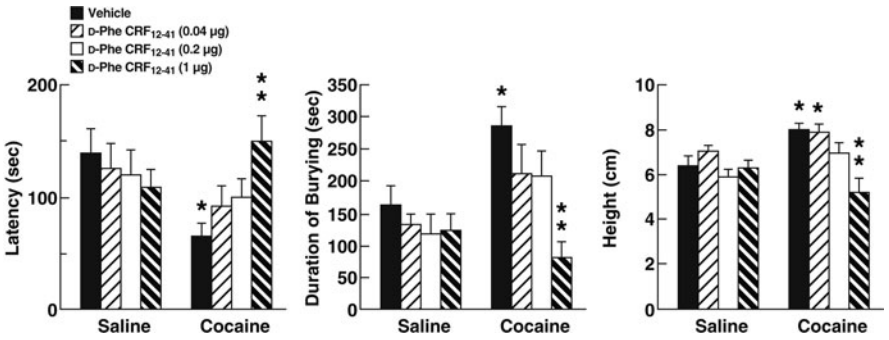

Fig. 2 Effect of intracerebroventricular administration of the corticotropin-releasing factor (CRF) antagonist D-Phe $CRF_{12–41}$ on anxiogenic-like effects in the defensive burying paradigm following chronic cocaine administration. Rats received chronic cocaine (20 mg/kg, intraperitoneally, for 14 days) or saline (1 ml/kg, intraperitoneally). Animals then were tested in the defensive burying paradigm 48 h after the last injection. D-Phe $CRF_{12–41}$ (0, 0.04, 0.2, and 1.0 mg/5 ml) was administered immediately after the animal touched the electrified probe and received the shock and 5 min before the testing session. Data are expressed as mean ± SEM (n = 10–14/group). The left panel shows the latency to start burying (in seconds) for all experimental groups ($^{*}p < 0.05$, compared with saline/vehicle group; $^{**}p < 0.01$, compared with cocaine/vehicle group; Duncan post hoc test). The middle panel represents the total duration of burying behavior expressed in seconds for all experimental groups ($^{*}p < 0.05$, compared with chronically saline-treated groups; $^{**}p < 0.01$, compared with cocaine/vehicle group; Duncan post hoc analysis). The right panel represents the height of bedding material, expressed in centimeters, at the junction between the probe and the wall of the testing cage ($^{*}p < 0.05$, compared with saline/vehicle group; $^{**}p < 0.01$, compared with other chronically cocaine-treated groups; Duncan post hoc analysis). Reprinted with permission from [13] (Springer Science+Business Media)

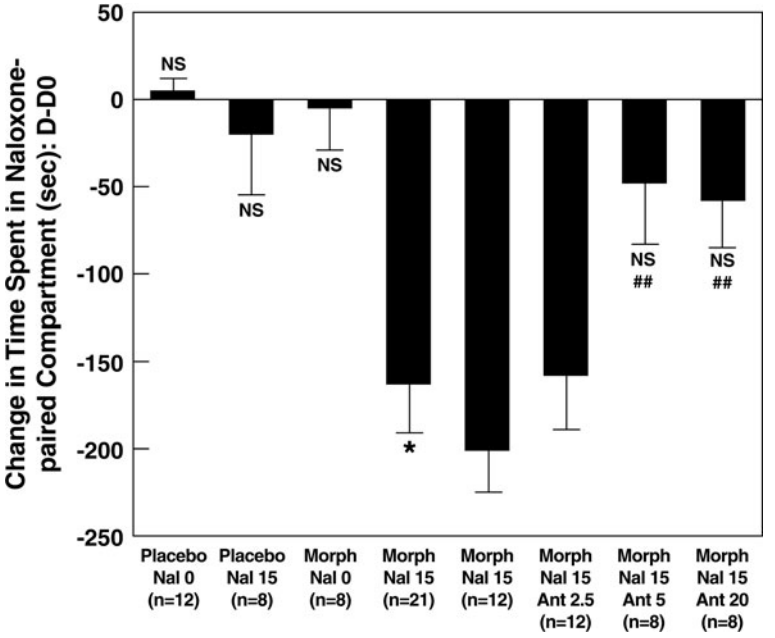

Fig. 3 The corticotropin-releasing factor −1 antagonist antalarmin (Ant) reduced naloxone (NAL)-precipitated place aversion conditioning in morphine (Morph)-dependent rats. Morphine dependence was induced by subcutaneous implantation of two slow-release, morphine-containing pellets, each containing 75 mg of morphine base. Placebo-pelleted rats received placebo morphine pellets also implanted subcutaneously. Separate groups of morphine-dependent rats that received naloxone (15 μg/kg, subcutaneously) immediately prior to conditioning (Morph-Nal) were also injected 30 min before naloxone on days 6, 8, and 10 with antalarmin (2.5, 5, 10, or 20 mg/kg, intraperitoneally; $n = 8$–12/group). Although antalarmin at doses of 2.5 and 5 mg/kg was ineffective, doses of 10 and 20 mg/kg blocked the place aversion produced by naloxone in morphine-dependent rats and returned values to levels observed with naloxone in placebo-pelleted rats and in morphine-without naloxone (Morph-Nal 0) rats. $^{*}p < 0.05$, within each dose group treatment, Wilcoxon signed-ranks test. NS refers to no significant place preference or place aversion with the Wilcoxon signed-ranks test. $^{\#\#}p < 0.01$, compared with Morph-Nal 15 group; between-group comparisons, Mann-Whitney test (ΔD). Reprinted with permission from [121]

that reflects a motivational component of acute withdrawal [9]. Similar acute withdrawal-like effects have been observed using anxiety-like responses following bolus injections of ethanol [148].

Reward Thresholds

Electrical brain stimulation reward or intracranial self-stimulation has a long history as a measure of activity of the brain reward system and of the acute reinforcing effects of drugs of abuse. All drugs of abuse, when administered acutely, decrease brain reward thresholds [68]. Brain stimulation reward involves widespread neurocircuitry in the brain, but the most sensitive sites defined by the lowest thresholds involve the trajectory of the medial forebrain bundle that connects the ventral tegmental area with the basal forebrain [88]. Although much emphasis was focused initially on the role of the ascending monoamine systems in the medial forebrain bundle, other non-dopaminergic, descending systems in the medial forebrain bundle clearly have a key role [47].

Acute intravenous cocaine self-administration in animals reduces reward thresholds, consistent with the well-documented effects of drugs of abuse in lowering brain reward thresholds [51]. However, with more prolonged access to the drug, the decreases in reward thresholds (i.e., rewarding effects) are replaced with elevations in reward threshold (i.e., anti-rewarding effects) after the initial decrease in reward thresholds,

presumably reflecting an acute withdrawal or opponent process-like effect. Such elevations in reward threshold begin rapidly, can be observed within a single session of self-administration, and are greater with greater exposure to cocaine [53], bearing a striking resemblance to human subjective reports [20, 130]. Chronic administration or self-administration of all drugs of abuse produces elevations in reward thresholds during spontaneous or precipitated acute withdrawal (Fig. 4). These elevations in threshold can be short (minutes to hours) or can last for days, depending on dose, drug, time of exposure, and precipitant.

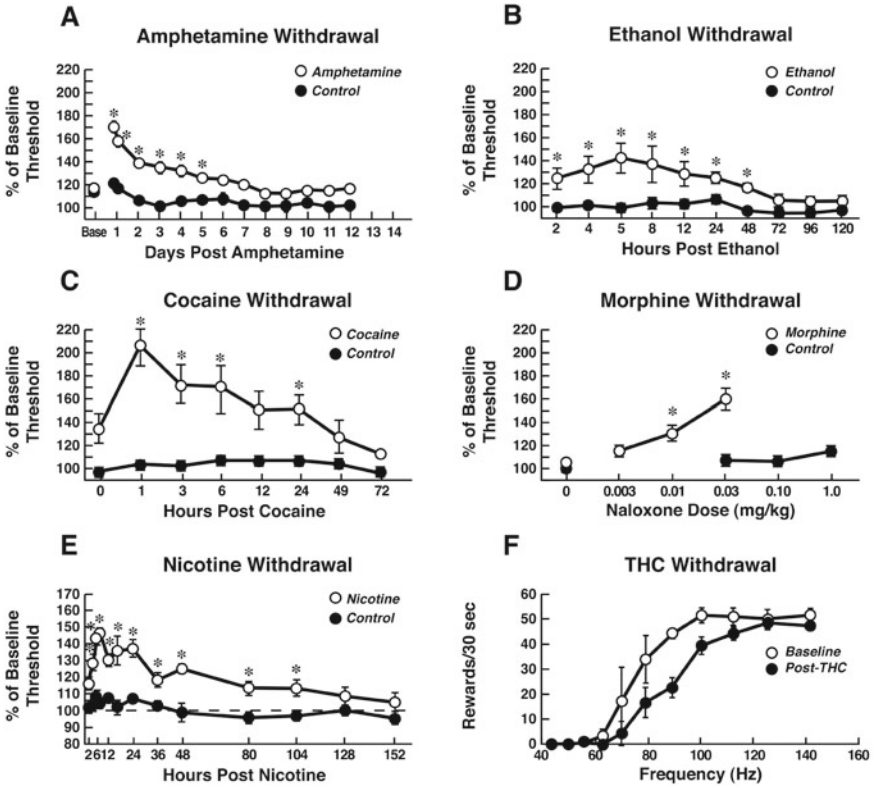

Fig. 4 (**A**) Mean intracranial self-stimulation reward thresholds (± SEM) in rats during amphetamine withdrawal (10 mg/kg/day for 6 days). Data are expressed as a percentage of the mean of the last five baseline values prior to drug treatment. $^{*}p < 0.05$, compared with saline control group. Reprinted with permission from [94] (Springer Science+Business Media). (**B**) Mean intracranial self-stimulation thresholds (± SEM) in rats during ethanol withdrawal (blood alcohol levels achieved: 197.29 mg%). Elevations in thresholds were time-dependent. $^{*}p < 0.05$, compared with control group. Reprinted with permission from [111]. (**C**) Mean intracranial self-stimulation thresholds (± SEM) in rats during cocaine withdrawal 24 h following cessation of cocaine self-administration. $^{*}p < 0.05$, compared with control group. Reprinted with permission from [73]. (**D**) Mean intracranial self-stimulation thresholds (± SEM) in rats during naloxone-precipitated morphine withdrawal. The minimum dose of naloxone that elevated intracranial self-stimulation thresholds in the morphine group was 0.01 mg/kg. $^{*}p < 0.05$, compared with control group. Reprinted with permission from [112]. (**E**) Mean intracranial self-stimulation thresholds (± SEM) in rats during spontaneous nicotine withdrawal following surgical removal of osmotic minipumps delivering nicotine hydrogen tartrate (9 mg/kg/day) or saline. $^{*}p < 0.05$, compared with control group. Data adapted from [30]. (**F**) Mean intracranial self-stimulation thresholds (± SEM) in rats during withdrawal from an acute 1.0-mg/kg dose of Δ^9-tetrahydrocannabinol (THC). Withdrawal significantly shifted the reward function to the right (indicating diminished reward). Reprinted with permission from [34] (Elsevier). Note that because different equipment systems and threshold procedures were used in the collection of the above data, direct comparisons among the magnitude of effects induced by these drugs cannot be made

Animal Models of Increased Drug Taking During Dependence

Escalation in Drug Self-Administration with Prolonged Access

A progressive increase in the frequency and intensity of drug use is one of the major behavioral phenomena characterizing the development of addiction and has face validity with the criteria of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition: "The substance is often taken in larger amounts and over a longer period than was intended" [6]. A framework with which to model the transition from drug use to drug addiction can be found in recent animal models of prolonged access to intravenous cocaine self-administration. Historically, animal models of cocaine self-administration involved the establishment of stable behavior from day to day to allow the reliable interpretation of data provided by within-subject designs aimed at exploring the neuropharmacological and neurobiological bases of the reinforcing effects of acute cocaine. Until 1998, after acquisition of self-administration, rats typically were allowed access to cocaine for 3 h or less per day to establish highly stable levels of intake and stable patterns of responding between daily sessions. This was a useful paradigm for exploring the neurobiological substrates for the acute reinforcing effects of drugs of abuse.

However, in an effort to explore the effects of differential access to intravenous cocaine self-administration on cocaine-seeking in rats, rats were allowed access to intravenous cocaine self-administration for 1 or 6 h per day [2]. One-hour access (short access) to intravenous cocaine per session produced low and stable intake as observed previously. In contrast, 6-h access (long access) to cocaine produced drug intake that gradually escalated over days (Fig. 5). Increased intake was observed in the extended-access group during the first hour of the session, with sustained intake over the entire session and an upward shift in the dose-effect function, suggesting an increase in hedonic set point. When animals were allowed access to different doses of cocaine, both the long- and short-access animals titrated their cocaine intake, but the long-access rats consistently self-administered almost twice as much cocaine at any dose tested, further suggesting an upward shift in the set point for cocaine reward in the escalated animals [3, 27, 72]. Such increased self-administration in dependent animals has now been observed with cocaine, methamphetamine, nicotine, heroin, and alcohol [2, 4, 37, 54, 87] (Fig. 5). This model is a key element for evaluating the motivational significance of changes in the brain reward and stress systems in addiction that lead to compulsivity in addiction. Similar changes in the reinforcing and incentive effects of cocaine have been observed following extended access and include increased cocaine-induced reinstatement after extinction and decreased latency to goal time in a runway model for cocaine reward [26]. Altogether, these results suggest that drug taking with extended access changes the motivation to seek the drug. Whether this enhanced drug taking reflects a sensitization of reward or a reward deficit state remains under discussion [132], but the brain reward and neuropharmacological studies outlined below argue for a reward deficit state driving the increased drug taking during extended access.

Withdrawal-Induced Drinking

Historically, animal models for the negative reinforcement associated with ethanol dependence have proven difficult, especially with rodents. Induction of physical dependence could enhance preference for ethanol [28, 29, 50, 101, 108, 110, 131, 146], but other reports did not support enhanced preference for ethanol in dependent animals [17, 82, 145]. Recently, reliable and useful models of ethanol consumption in dependent rats and mice have been developed in several laboratories. For example, in a major advance, ethanol first was established as a reinforcer, and then the animals were made dependent. The

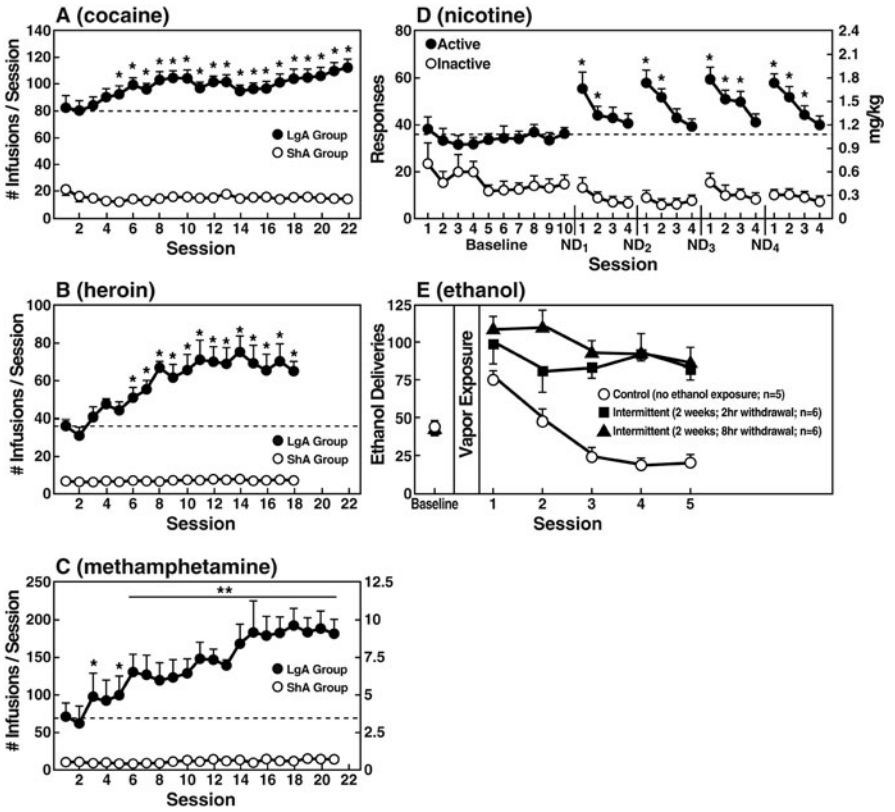

Fig. 5 (**A**) Effect of drug availability on cocaine intake (mean ± SEM). In long-access (LgA) rats ($n = 12$) but not in short-access (ShA) rats ($n = 12$), mean total cocaine intake started to increase significantly from session 5 ($p < 0.05$; sessions 5 to 22 compared with session 1) and continued to increase thereafter ($p < 0.05$; session 5 compared with sessions 8–10, 12, 13, 17–22). Reprinted with permission from [2] (American Association for the Advancement of Science). (**B**) Effect of drug availability on total intravenous heroin self-infusions (mean ± SEM). During the escalation phase, rats had access to heroin (40 mg per infusion) for 1 h (ShA rats, $n = 5$–6) or 11 h per session (LgA rats, $n = 5$–6). Regular 1-h (ShA rats) or 11-h (LgA rats) sessions of heroin self-administration were performed 6 days per week. The *dotted line* indicates the mean (± SEM) number of heroin self-infusions of LgA rats during the first 11-h session. $^{*}p < 0.05$ compared with first session (paired *t*-test). Reprinted with permission from [4]. (**C**) Effect of extended access to intravenous methamphetamine self-administration as a function of daily sessions in rats trained to self-administer 0.05-mg/kg/infusion of intravenous methamphetamine during a 6-h session. Short-access group (ShA), 1-h session ($n = 6$). Long-access group (LgA), 6-h session ($n = 4$). All data were analyzed using two-way analysis of variance (dose × escalation session within ShA or LgA group). $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, vs. Day 1. Reprinted with permission from [54] (Springer Science+Business Media). (**D**) Total 23-h active and inactive responses after repeated cycles of 72 h of nicotine deprivation (ND) followed by 4 days of self-administration ($^{*}p < 0.05$ vs. baseline). Reprinted with permission from [37]. (**E**) Ethanol deliveries (mean ± SEM) in rats trained to respond for 10% ethanol and then either not exposed to ethanol vapor (control, $n = 5$) or exposed to intermittent ethanol vapor (14 h on/10 h off) for 2 weeks and then tested either 2 h ($n = 6$) or 8 h ($n = 6$) after removal from ethanol vapor. $^{*}p < 0.05$, significant increase in operant self-administration of ethanol in rats receiving intermittent vapor exposure compared with control. No difference was observed between rats exposed to intermittent vapor and tested either 2 or 8 h after ethanol withdrawal. Reprinted with permission from [87] (Wiley)

animals were maintained through liquid diet or continuous alcohol vapor exposure at blood alcohol levels that produced mild-to-moderate physical withdrawal symptoms when the ethanol was removed, but significant motivational signs measured by changes in brain stimulation reward during acute withdrawal from ethanol were observed [111]. Therefore, any somatic

withdrawal symptoms that the rats experienced would be predictably quite mild and would not be expected to physically interfere with their ability to respond. Animals showed reliable increases in self-administration of ethanol during withdrawal in which the amount of intake approximately doubled and the animals had blood alcohol levels from 0.10 to 0.15 gm% after 12 h of self-administration [101].

Further development of this model showed that animals exposed intermittently (14 h on/10 h off) to the same amount of ethanol as continuously exposed animals showed even more dramatic increases in self-administration during acute withdrawal [87] (Fig. 5). Systematic exploration of the parameters that determine the maximum increase in ethanol self-administration and blood alcohol levels showed that animals exposed to intermittent ethanol via alcohol vapor chambers developed dependence more rapidly [87]. The intermittent paradigm has produced dependent animals that achieved blood alcohol levels of 0.15 gm% in a 30-min session [97] and display increased responding on a progressive-ratio schedule, indicative of increased motivation to consume alcohol [136].

Relapse, or the return to alcohol abuse following periods of abstinence, is one of the principle characteristics of substance dependence on alcohol. The development of dependence has been suggested to play an important role in the maintenance of compulsive use and relapse following periods of abstinence.

In human alcoholics, numerous symptoms that can be characterized by negative emotional states persist long after acute physical withdrawal from ethanol. Fatigue and tension have been reported to persist up to 5 weeks post-withdrawal [5]. Anxiety has been shown to persist up to 9 months [105], and anxiety and depression have been shown to persist in up to 20–25% of alcoholics for up to 2 years post-withdrawal. These symptoms, post-acute withdrawal, tend to be affective in nature and subacute and often precede relapse [7, 48]. A factor analysis of Marlatt's relapse taxonomy found that negative emotion, including elements of anger, frustration, sadness, anxiety, and guilt, was a key factor in relapse [149], and the leading precipitant of relapse in a large-scale replication of Marlatt's taxonomy was negative affect [70]. In secondary analyses of participants in a 12-week clinical trial with alcohol dependence and not meeting criteria for any other *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, mood disorder, the association with relapse and a subclinical negative affective state was particularly strong [78]. This state has been termed "protracted abstinence" and has been defined in humans as showing a Hamilton Depression rating $\geq$8 with the following three items consistently reported by subjects: depressed mood, anxiety, and guilt [78].

Animal work has shown that prior dependence lowers the "dependence threshold" such that previously dependent animals made dependent again display more severe physical and motivational withdrawal symptoms than groups receiving alcohol for the first time [14, 15, 18, 19]. This supports the hypothesis that alcohol experience and the development of dependence in particular can lead to relatively permanent alterations in responsiveness to alcohol. However, relapse often occurs even after physical withdrawal signs have ceased, suggesting that the neurochemical changes that occur during the development of dependence can persist beyond the final overt signs of withdrawal ("motivational withdrawal syndrome").

A history of dependence in male Wistar rats can produce a prolonged elevation in ethanol self-administration in daily 30-min sessions after acute withdrawal and detoxification [99, 100, 102, 117]. This increase in self-administration of ethanol is accompanied by increases in blood alcohol levels and persists for up to 8 weeks post-detoxification. The increase in self-administration is also accompanied by increased behavioral responsivity to stressors and increased responsivity to antagonists of the brain corticotropin-releasing factor systems [35, 117, 129]. The persistent increase in ethanol self-administration has been hypothesized to involve an allostatic-like adjustment such that the set point for ethanol reward is elevated [64, 102]. These persistent alterations

in ethanol self-administration and residual sensitivity to stressors can be arbitrarily defined as a state of "protracted abstinence." Protracted abstinence defined as such in the rat spans a period after acute physical withdrawal has disappeared when elevations in ethanol intake over baseline and increased behavioral responsivity to stress persist (2–8 weeks post-withdrawal from chronic ethanol).

Significant self-administration of high amounts of ethanol similar to those observed in alcohol-preferring animals and during protracted abstinence has been observed using other methods. Here, the animals showed tolerance but no somatic withdrawal; motivational withdrawal has not yet been evaluated. Rats that receive passive intragastric infusion of ethanol for 3–6 days at levels observed in ethanol-preferring strains (3.3–12.2 g/kg/d) and are allowed access to intragastric self-infusion maintained high levels of ethanol self-administration (4–7 g/kg/d) [31]. Intermittent access to 20% ethanol (three 24-h sessions per week for 6 weeks) using a two-bottle choice procedure induced high ethanol consumption in rats to levels up to 5–6 g/kg/d [116]. However, blood alcohol levels in 30-min two-bottle choice sessions in the intermittent 20% animals were significantly lower (averaging approximately 60 mg% in Wistar rats) than those observed in dependent animals (see above).

Motivational Changes Associated with Increased Drug Intake During Dependence

The hypothesis that compulsive drug use is accompanied by a chronic perturbation in brain reward homeostasis has been tested in an animal model of escalation in drug intake with prolonged access combined with measures of brain stimulation reward thresholds. Animals implanted with intravenous catheters and allowed differential access to intravenous self-administration of cocaine or heroin showed increases in drug self-administration from day to day in the long-access group but not in the short-access group. The differential exposure to drug self-administration had dramatic effects on reward thresholds that progressively increased in long-access rats but not in short-access or control rats across successive self-administration sessions [1, 52] (Fig. 6). Elevation in baseline reward thresholds temporally preceded and was highly correlated with escalation in cocaine intake. Post-session elevations in reward thresholds failed to return to baseline levels before the onset of each subsequent self-administration session, thereby deviating more and more from control levels. The progressive elevation in reward thresholds was associated with the dramatic escalation in cocaine consumption that was observed previously. After escalation had occurred, an acute cocaine challenge facilitated brain reward responsiveness to the same degree as before but resulted in higher absolute brain reward thresholds in long-access compared with short-access rats [1]. Similar results have been observed with extended access to heroin [52] in which rats allowed 23-h access to heroin showed a time-dependent increase in reward thresholds that paralleled the increases in heroin intake (Fig. 6).

Another reflection of the change in motivation associated with dependence is a measure of reinforcement efficacy measured by changes in progressive-ratio responding. In the progressive-ratio procedure, rats are allowed to reach baseline responding for cocaine under a fixed-ratio 1 schedule of reinforcement. For a progressive-ratio schedule, the response requirement (i.e., the number of lever responses required to receive a drug injection, or "ratio") increases using an exponential function, such as $5^{(0.2 \cdot \text{infusion number})} - 5$, yielding response requirements of 1, 2, 4, 6, 9, 12, 15, 20, 25, 32, 40, 50, 62, 77, 95, 118, 146, 178, 219, 268, etc. [103]. Sessions on this schedule are terminated when more than three-times the animal's longest baseline inter-response time has elapsed since the last self-administered cocaine injection [16]. Animals normally respond for 11–15 injections of cocaine, and the breakpoint is defined as

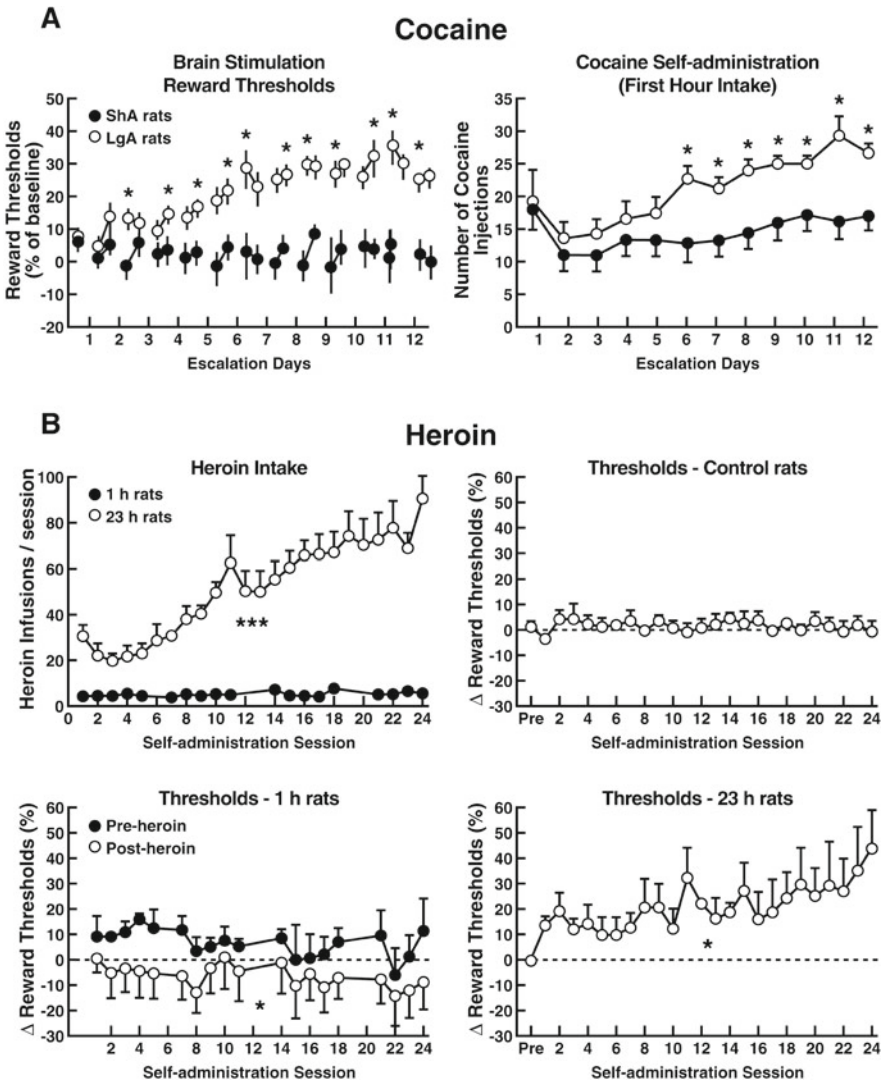

Fig. 6 (**A**) Relationship between elevation in intracranial self-stimulation reward thresholds and cocaine intake escalation in short-access (1-h, ShA) and long-access (6-h, LgA) rats. (*Left*) Percent change from baseline intracranial self-stimulation thresholds. (*Right*) Number of cocaine injections earned during the first hour of each session. $^{*}p < 0.05$, compared with drug-naive and/or ShA rats, tests of simple main effects. Reprinted with permission from [1]. (**B**) Unlimited daily access to heroin escalated heroin intake and decreased the excitability of brain reward systems. (*Top left*) Heroin intake (20 μg per infusion) in rats during limited (1-h) or unlimited (23-h) self-administration sessions. $^{***}p < 0.001$, main effect of access (1 or 23 h; two-way, repeated-measures analysis of variance). (*Top right*) Percent change from baseline intracranial self-stimulation thresholds in control rats that remained heroin-naive for the duration of the experiment and had intracranial self-stimulation thresholds assessed at the same time-points as the 23-h rats. (*Bottom left*) Percent change from baseline intracranial self-stimulation thresholds in 1-h rats. Daily post-thresholds assessed immediately after each heroin self-administration session were lowered compared with pre-thresholds assessed immediately before each self-administration session in 1-h rats. $^{*}p < 0.05$, main effect of heroin on reward thresholds (two-way, repeated-measures analysis of variance). (*Bottom right*) Percent change from baseline intracranial self-stimulation thresholds in 23-h rats. Reward thresholds assessed immediately after each daily 23-h self-administration session became progressively more elevated as exposure to self-administered heroin increased across sessions. $^{*}p < 0.05$, main effect of heroin on reward thresholds (two-way, repeated-measures analysis of variance). Reprinted with permission from [52]

the highest completed ratio in a session. The dependent measure in the progressive-ratio experiments is the total number of injections obtained per session and the breakpoint. Extended access to drugs resulting in escalation also is associated with an increase in breakpoint for cocaine in a progressive-ratio schedule, suggesting an enhanced motivation to seek cocaine or an enhanced efficacy of cocaine reward [93, 140]. Similar results have been observed with methamphetamine and withdrawal-induced drinking in rats made dependent with ethanol vapor [136] (Fig. 7).

Neurobiological Bases of Increased Drug Taking During Dependence

In a within-system adaptation, repeated drug administration elicits an opposing reaction within the same system in which the drug elicits its primary reinforcing actions. For example, if the synaptic availability of the neurotransmitter dopamine is responsible for the acute reinforcing actions of cocaine, then the within-system opponent process neuroadaptation would be a decrease in synaptic availability of dopamine.

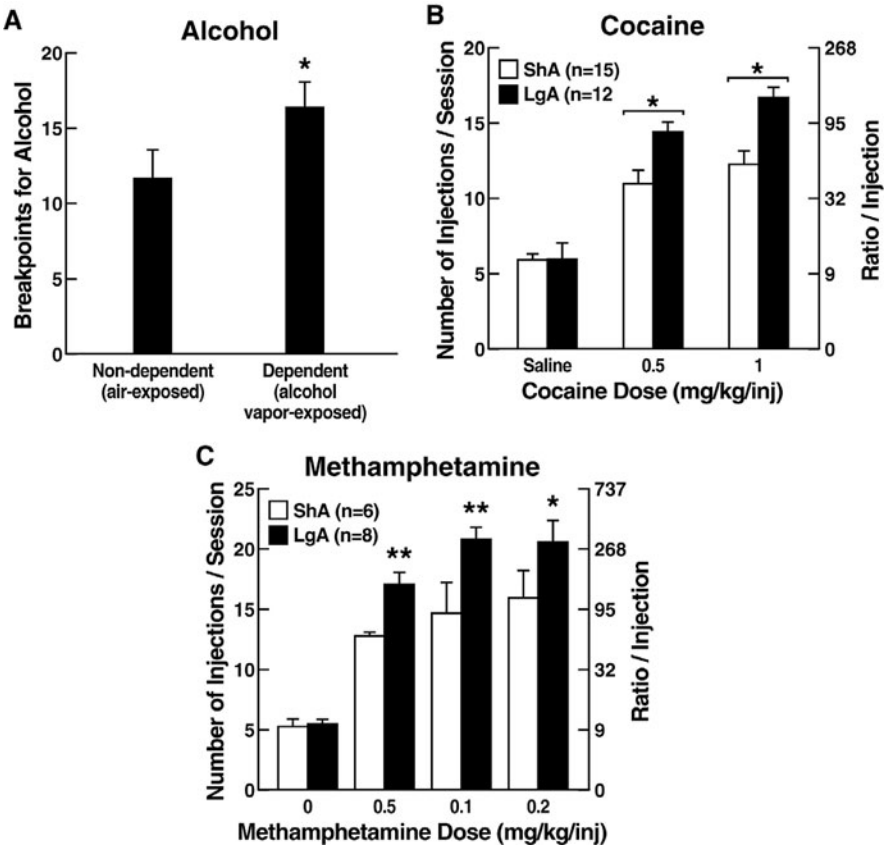

Fig. 7 (**A**) Breakpoints for responding for alcohol in dependent and non-dependent rats. $^{**}p < 0.01$, significant effect of alcohol exposure. Reprinted with permission from [136] (Wiley). (**B**) Dose-response function of cocaine responding under a progressive-ratio schedule of reinforcement in short-access (1-h, ShA) and long-access (6-h, LgA) rats. Test sessions ended when rats did not achieve reinforcement within 1 h. Data are expressed as the number of injections/session on the left axis and the ratio per injection (inj) on the right axis. $^{*}p < 0.05$, compared with ShA at each dose tested. Reprinted with permission from [140] (Elsevier). (**C**) Dose-response function of methamphetamine responding under a progressive-ratio schedule of reinforcement in short-access (1-h, ShA) and long-access (6-h, LgA) rats. Test sessions ended when rats did not achieve reinforcement within 1 h. Data are expressed as the number of injections/session on the left axis and the ratio per injection on the right axis. $^{*}p < 0.05$, $^{**}p < 0.01$, compared with ShA at each dose tested. Reprinted with permission from [141]

In a between-system adaptation, repeated drug administration recruits a different neurochemical system, one not involved in the acute reinforcing effects of the drug but that when activated or engaged acts in opposition to the primary reinforcing effects of the drug. For example, chronic cocaine may activate the neuropeptide dynorphin, and dynorphin produces dysphoria-like effects that would be opposite to those of dopamine.

Within-System Changes: Dopamine

Within-system neuroadaptations to chronic drug exposure include decreases in function of the same neurotransmitter systems in the same neurocircuits implicated in the acute reinforcing effects of drugs of abuse during drug withdrawal in animal studies. Decreases in activity of the mesolimbic dopamine system and decreases in serotonergic neurotransmission in the nucleus accumbens are well documented [79, 106, 143, 144]. Imaging studies in drug-addicted humans have consistently shown long-lasting decreases in the numbers of dopamine D_2 receptors in drug abusers compared with controls [134]. Additionally, cocaine abusers have reduced dopamine release in response to a pharmacological challenge with a stimulant drug [77, 135]. Decreases in the number of dopamine D_2 receptors, coupled with the decrease in dopaminergic activity, in cocaine, nicotine, and alcohol abusers results in decreased sensitivity of reward circuits to stimulation by natural reinforcers [74, 133]. These findings suggest an overall reduction in the sensitivity of the dopamine component of reward circuitry to natural reinforcers and other drugs in drug-addicted individuals.

Psychostimulant withdrawal in humans is associated with fatigue, decreased mood, and psychomotor retardation and in animals is associated with decreased motivation to work for natural rewards [12] and decreased locomotor activity [95], behavioral effects that may involve decreased dopaminergic function. Animals during amphetamine withdrawal show decreased responding on a progressive-ratio schedule for a sweet solution, and this decreased responding was reversed by the dopamine partial agonist terguride [12, 90], suggesting that low dopamine tone contributes to the motivational deficits associated with psychostimulant withdrawal.

Under this conceptual framework, other within-system neuroadaptations would induce increased sensitivity of receptor transduction mechanisms in the nucleus accumbens. Activation of adenylate cyclase, protein kinase A, cyclic adenosine monophosphate response-element binding protein, and ΔFosB has been observed during drug withdrawal [84, 86, 114, 115]. The ΔFosB response is hypothesized to represent a neuroadaptive change that extends long into protracted abstinence [85].

Between-System Changes: Role of Corticotropin-Releasing Factor

A prominent role for activation of brain stress systems in acute withdrawal and protracted abstinence has been established [58]. Corticotropin-releasing factor, norepinephrine, and dynorphin all have been shown to be activated by withdrawal from drugs of abuse. Perhaps the most compelling data derive from studies of the extrahypothalamic corticotropin-releasing factor system. Corticotropin-releasing factor controls hormonal and behavioral responses to stressors, but the extrahypothalamic corticotropin-releasing factor system is hypothesized to mediate behavioral responses to stressors [45]. Small molecule corticotropin-releasing factor−1 antagonists [55, 91] and intracerebral administration of a peptidergic corticotropin-releasing factor−1/corticotropin-releasing factor−2 antagonist into the amygdala [96] blocked the anxiety-like behavior induced by acute ethanol withdrawal. Corticotropin-releasing factor antagonists injected intracerebroventricularly or systemically also block the potentiated anxiety-like

responses to stressors observed during protracted abstinence from chronic ethanol [19, 129]. The effects of corticotropin-releasing factor antagonists have been localized to the central nucleus of the amygdala [96]. Precipitated withdrawal from nicotine produces anxiety-like responses that are also reversed by corticotropin-releasing factor antagonists [37, 127].

Using the conditioned place aversion paradigm, the opioid partial agonist buprenorphine dose-dependently decreased the place aversion produced by precipitated opioid withdrawal. Systemic administration of a corticotropin-releasing factor−1 receptor antagonist and direct intracerebral administration of a peptide corticotropin-releasing factor−1/corticotropin-releasing factor−2 antagonist also decreased opioid withdrawal-induced place aversions [46, 121]. Functional noradrenergic antagonists also blocked opioid withdrawal-induced place aversion [25].

The ability of corticotropin-releasing factor antagonists to block the anxiogenic-like and aversive-like motivational effects of drug withdrawal would predict motivational effects of corticotropin-releasing factor antagonists in animal models of extended access to drugs (Table 3). Corticotropin-releasing factor antagonists selectively blocked the increased self-administration of drugs associated with extended access to intravenous self-administration of cocaine [119], nicotine [37], and heroin [41].

A particularly dramatic example of the motivational effects of corticotropin-releasing factor in dependence can be observed in animal models of ethanol self-administration in dependent animals. During ethanol withdrawal, extrahypothalamic corticotropin-releasing factor systems become hyperactive, with an increase in extracellular corticotropin-releasing factor within the central nucleus of the amygdala and bed nucleus of the stria terminalis of dependent rats [32, 80, 89]. The dysregulation of brain corticotropin-releasing factor systems is hypothesized to underlie not only the enhanced anxiety-like behaviors but also the enhanced ethanol self-administration associated with ethanol withdrawal.

Supporting this hypothesis, exposure to repeated cycles of chronic ethanol vapor produced substantial increases in ethanol intake in rats both during acute withdrawal and during protracted abstinence (2 weeks post-acute withdrawal) [87, 99]. The subtype non-selective corticotropin-releasing factor receptor antagonists α-helical corticotropin-releasing factor$_{9–41}$ and D-Phe corticotropin-releasing factor$_{12–41}$ (intracerebroventricular administration) reduced ethanol self-administration in dependent and post-dependent animals [117, 128]. When administered directly into the central nucleus of the amygdala, a corticotropin-releasing factor−1/corticotropin-releasing factor−2 antagonist blocked ethanol self-administration in ethanol-dependent rats during withdrawal

Table 3 Role of corticotropin-releasing factor in dependence

		Corticotropin-releasing factor antagonist effects			
Drug	Withdrawal-induced changes in extracellular corticotropin-releasing factor in CeA	Withdrawal-induced anxiety-like or aversive responses	Baseline self-administration or place preference	Dependence-induced increases in self-administration	Stress-induced reinstatement
Cocaine	↑	↓	—	↓	↓
Opioids	↑	↓	—	↓	↓
Ethanol	↑	↓	—	↓	↓
Nicotine	↑	↓	—	↓	↓
Δ^9-THC	↑	↓

[32]. Systemic injections of small-molecule corticotropin-releasing factor−1 antagonists also blocked the increased ethanol intake associated with acute withdrawal [33, 55, 91]. These data suggest an important role for corticotropin-releasing factor, primarily within the central nucleus of the amygdala, in mediating the increased self-administration associated with dependence (Table 3).

Between-System Changes: Role of Other Neuropharmacological Systems

Although less well developed, functional norepinephrine antagonists block excessive drug intake associated with dependence on ethanol [138], cocaine [140], and opioids [42]. A focal point for many of these effects is the extended amygdala but at the level of the bed nucleus of the stria terminalis.

A kappa-opioid antagonist also blocks the excessive drinking associated with ethanol withdrawal and dependence [137]. Recently, some have argued that the effects of corticotropin-releasing factor in producing negative emotional states are mediated by activation of κ opioid systems [69]. However, κ receptor activation can activate corticotropin-releasing factor systems in the spinal cord [118], and there is pharmacological evidence that dynorphin systems can also activate the corticotropin-releasing factor system.

Significant evidence suggests that activation of neuropeptide Y in the central nucleus of the amygdala can block the motivational aspects of dependence associated with chronic ethanol administration. Neuropeptide Y administered intracerebroventricularly blocked the increased drug intake associated with ethanol dependence [125, 126]. Injection of neuropeptide Y directly into the central nucleus of the amygdala [38] and viral vector-enhanced expression of neuropeptide Y in the central nucleus of the amygdala also blocked the increased drug intake associated with ethanol dependence [124].

Thus, acute withdrawal from drugs of abuse increases corticotropin-releasing factor in the central nucleus of the amygdala that has motivational significance for the anxiety-like effects of acute withdrawal and the increased drug intake associated with dependence (Fig. 8). Acute withdrawal also may increase the release of norepinephrine in the bed nucleus of the stria terminalis and dynorphin in the nucleus accumbens, and both may contribute to the negative emotional state associated with dependence. Decreased activity of neuropeptide Y in the central nucleus of the amygdala also may contribute to the anxiety-like state associated with ethanol dependence. Activation of brain stress systems (corticotropin-releasing factor, norepinephrine, dynorphin) combined with inactivation of brain anti-stress systems (neuropeptide Y) elicits powerful emotional dysregulation in the extended amygdala. Such dysregulation of emotional processing may be a significant contribution to the between-system opponent processes that help maintain dependence and also set the stage for more prolonged state changes in emotionality such as protracted abstinence.

Homeostatic vs. Allostatic View of Dependence

The development of the aversive emotional state that drives the negative reinforcement of addiction has been defined as the “dark side” of addiction [65, 66] and is hypothesized to be the b-process of the hedonic dynamic known as opponent process when the a-process is euphoria. Two processes are hypothesized to form the neurobiological basis for the b-process: loss of function in the reward systems (within-system neuroadaptation) and recruitment of a negative emotional state via the brain stress or anti-reward systems (between-system neuroadaptation) [61, 63]. Anti-reward is a construct based on the hypothesis that brain systems are in place to limit reward [66]. As dependence and withdrawal develop, brain stress systems such as corticotropin-releasing factor, norepinephrine,

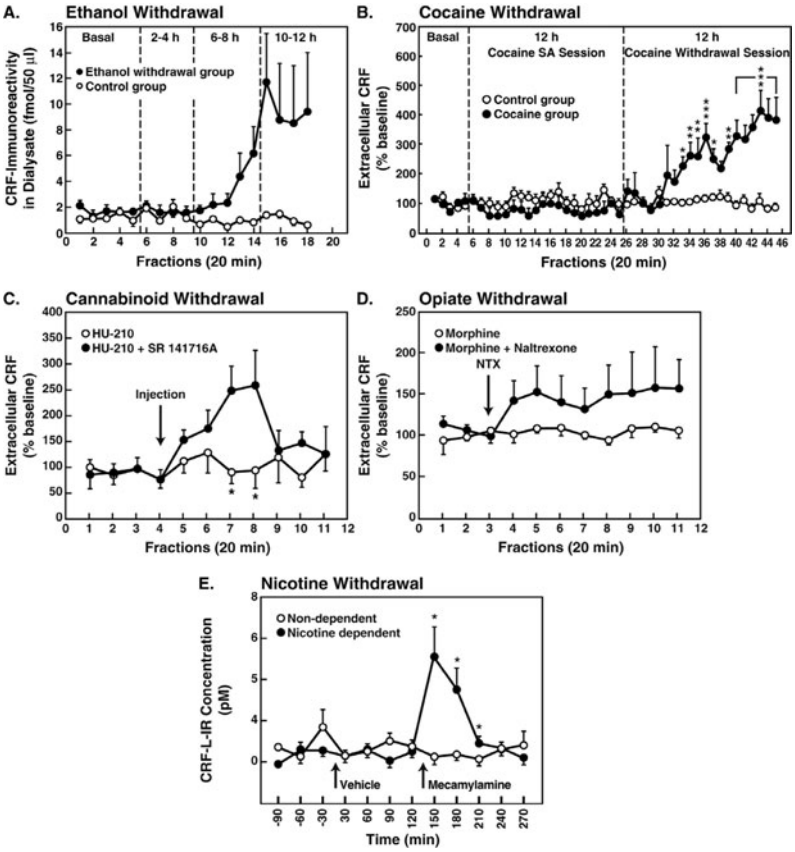

Fig. 8 (**A**) Effects of ethanol withdrawal on corticotropin-releasing factor (CRF)-like immunoreactivity in the rat amygdala determined by microdialysis. Dialysate was collected over four 2-h periods regularly alternated with non-sampling 2-h periods. The four sampling periods corresponded to the basal collection (before removal of ethanol), and 2–4 h, 6–8 h, and 10–12 h after withdrawal. Fractions were collected every 20 min. Data are represented as mean ± SEM ($n = 5$ per group). Analysis of variance confirmed significant differences between the two groups over time ($p < 0.05$). Reprinted with permission from [80]. (**B**) Mean (± SEM) dialysate corticotropin-releasing factor (CRF) concentrations collected from the central nucleus of the amygdala of rats during baseline, 12 h cocaine self-administration (SA), and a subsequent 12-h withdrawal period (cocaine group, $n = 5$). CRF levels in rats with the same history of cocaine self-administration training and drug exposure, but not given access to cocaine on the test day (Control group, $n = 6$). Data are expressed as percentages of basal CRF concentrations. Dialysates were collected over 2-h periods alternating with 1-h non-sampling periods as shown by the timeline at the top. During cocaine self-administration, dialysate CRF concentrations in the cocaine group were decreased by about 25% compared with control animals. In contrast, termination of access to cocaine resulted in a significant increase in CRF release that began approximately 5 h post-cocaine and reached about 400% of pre-session baseline levels at the end of the withdrawal session. $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, Simple effects after overall mixed-factorial analysis of variance. Reprinted with permission from [98] (John Wiley & Sons, Inc). (**C**) Effects of cannabinoid CB_1 antagonist SR 141716A (3 mg/kg) on CRF release from the central nucleus of the amygdala in rats pretreated for 14 days with cannabinoid CB_1 agonist HU-210 (100 mg/kg). Cannabinoid withdrawal induced by SR 141716A was associated with increased CRF release ($^{*}p < 0.005$, $n = 5$–8). Vehicle injections did not alter CRF release ($n = 5$–7). Data were standardized by transforming dialysate CRF concentrations into percentages of baseline values based on averages of the first four fractions. Reprinted with permission from [104] (American Association for the Advancement of Science). (**D**) Effects of morphine withdrawal on corticotropin-releasing factor (CRF) release in the central nucleus of the amygdala. Withdrawal was precipitated by administration of naltrexone (NTX) (0.1 mg/kg) in rats prepared with chronic morphine pellet implants. Reprinted with permission from [142] (Wiley). (**E**) Effect of mecamylamine (1.5 mg/kg, intraperitoneally)-precipitated nicotine withdrawal on CRF release in the central nucleus of the amygdala measured by in vivo microdialysis in chronic nicotine pump-treated (nicotine-dependent, $n = 7$) and chronic saline pump-treated (non-dependent, $n = 6$) rats. $^{*}p < 0.05$ compared with non-dependent. Reprinted with permission from [37]

and dynorphin are recruited (Fig. 8), producing the negative emotional state [8, 56, 83]. At the same time, within the motivational circuits of the ventral striatum-dorsal striatum, reward function decreases. The combination of decreases in reward neurotransmitter function and recruitment of anti-reward systems provides a powerful source of negative reinforcement that contributes to compulsive drug-seeking behavior and addiction.

An overall conceptual theme argued here is that drug addiction represents a break with homeostatic brain regulatory mechanisms that regulate the emotional state of the animal. However, the view that drug addiction represents a simple break with homeostasis is not sufficient to explain a number of key elements of addiction. Drug addiction, similar to other chronic physiological disorders such as high blood pressure, worsens over time, is subject to significant environmental influences, and leaves a residual neuroadaptive trace that allows rapid "re-addiction" even months and years after detoxification and abstinence. These characteristics of drug addiction imply more than simply a homeostatic dysregulation of hedonic function and executive function, but rather a dynamic break with homeostasis of these systems that has been termed "allostasis."

Allostasis, originally conceptualized to explain persistent morbidity of arousal and autonomic function, is defined as "stability through change," and differs significantly from homeostasis [120]. Allostasis involves a feed-forward mechanism rather than the negative feedback mechanisms of homeostasis, with continuous reevaluation of need and continuous readjustment of all parameters toward new set points. Allostatic mechanisms have been hypothesized to be involved in maintaining a functioning brain reward system that has relevance for the pathology of addiction [64]. Repeated challenges, such is the case with drugs of abuse, lead to attempts of the brain via molecular, cellular, and neurocircuitry changes to maintain reward stability but at a cost. For the drug addiction framework elaborated here, the residual deviation from normal brain reward threshold regulation is termed an "allostatic state." This state represents a combination of chronic elevation of reward set point engaged by the motivational changes involving decreased function of reward circuits and recruitment of anti-reward systems, and both may contribute to the compulsivity of drug seeking and drug taking. How these systems are modulated by other known brain emotional systems localized to the extended amygdala and how individuals differ at the molecular-genetic level of analysis to convey loading on these circuits remain challenges for future research.

Animal Models of Dependence: Validity and Relevance to Treatment

Relevance of Face Validity

Animal models of motivational dependence with a lowercase "d" have substantial face validity. The hypothetical constructs associated with the models of motivational dependence—anxiety, dysphoria, and decreased reward—all are hypothesized to reflect such symptoms in humans. However, the major limitation of face validity here is that arguing that a rat is truly experiencing "dysphoria" is virtually impossible because no verbal reports can be obtained from a rat. In contrast, from a behaviorist perspective, one could argue that a verbal report in a human is only one measure of dysphoria and that the human symptoms could also be measured in a place aversion situation. Clearly, the translation of animal models to the human condition has not reached such a level of sophistication. With regard to other symptoms of addiction associated with dependence, such as escalation with extended access or dependence-induced drinking, face validity is again limited. Animals in the conditions constructed by the researcher are indeed self-administering intoxicating amounts of drugs. However, the social situations for animals versus humans are vastly different, and a requirement for true face validity would be restrictive and non-productive. Certainly, some new information would be obtained if one had

a model of free-ranging rats drinking ethanol in the context of burrow dominance hierarchy. Such studies can and have been done with success in non-human primates in which the social impact has more construct validity for the human condition. Indeed, construct validity—not face validity—in animal models is critical for the heuristic study of biological processes in the human condition and more specifically the understanding of the neurobiology of addiction.

Construct Validity

The models of dependence with a lowercase "d" and other symptoms associated with Dependence with a capital "D" outlined in this chapter have construct validity (i.e., they have explanatory power for the human condition or functional equivalence for the human condition). For example, ample evidence indicates impaired reward function in animals showing escalation in drug intake with extended access to intravenous drugs of abuse and in animals with withdrawal-induced excessive drinking. Similarly, evidence exists for impaired stress responsivity during drug withdrawal that is paralleled in the human condition [39, 62, 97]. Ample evidence suggests that the decrease in dopaminergic function in the mesolimbic dopamine system in rats during acute withdrawal is robust in humans [133].

Emphases on face validity [23] may be misplaced and can be argued to undermine progress in the field. For example, the method of induction of opioid dependence (e.g., pellets vs. self-administration) appears to matter little compared with the dose of opioid employed (Table 4). Clearly, high opioid doses over time produce dose-dependent dependence with a lowercase "d" and excessive drug seeking measured by intake or reinforcement efficacy. Different patterns of administration of the drug (intermittent exposure to ethanol vs. continuous ethanol) may also ultimately have motivational effects [87]. However, the unspoken view that to have a valid model of alcoholism "one must show that a rat can drink whiskey from a bottle in a paper bag on a street corner while smoking a cigarette" is misleading and counterproductive. A case in point is a comparison of a classic Southern European alcoholic (who never showed public intoxication but imbibed several bottles of wine per day and clearly met the criteria for Dependence with a capital "D" when deprived of alcohol) to the binge alcoholic of Northern Europe. Would one argue that the biological bases of liver toxicity, frontal cortex dysfunction, or activation of the brain stress systems during motivational withdrawal sufficient to induce excessive drinking are different for such different phenotypes of alcoholism?—presumably not in the domin of cancer, diabetes, pain, and obesity. Numerous examples exist of induction of a disease state independent of the exact human pattern of disease induction that have construct validity for understanding the underlying biology, but not necessarily face validity, of cancer, diabetes, pain, and obesity. Thus, emphasis must be placed on construct validity and reliability of animal models and not the red herring of face validity.

Relevance to Medications Development

The thesis of this chapter is that animal models of motivational dependence provide a heuristic

Table 4 Heroin self-administration as a function of opioid induction procedure

Method of induction	Escalation time	Total heroin intake*	References
Morphine pellets (2 × 75 mg, subcutaneously)	0–3 days	~1,200 μg/kg (8 h)	[139]
Heroin self-administration (12-h access; 60 μg/kg/infusion)	0–20 days	~2,400 μg/kg (12 h)	[42]
Heroin self-administration (23-h access; 60 μg/kg/infusion)	0–35 days	~3,000 μ/kg (23 h)	[21]

*Note that the total dose per day, extrapolated to 24 h, would be similar with all three methods of induction.

framework for understanding a key, and previously neglected, source of reinforcement associated with addiction. An interactive, iterative process can be established whereby existing medications that interact with the withdrawal/negative affect stage of the addiction cycle would be used to validate and improve animal and human laboratory models and then predict viable candidates for novel medications [60, 67]. Medications currently on the market for the treatment of addiction have provided not only a window on the opportunities for facilitating treatment but also are forming a means for evaluating future medications development. A combination of excellent and validated animal models of addiction and an enormous surge in understanding through basic research of the neurocircuits and neuropharmacological mechanisms involved in the neuroadaptative changes that account for the transition to dependence and the vulnerability to relapse have provided numerous viable targets for future medications development. Development of human laboratory studies for these stages of the addiction cycle is critical and will allow dynamic iterative feedback to and from the animal models key to the identification of novel candidates for treatment [67]. Novel neurobiological targets will be derived from this basic research on addiction with a focus on the withdrawal/negative affect stage and protracted abstinence component of the preoccupation/anticipation stages of the addiction cycle. Indeed, some would argue that targets that restore homeostasis of reward function rather than block reward function will be significantly more valuable to the field [66, 67].

Novel Methodologies: Proteomic Approaches in Substance Abuse Research

Scott E. Hemby, Wendy J. Lynch, and Nilesh S. Tannu

Contents

Introduction

The comprehensive sequencing of human and other important genomes has enhanced our understanding of the cellular organization and function in higher organisms. This has been largely accomplished by the innovations in large-scale analysis of mRNA expression (microarrays, serial analysis of gene expression, and differential display). Genomics-based approaches have led to unprecedented advances in our understanding of the biological basis of substance abuse; however, the next step in systems biology is the examination of coordinated expression of the entire complement of proteins including modifications and protein-protein interactions—proteomics. The broad scale analysis of proteins in health and disease is essential given that proteins are central components of cellular physiology carrying out the greater part of biological events in the cell, even though certain mRNAs can act as effector molecules. Furthermore, it is important to note that mRNA and protein analysis are not interchangeable, with each governed by distinct spatial, temporal, and physiological processes that generally prevent correlation of mRNA and protein expression in neuronal systems [1, 19].

Proteomics involves the evaluation of the entire complement of proteins in a biological system with respect to structure, expression level, protein-protein interactions, and post-translational modifications—often referred to as structural, functional, and expression proteomics, respectively. The majority of early efforts in proteomics have been directed toward comparison of differential protein expression and identification in disease and control tissues. However, changes in protein abundance do not define protein function exclusively as many vital functions are brought about by post-translational modifications, interactions among proteins, and differential distribution in subcellular components. Multiple proteomic strategies are needed to capture the involvement of regulatory mechanisms that affect protein abundance and function such as protein-protein interactions and subcellular distribution.

The advent of proteomics can be attributed in part to the rapid development of mass spectrometry, bioinformatics and the current accessibility of vast protein database from various organisms. These rapid advancements have improved our understanding of the cellular structure and function within the brain and the roles of various proteins and protein interactions in health and disease. However, the central nervous system poses unique challenges to proteomic inquires including the temporal and spatial expression characteristics of neurons and glia, the cellular heterogeneity of brain regions, the connectivity and communication between neurons and the dynamic structural and functional alterations in neurons and glia that occur as a function of the interaction between the organism and the environment, development, learning and memory, and disease. These challenges can be overcome to some extent by combining specific isolation and fractionation procedures with high-throughput protein separation and analysis strategies to yield a more global view of the proteome in different physiological states than has been available previously. For example, prior to the advent of high-throughput proteomics technologies, our knowledge of protein alterations and the durations of those alterations induced by substance abuse was limited to less than 100 proteins—primarily expression levels of protein assessed either individually or a few proteins at a time. With the development of proteomic technologies and strategies, it is now possible to evaluate significant portions of the neuroproteome (thousands of proteins) from crude homogenates to discrete cellular domains. Proteomic analysis strategies allow the simultaneous assessment of thousands of proteins of known and unknown function, thereby enabling a more comprehensive view of the protein orchestration in addictive disorders. Broad-scale evaluations of protein expression are well suited to the study of drug abuse, particularly in light of the complexity of the brain compared with other tissues, the multigenic nature of drug addiction, the vast representation of expressed proteins in the brain, and our relatively limited knowledge of the molecular pathology of this illness.

The development of innovative strategies has been ongoing in neuro-proteomics, particularly for studying the post-translational modifications, mapping of proteins from multi-protein complexes, and mapping of organelle proteomes [13]. An understanding of the proteins in neurons along with their expression levels and their post-translational modifications, as well as the protein-protein interaction maps, would revolutionize addiction biology and addiction medicine in that we would then be able to expand our knowledge of the biochemical alterations specifically associated with substance abuse. Such information would be used to identify new targets for medication development.

Technology and Methods for Expression Proteomics

Protein Fractionation

The biological samples subjected to proteomic analysis in neuroscience include tissue, distinct cell populations and cerebrospinal fluid. Each type of sample is extremely complex as the protein constituents vary in charge, molecular mass, hydrophobicity, and post-translational modification, as well as spatial and temporal expression. The coding genes for the central nervous system fluctuate between 25,000 and 30,000 [81]. This added complexity of neuro-proteome will be overwhelming if we hypothesize that each protein on average has 10 splice variants, cleavage products, and post-translational modifications, yielding approximately 250,000–300,000 protein isoforms to assess. Currently, there are no proteomic methods that have the capacity to separate and identify the entire proteome. One approach is to reduce the complexity of the proteome by subcellular fractionation procedures, allowing a more thorough assessment of cellular domains (e.g. synapse, membrane, nucleus, and cytoplasm) while enriching less abundant proteins that may not be detectable at the level of whole cell protein analysis [88].

Protein stability and purity as well as prevention of protein degradation and modification are of critical importance throughout various stages of proteomic analysis. Rapid removal of brain tissue, dissection, and freezing are imperative for the maintenance of the proteome state in the sample. Protease and phosphatase inhibitors are used to help prevent degradation and dephosphorylation of proteins during protein preparation [61]; however, care should be taken that adducts and charge trains are not introduced by these inhibitors. Purification of proteins from other cellular substances is also necessary; for example, lipids, several proteins (e.g., albumin and immunoglobulin are particularly abundant in the brain), and nucleic acids should be eliminated from the protein sample. The most common methods of purification rely on selective precipitation including acetone and trichloroacetic acid, although a number of commercially available kits are available [70].

Cerebrospinal Fluid

Cerebrospinal fluid is secreted by the choroid plexus in the lateral ventricles and is found in the cerebral ventricles and in the subarachnoid space flowing down the spinal canal, as well as upwards over the brain convexities. Cerebrospinal fluid is an important determinant of extracellular fluid surrounding neurons and glia in the central nervous system, removes harmful brain metabolites, provides mechanical cushion, and serves as a conduit for peptide hormones secreted by hypothalamus. Cerebrospinal fluid is in steady state with the extracellular fluid; thus it is considered to contain biochemical constituents that reflect neural activity.

While proteomic studies of neuronal tissue have multiple challenges including the use of post-mortem tissue and invasive biopsies from ante-mortem tissues, cerebrospinal fluid proteomics is amenable for serial analysis by minimally invasive lumbar puncture. A change in the expression of cerebrospinal fluid constituents may provide important insights into various central nervous system diseases by improving our understanding of the molecular basis of disease as well as providing disease biomarkers. Given the low protein concentration (~150–450 μg/ml) and high salt concentration (>150 mmol/L) of cerebrospinal fluid and the abundance of albumin (~60% of the total cerebrospinal fluid protein) and immunoglobulin [23], it is necessary to deplete these abundant proteins (e.g. affinity removal and solid phase extraction) and reduce the salt concentration (e.g. protein affinity columns, ultrafiltration, and dialysis) to improve protein recovery and allow better detection of less abundant proteins. The limitation, depletion of some of the proteins of interest, can be overcome by a separate analysis of the depleted abundant proteins to ensure analysis of proteins interacting with the abundant proteins.

Cellular Domains

Several recent proteomics studies have employed fractionation methods that allow collection of multiple cellular components from one tissue source [16, 31, 85]. This allows a greater amount of each fraction to be used at the start, thereby enabling analysis of less abundant proteins. As the fractions are generated from the same samples, the experimental variability is reduced, with the additional advantage of an additive increase in the whole proteome analyzed. The crucial drawback has been the overlap of the proteins between fractions.

Cytoplasm

Since the current proteomic strategies rely heavily of two-dimensional gel electrophoresis, which has been optimized for the analysis of soluble protein fractions, it is not surprising that the vast majority of initial phases of proteomic analysis have focused on profiling of the cytoplasm. The vast majority of key regulators of the signaling pathways are housed in the cytoplasm, besides regulating the expression of receptors and channeling important cytodynamic

information between the nucleus and the membrane proteins. Some of the recent studies profiling the cytoplasm have revealed interesting new paradigms in our understanding of neurobiology.

Nucleus

The nucleus has a high degree of organization, consisting of structurally and functionally distinct compartments: nucleolus, nuclear speckles, nuclear pore complex, and nuclear envelope. The nucleus is a highly organized organelle consisting of domains fundamental for preserving the homeostasis of the cellular milieu. The profiling of the nuclear proteome in neuroscience has been the slowest of all subcellular fractions. However, there have been some good studies documenting the need to do so. In addition to the soluble fraction of the nucleus, there has been an interest in other compartments of the nucleus—nuclear envelope, nuclear pore complex and nucleolus—although no studies using such methods have been published to date in addiction biology research.

Mitochondria

The mitochondria is a complex structure involved in fundamental processes, such as the tricarboxylic acid cycle, β-oxidation of fatty acids, urea cycle, electron transport, oxidative phosphorylation, apoptosis and heme synthesis. Neuroproteomic analyses of the mitochondria have focused on the abundance in different brain regions [45, 103]. Datasets from mitochondrial proteomes from different species and tissues have documented 400–700 mitochondrial associated proteins which will enable scientists to better understand the mitochondrial machinery in health and disease [54, 89].

Membrane

Membrane and the membrane-associated proteins constitute nearly a third of the cellular proteins and represent targets of approximately two thirds of pharmaceutical agents [82, 99]. These proteins are involved in various cellular processes including signal transduction, cell adhesion, exocytosis, metabolite, and ion transport. As membrane proteins are amphipathic, the hydrophobicity nature makes them difficult to study and necessitates different strategies for analysis as compared with cytosolic proteins, for example. Therefore, while great strides have been made toward the analysis of soluble cellular proteins, the analysis of membrane proteins reported in proteomic analyses has been under-represented [97]. The traditional proteomic approach of two-dimensional gel electrophoresis has many limitations for analyzing membrane proteins [11], including the insolubility of hydrophobic proteins in non-detergent sample buffer, alkaline isoelectric points of most hydrophobic proteins, which are difficult to resolve on the basic extent of acrylamide gels. To a large extent, these issues can be overcome using a variety of combinations of liquid chromatographic separation techniques.

Synaptosomes and Postsynaptic Density

Synapses can be fractionated into synaptosomes as well as distinct pre and post-synaptic components. Synaptosomes constitute of the entire presynaptic terminal (including mitochondria and synaptic vesicles) and portions of the postsynaptic terminal (including postsynaptic membrane and postsynaptic density). The study of synaptic proteomes is an important starting point in neuroscience to understand complex brain functions. Critical for understanding neuroplasticity as well as neuropathology associated with drugs of abuse.

Synaptosomes are subcellular membranous structures formed during mild disruption of brain tissue. The shearing forces cause the nerve endings to break off and subsequent resealing of the membranes form the synaptosomes. The synaptosomes have a complex structure equipped with components of signal transduction, metabolic pathways, and organelles as well

as structural components required for vesicular transport. Synaptosomes can be isolated from brain homogenate by differential and density-gradient centrifugation [76].

The postsynaptic density is a disk-like structure with a thickness of ~30–40 nm and width of ~100–200 nm. The most important structures associated with it are the cytoskeletal proteins, regulatory enzymes, and neurotransmitter receptors and associated proteins. These constitute a very highly structured framework with a definite association of the receptors and ion channels with the signaling molecules and the cytoskeletal elements to play an imperative role in signal transduction as well as synaptic plasticity. There are several available fractionation methods for isolation of the postsynaptic density [64, 91].

Separation

Gel-Based Methods

Expression proteomics refers to the determination of protein levels without regard to post-translational modifications. Gel-based as well as chromatographic separation approaches have been integral in generating proteomic profiles in numerous tissues including brain; however, research into the neuroproteome to date has been predominantly gel based.

Two-Dimensional Gel Electrophoresis

The basic principles of two-dimensional gel electrophoresis remain the same since its introduction, namely the separation of proteins by isoelectric focusing (1st dimension) followed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (2nd dimension), which involves the separation by molecular weight of proteins [41, 60]. In standard two-dimensional gel electrophoresis experiments, approximately 1,000–2,000 protein spots are visualized on a gel representing the most abundant proteins while other less abundant proteins are largely obscured by the more abundant proteins. Subcellular fractionation can be used to enrich the representation of less abundant proteins. Caveats of the two-dimensional gel electrophoresis procedure include: (1) the possibility of co-migration of proteins (i.e. many proteins in a spot, (2) migration of proteins as multiple spots (i.e. due to charge trains, post-translational modifications, isoforms, etc.), (3) intensive image analysis requiring manual removal of artifacts, (4) inability or difficulty of large and hydrophobic proteins to isolated in first dimension gels, and (5) poor representation of highly acidic and basic proteins (i.e. membrane bound proteins). In general, two-dimensional gel electrophoresis variability is approximately 20–30% due to sample preparation, reagent sources, staining methods, image analysis software, and technical expertise and experience [53].

Isoelectric Focusing

Following protein solubilization, the next step in two-dimensional gel electrophoresis is isoelectric focusing, which separates the proteins in the first dimension according to their isoelectric point. The isoelectric point of a protein is primarily a function of the amino acid side chains, which are protonated or deprotonated depending on the pH of the solution in which the protein is present. For isoelectric focusing, protein samples are loaded onto strip gels consisting of a gradient of pH values and electrophoresis leads protein migration depending on the net charge of each protein in the sample. At a specific isoelectric point, the protein will reach the point in the pH gradient where the net charge of the protein is zero and stop migrating.

Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis

Next, the isoelectric focusing gel or strip is equilibrated with sodium dodecyl sulfate and placed on top of the sodium dodecyl sulfate acrylamide gel. The equilibration step is necessary to allow the sodium dodecyl sulfate molecules to complex with the proteins and produce anionic

complexes with net negative charge roughly equivalent to the molecular weight of the protein. Proteins are electrophoresed migrating out of the isoelectric focusing gel and into the sodium dodecyl sulfate gel, where they separate according to molecular weight (second dimension). Both conventional sodium dodecyl sulfate-polyacrylamide gel electrophoresis instruments, such as those used for Western blotting and special purpose apparatuses can be used for this step.

Gel Staining

Following electrophoresis, it is imperative to visualize gel spots for subsequent isolation and mass spectrometry analysis. Coomassie Brilliant Blue, silver nitrate, and negative staining are common post-electrophoresis methods available for the two-dimensional gel-based proteomics analysis. The sensitivity of these stains range from 100 ng (e.g. Coomassie Brilliant Blue) to 1 ng (e.g. silver) for individual protein spot detection [59, 75]. In acidic medium, Coomassie Brilliant Blue binds to the amino acids by electrostatic and hydrophobic interactions; however, some of the proteins release the dye during the de-staining procedure, which may cause problems with reproducibility and quantitative reliability. Coomassie Brilliant Blue is compatible with mass spectrometry as complete de-staining of the gel can be achieved using bicarbonate. As a rule of thumb, proteins detected visually by Coomassie stain are sufficiently abundant enough for characterization by mass spectrometry. Disadvantages of Coomassie Brilliant Blue staining include low sensitivity and a narrow dynamic range, which is, however, better than silver stain. Silver staining is widely used for quantitative analysis due to its high sensitivity. Despite its excellent sensitivity, silver staining lacks reproducibility, has a limited linear dynamic range, involves subjective judgment of the staining end-point, and interferes with the mass spectrometry compatibility, resulting in a much lower sequence coverage compared with Coomassie staining [55]. Even though silver staining is still used currently, there has been an increasing trend to use the new-generation fluorescent stains.

Fluorescence-based detection methods are more sensitive than the absorbance based methods given the difference in detected and incident wavelengths, which lead to lower background values [96]. SyproRuby™ dye (Molecular Probes, Eugene, OR), the first of the fluorescent stains, is part of a stable organic complex composed of ruthenium that interacts non-covalently with basic amino acids in proteins [6]. The stain can be visualized using a wide range of excitation sources commonly used in the image analysis systems. It has a sensitivity that approximates silver staining with a linear dynamic range of three orders of magnitude. DeepPurple™ (GE Healthcare, Piscataway, NJ) possesses a broad dynamic detection range over four orders of magnitude with limited speckling and background staining [49, 79], appears to result in increased peptide recovery from in-gel digests compared with SyproRuby™ stain, and improves matrix-assisted laser desorption ionization-time of flight mass spectrometry-based identification of less abundant protein spots by increasing sequence coverage [87].

Two-Dimensional Difference in Gel Electrophoresis

Whereas two-dimensional gel electrophoresis has been the workhorse of proteomics for several decades, the method has been plagued by issues of reproducibility and quantitation given that multiple gels have to be compared. Two-dimensional difference in gel electrophoresis [92] allows the labeling of two to three samples with different dyes on the same two-dimensional gel, thereby reducing spot pattern variability and the number of gels in an experiment—with the result of making spot matching much more simple and accurate. The most popularized experimental design has been the use of a pooled internal standard (sample composed of equal aliquots of each sample in the experiment) labeled with the Cy2 dye and labeling control and experimental samples with Cy3 or

Cy5 dyes swapped equally across the samples, respectively. Following 1st and 2nd dimension electrophoresis, gels are sequentially scanned for Cy2, Cy3, and Cy5 labeled proteins by the following lasers/emission filters; 488-/520-, 532-/580- and 633-nm/670-nm, respectively. The scanned images of the fluorescence labeled proteins are sequentially analyzed by differential in-gel analysis (performs Cy5/Cy3: Cy2 normalization) followed by biological variation analysis (performs inter-gel statistical analysis to provide relative abundance in various groups). These log abundance ratios are then compared between the control and diseased/treatment samples from all the gels using statistical analysis (t-test and analysis of variance).

A modification of two-dimensional difference in gel electrophoresis in which cyanine dyes that label all of the cystine residues of proteins are labeled has been introduced with a detection limit for saturation labeling of 0.1 ng or protein per spot as opposed to 1 ng protein per spot thereby reducing the amount of protein sample required for analysis [78]. This procedure provides a very attractive alternative for performing quantitative two-dimensional difference in gel electrophoresis when dealing with low sample amounts, typical in neuroscience, even though only two saturation dyes are currently available (Cy3 and Cy5).

Chromatographic Separation of Proteins

The coupling of efficient chromatographic and electrophoretic separation methods with high-performance mass spectrometry hold great promise for qualitative and quantitative characterization of highly complex protein mixtures. The advances in chemical tagging and isotope labeling techniques have enabled the quantitative analysis of proteomes. Multidimensional liquid chromatographic separation (also known as multidimensional protein identification technology [94]) is typically based on using ≥ 2 physical properties of peptides (size, charge, hydrophobicity, and affinity) to reduce the complexity of the proteome. Methods commonly used employed to separate peptides based on physical and chemical properties include ultracentrifugation (density), capillary electrophoresis (size and charge), isoelectric focusing (isoelectric point), size-exclusion chromatography (stoke's radius), ion-exchange chromatography (charge), hydrophobic interaction chromatography (hydrophobicity), reverse-phase chromatography (hydrophobicity), and affinity chromatography (biomolecular interactions).

A major advantage of multidimensional approaches over two-dimensional gel electrophoresis methods is the ability to isolate less abundant proteins as well as the proteins with extreme isoelectric point, molecular weight, and hydrophobicity [20, 63, 94]. In most multidimensional separation approaches, proteins are digested into peptides prior to separation, yielding complex peptide mixtures but with increased solubility due to the elimination of non-soluble hydrophobic peptides—a critical caveat for the study of membrane proteins that are insoluble in aqueous buffers.

Several strategies have been developed for relative quantitation of protein expression between samples, including: (1) isotopic labeling of separate protein mixtures, (2) combined digestion of the labeled proteins followed by multidimensional liquid chromatographic separation, (3) automated tandem mass spectrometry of the separated peptides, and (4) automated database search to identify the peptide sequences and quantify the relative protein abundance based on the tandem mass spectrometry.

Isotope-Coded Affinity Tags (ICAT and iTRAQ)

ICAT used to be one of the most popular methods for quantitative proteome analysis before the inception of iTRAQ multiplex quantitation strategy [22]. The ICAT reagent is comprised of a cysteine-reactive group, a linker containing the heavy or light isotopes (d8/d0) and a biotin affinity tag. The labeling method involves *in vitro* derivatization of cysteine residues in a protein with d0 or d8 followed by enzymatic

digestion of the combined sample. All cysteine biotin tagged residues are selectively separated by avidin column followed by further separation using reverse phase chromatography. The isotopically tagged peptides give quantitative mass spectrometry analysis based on the relative peak intensities/areas of d0 and d8 labeled peptides [22]. Another advantage is the ability to analyze peptides with molecular weight more than 3,000 daltons easily due to the mass difference between the coded isoforms is sufficiently large.

A major limitation of ICAT is the exclusive analysis of cysteine-containing peptides (10–20% of the peptides). The resolution is greatest in the case of smaller peptides where the d8/d0 ratio is higher and with peptides that have multiple cysteine residues [73]. Another limitation is that the biotin affinity tag remains linked to the peptides throughout the analysis causing shifts in chromatographic separation, shifts in the mass/charge ratio and changes to tandem mass spectrometry spectra relative to the unlabelled peptides complicating the manual or computer–assisted interpretation [15, 22]. Most analyses of ICAT have utilized the combination of strong cation exchange chromatography with reverse-phase microbore liquid chromatography coupled with on-line mass spectrometry and tandem mass spectrometry [21, 44, 94]. Data-dependent software is used to select specific mass/charge peptides for collision-induced dissociation, alternating mass spectrometry and tandem mass spectrometry scans for collecting qualitative and quantitative data. Alternative strategies such as per-methyl esterification of carboxylic acid groups [17], specific labeling of lysine residues [65], and peptide *N*-termini [56] have also been used recently. Quantification software have been developed that can assemble a composite ratio for a protein based on the calculated expression ratio from all the peptides from a single protein such as XPRESS (http://tools.proteomecenter.org/XPRESS.php) and ProICAT™ (Applied Biosystems, Foster City, CA). The data obtained from the above software programs can be analyzed collectively using INTERACT for multiple experiments [24].

iTRAQ methodology is an extension of ICAT, which uses four isobaric reagents (114, 115, 116 and 117), allowing the multiplexing of four different samples in a single liquid chromatography-tandem mass spectrometry experiment. More recently, iTRAQ 8Plex, which has four more isobaric reagents (113, 118, 119 and 121) in addition to the traditional four iTRAQ reagents, expands the possibilities of using more experimental variables for comparison. A major advantage of this technique over the ICAT is the ability to label multiple peptides per protein, which increases the confidence of identification as well as quantitation. A recent study comparing two-dimensional gel electrophoresis and iTRAQ reported a confidence interval of 0.24 for isobaric tagging versus 0.31 for two-dimensional gel electrophoresis as well a greater range of expression ratios [10]. A more recent study compared two-dimensional difference in gel electrophoresis, ICAT and iTRAQ, and reported that iTRAQ was more sensitive than the ICAT, which was equi-sensitive to two-dimensional difference in gel electrophoresis. The complementary nature of these techniques was confirmed by the limited overlap of the proteins characterized [100].

Top–Down Proteomics

The aforementioned techniques (bottom–up proteomics) are based on consistent enzymatic conversion of proteins to peptides. It is customary to accurately make mass measurements by a tandem mass spectrometry of lower molecular weight peptides rather than higher molecular weight intact proteins; however, bottom–up approach increases the sample complexity and the entire sequence coverage for proteins is rarely achieved—limiting site-specific post-translational modification analysis of proteins. Such limitations have renewed interest in top–down proteome characterization strategies. Such techniques characterize individual proteins by mass spectrometry *without* prior enzymatic cleavage. Capillary isoelectric focusing coupled with Fourier transform-ion cyclotron resonance

mass spectrometry is one such strategy for analyzing complex protein mixtures using a top–down approach [35, 93]. One potential major limitation is the level of information is not always sufficient for confident protein identification due to the possibilities of point mutations, post-translational modifications and the presence of open reading frames having high sequence homology. This problem can be overcome somewhat by incorporation of isotopically labeled amino acids into the cellular proteins of unicellular model organisms. The partial amino acid content information obtained combined with capillary isoelectric focusing-Fourier transform-ion cyclotron resonance, enables identification of proteins from genome databases without tandem mass spectrometry information [35, 51]. Other limitations include the large amount of sample required and the low throughput that is not amenable to automation.

Mass Spectrometry

Mass spectrometers consist of three major units: the ion source, the mass analyzer, and the ion detection system. Mass spectrometry is based on the separation of ionized proteins or peptides based on the mass/charge ratio. Tandem mass spectrometry, on the other hand, couples two mass spectrometers in time and space and has revolutionized the field of expression and functional proteomics [80]. Tandem mass spectrometry involves selection of peptides of a certain mass and the subsequent fragmentation and mass analysis (in two stages). In the first stage, the precursor ion produced by the ion source is selected for fragmentation. The fragmentation results in production of product ions to be analyzed in the second stage of mass analysis. The inconvertible link between the precursor ion and the product ions is responsible for the unique molecular specificity of tandem mass spectrometry.

Ion Source

A number of ionization technologies exist including: fast ion bombardment [4], matrix-assisted laser desorption ionization [37], and electrospray ionization [14]. Matrix-assisted laser desorption ionization and electrospray ionization are the techniques of choice for most proteomic applications of neuroscience research. Matrix-assisted laser desorption ionization works through mixing the protein sample with a light-absorbing matrix that forms a crystal. This is usually done on some form of plate with multiple positions for different samples. When the plate is pulsed with a laser of a particular wavelength, the energy from the laser is absorbed by the crystal matrix and the proteins within the crystal are ionized and desorbed (ejected) from the plate into the mass analyzer.

In electrospray ionization (and nanospray ionization), ions are produced in a liquid phase. The protein sample, in a solvent solution, is ejected as a mist of droplets from a charged capillary tip. As the solvent in the droplets evaporates the total charges of the proteins in the droplet remain but with a reduced surface area of the droplet. This continues to a point at which individual ions leave the droplet. Individual ions then pass on into the mass analyzer.

Mass Analyzers

Whichever method of ionization is used, once the ions are created they must be separated before being detected in such a way as to provide information on the mass/charge ratio. Mass analyzers do not actually detect the ions or measure ion mass; they are only used to separate ions according to their mass/charge ratio. A number of mass analyzer types exist: time of flight, quadrupole, ion trap, and Fourier transform-ion cyclotron resonance.

Time-of-flight mass analyzers can be thought of as a tube. The ionized proteins enter the tube by passing through a high voltage accelerator. The speed at which the ion travels is proportional to its mass. A number of ions are produced simultaneously and pass through the time-of-flight tube and to a detector; the ions with a higher mass/charge ratio will travel faster and

reach the detector first. Since the distance traveled and time are all known, the mass/charge ratio can be calculated, and from that the mass.

Quadrupole mass analyzers also involve ions traveling down what can be thought of as a tube. In this case though, the tube consists of four parallel rods. The rods are two pairs of two that can be tuned to different currents and radio frequencies. The two pairs of rods have opposite currents and shifted radio frequencies allowing a form of tuning in which only ions of a particular mass/charge ratio pass though the tube. A range of mass/charge ratios can be scanned, generating a mass/charge profile of the sample. Quadrupole mass analyzers are often used with an electrospray ionization ion source.

Ion trap mass analyzers use the same principles as the quadrupole in that specific combinations of current and radio frequencies are used to select particular mass/charge ratios. The ion trap can be thought of as a small ball with one electrode around the equator and two more electrodes at the poles. Ions are introduced into the center of the ball and are kept in orbits within the trap. By changing current and radio frequency combinations, particular mass/charge ratio ions are ejected from the ion trap through a port to the detector. By scanning though these voltages and radio frequencies, a complete mass/charge profile can be made.

A number of hybrids of these separation strategies exist, all of which are generally designed to increase the accuracy of mass/charge ratio measurements and sensitivity to less abundant ions. Time-of-flight analyzers can be placed in series (time of flight/time of flight) with a reflectron or collision cell between them; quadrupoles and time of flight can be placed in series (Q-time of flight), and extremely powerful magnets and Fourier transform algorithms (Fourier transform-ion cyclotron resonance) can be used to determine the mass/charge ratios of all ions within an ion trap. Detectors change the kinetic energy of the ions into an electrical current that can be measured and passed along to a computer. While these detectors give information on abundance of ions, quantitation of protein abundance differences between samples by mass spectrometry is limited unless samples are linked to isotopes (see ICAT).

All of these mass spectrometry techniques can be applied to complex protein samples, i.e. a mixture of hundreds or thousands of proteins. It is important to separate the use of mass spectrometry instruments to separate proteins from the mass spectrometry used for protein identification, as will be described later. As described below, quantitative analysis by mass spectrometry is limited to techniques like ICAT. For researchers looking to profile the expression of proteins in a large number of samples, mass spectrometry can be problematic and requires a great deal of time on expensive instruments.

Protein Identification

No matter the separation and quantitation methods used, at the end of the experiment the proteins must be identified. Most approaches use mass spectrometry. Peptide mass fingerprinting and tandem mass spectrometry are the main methods for determining protein identities. Peptide mass fingerprinting was developed by a number of research groups [32, 50, 62] and begins with digestion of a protein with an enzyme, typically trypsin. Trypsin cleaves proteins at very specific locations, resulting in a series of peptides. If this mixture of peptides is analyzed by mass spectrometry, a series of peptide masses is created. These masses are searched against databases using one of a number of programs (e.g. ProFound and MASCOT). These programs take DNA sequence databases translated into protein sequence and calculate the resulting peptide masses if these protein sequences were digested with trypsin. The peptide masses generated from the mass spectrometry of the digested protein of interest are then compared against these databases and the protein can be identified. Peptide mass fingerprinting of spots from two-dimensional gel electrophoresis is one very common application. Gel plugs are either excised by hand or by robot. These plugs contain the proteins of interest, and the proteins are digested in the plugs with trypsin. With

visual stains, the plug must often be destained, and some stains work better than others. Silver stains which use gluteraldehyde are not compatible with mass spectrometry.

Even if mass spectrometry instead of two-dimensional gel electrophoresis is chosen as the method of protein separation, mass spectrometry is also used for protein identification, through a process called tandem mass spectrometry. A number of different strategies exist for tandem mass spectrometry; in general the process entails the selection of one ion/peptide generated during initial mass spectrometry and then fragmenting this ion/peptide into smaller pieces and measuring the mass of the resulting ions. These secondary ions can be decoded into peptide sequence information, which is searched against protein sequence databases to identify the protein. Almost all of the ionization and mass analyzer types can be used for tandem mass spectrometry, provided that the instrument is appropriately configured. One tandem mass spectrometry method that is particularly suited for proteome determination, but less so for quantitation, is multidimensional protein identification technology [94]. In this method, all the proteins in a sample are digested and loaded onto liquid chromatographic columns (see previous explanation). After fractionation of the peptides, the peptides are fed into a tandem mass spectrometry instrument for protein identification. This method has identified thousands of proteins, can detect membrane proteins, and is similar in concept to shotgun sequencing of DNA.

Some of the more traditional methods for identifying proteins are still used for proteomic experiments. Edman protein sequencing can be performed on proteins or peptides extracted from gels or blotted from gels, although the method is limited by low throughput and requires a comparatively large amount of protein. Another technique is the Far Western blot where a two-dimensional gel electrophoresis gel is blotted and probed with an antibody against a specific protein. This approach does not offer much progress over conventional immunoblotting.

Protein Arrays

Due to some of the limitations of electrophoresis and mass spectrometry methods, selected research groups are attempting to create proteomic chips/arrays [66, 98]. Antibodies or other affinity reagents (e.g. aptamers, peptides) are spotted onto some sort of matrix. Hundreds to thousands of spots are on a single array. A labeled sample is then washed across the array and proteins bind to their specific antibody. The process can also be reversed whereby the protein samples of interest are spotted onto the matrix and then probed with different affinity reagents. While these array or chip approaches have potential for greatly increasing the throughput of proteomic experiments, the use of affinity reagents as the separation method is a severely limiting factor and cannot be ignored. A high-quality antibody is needed for each protein of interest and each modification of that protein. In order to generate quantitative data from antibody arrays, and because association kinetics between different antibodies and antigens can vary tremendously, relative concentrations of each antibody and antigen have to optimized for each protein. Though there seem to be a number of pitfalls to proteomic chips/arrays as an open screen technique they do hold promise for routine examination of a small group of proteins. Well-known pathways or gene families could be easily examined by such an approach.

Implementation for Drug Abuse Studies

Proteomic Analysis of Cocaine

Whereas several studies have assessed gene and subsequent protein expression as a function of cocaine administration in humans and animal models, few studies to date have employed high-throughput proteomic technologies to examine the effects of psychomotor stimulant administration on protein expression patterns in discrete

brain regions. Two examples of such approaches in this area include comparative analyses of proteomic alterations in the nucleus accumbens of cocaine overdose victims and controls and a complementary study in this region from rhesus monkeys self-administering cocaine for 18 months and controls.

The abuse liability of cocaine has been linked to the direct effects of the drug on dopamine uptake blockade, yielding elevated extracellular dopamine concentrations that occur in discrete areas of the brain, specifically the nucleus accumbens, ventral tegmental area, and prefrontal cortex—regions of the mesolimbic dopamine pathway, which originates in the ventral tegmental area and projects to several forebrain regions, most notably the nucleus accumbens. Numerous studies in rodent self-administration models have demonstrated definitively an important role for the nucleus accumbens in the reinforcing effects of cocaine [27, 29, 30, 67, 104]. Recent imaging studies in humans have revealed cocaine-induced functional activation of the nucleus accumbens following acute drug administration in cocaine-dependent subjects [7] and bilateral activation of the nucleus accumbens following imagery-induced drug craving [40]. In addition to the acute neurochemical and neurophysiological changes that occur as a function of cocaine, continued administration exerts biochemical adaptations in reinforcement-relevant brain regions [43, 57, 95] that are apparent at the structural, genomic, and proteomic levels and likely provide the biochemical foundation for sensitization, craving, withdrawal, and relapse [58]. For example, studies in rodent models indicate that chronic cocaine administration leads to persistent or even permanent biochemical alterations in the cyclic AMP pathway (e.g. [9, 69, 77, 90]), activator protein 1 family members (e.g. [33, 34, 68]), glutamate, dopamine, gamma-aminobutyric acid and opiate receptors, growth factors, cytoskeletal elements, and circadian genes [2, 3, 18, 28, 36, 46, 84, 101, 102].

Whereas animal studies have advanced our understanding of the neurobiological basis of drug addiction, the evaluation of similar questions in human tissue are few, yet are essential. Although there are many difficulties with post-mortem brain studies, it is one of the most promising ways to view biochemical changes that are relevant to human drug abusers and to educate the public about the consequences of cocaine abuse. By assessing changes in defined biochemical pathways in human post-mortem tissue, we can begin to ascertain the fundamental molecular and biochemical processes that are associated with long-term cocaine use. Furthermore, studies utilizing human post-mortem tissue will reveal whether the regulatory adaptations that occur in rodents and monkeys are applicable to human brain, and will reveal which changes are state or trait markers in human drug abusers.

To examine the neuropathological consequences of chronic cocaine abuse in the human brain, two-dimensional gel electrophoresis was used to compare protein alterations in the nucleus accumbens between cocaine overdose victims and controls [86]. The nucleus accumbens was dissected from coronal blocks of frozen brain tissue that had been obtained previously from subjects that were matched on a number of demographic and pathological indices. Tissue was fractionated into membrane, nuclear, and cytoplasmic fractions as previously described [31, 83], with only cytosolic fractions used for this study. Following image normalization between gels, spots with significantly differential image intensities were identified, excised, and trypsin digested. Differentially expressed proteins were identified by matrix-assisted laser desorption ionization-time of flight-time of flight mass spectrometry. Mass lists were submitted to MASCOT using GPS Explorer to search against the National Centre for Biotechnology Information non-redundant *primate* database for protein identification. The criterion for identification included a MASCOT confidence interval greater than 95%. Protein identification was confirmed by checking the protein mass and isoelectric point accuracy. One thousand four hundred seven spots were found to be present in a minimum of 5 subjects per group, and the intensity of 18 spots was found to be

differentially abundant between the groups, leading to the eventual positive identification of 15 proteins by peptide mass fingerprinting. In addition, 32 spots that were constitutively expressed were positively identified by peptide mass fingerprinting. The identified proteins can be categorized as cell structure, synaptic plasticity/signal transduction, mitochondria, and metabolism and are representative of functional classes that have been shown to be affected either directly or indirectly by cocaine administration. For example, previous studies in human cocaine overdose victims have reported significant dysregulation of ionotropic glutamate receptors in mesolimbic brain areas (ventral tegmental area and nucleus accumbens)—an effect that likely has far-reaching implications in terms of the mechanisms that support increased expression as well as the physiological implications of this upregulation. For example, liprin α3 (up-regulated over 2.5-fold in cocaine overdose victims) belongs to a family of proteins whose post-synaptic expression is involved in the transport of *N*-methyl-*D*-aspartate receptor vesicles along microtubules. Along with increased beta-tubulin (2.72-fold in cocaine overdose victims), these results begin to provide a framework that could mediate the increased levels of ionotropic glutamate receptor subunits at the membrane surface in cocaine overdose victims [31].

In addition to protein alterations that likely are involved in the maintenance of ionotropic glutamate receptor expression, the abundance of several metabolic proteins was altered in cocaine overdose victims, which may be related to the consequence of increased ionotropic glutamate receptor expression—such as increased calcium flux and resulting oxidative stress. For example, peroxiredoxin 2, a neuronal protein involved in redox regulation, was decreased in cocaine overdose victims. Previous studies have shown that cocaine administration increases lipid peroxidation [42], alters antioxidant enzyme activity, and elevates reactive oxygen species in dopaminergic projection areas [12, 48]. The mitochondrial protein ATP synthase beta chain, a protein that produces ATP from ADP, which is generated from electron transport complexes involved in mitochondrial respiration, was also decreased in cocaine overdose victims. These data provide but two examples by which chronic cocaine profoundly affects processes that are integral to normal neuronal function (i.e. decreased ability to reduce reactive oxygen species and improper functioning of energy metabolism). Such changes are likely reflected in changes in glucose metabolism and utilization following cocaine administration in rats [71], monkeys [47, 72], and humans [7, 74]. Understanding the coordinated involvement of multiple proteins in the human brain as a function of cocaine abuse provides unique insight into the molecular basis of the disease, offers new targets for pharmacotherapeutic intervention for drug abuse-related disorders, and has the potential to reshape the debate on which biochemical indices are most relevant to the human condition.

Whereas studies in the human brain are important for understanding the neuropathological consequences of chronic cocaine intake, factors such as agonal state, post-mortem interval, variability in drug intake, disease comorbidity, etc. may affect the stability of proteins as well as their post-translational modification. The use of non-human primate models of cocaine self-administration provides a critical bridge between human studies and basic research whereby the aforementioned variables that may confound human post-mortem studies are better controlled, allowing more precise correlation between drug intake and altered protein expression and function. Using a non-human primate model of cocaine self-administration with chronic access (18 months), the effects on protein abundance and phosphorylation were determined in the nucleus accumbens of rhesus monkeys using two-dimensional difference in gel electrophoresis and two-dimensional gel electrophoresis followed by gel staining with Pro-Q® Diamond phospho-protein gel stain, respectively. As detailed for the aforementioned studies in human post-mortem tissue, gel images were normalized for each set of experiments and spots with significantly differential image intensities

($P < 0.05$) were identified, excised, and trypsin digested and analyzed by matrix-assisted laser desorption ionization time of flight/time of flight mass spectrometry. Eighteen positively identified were found to be differentially expressed in the accumbens between the groups—a significant number of which were either directly or indirectly related to the hyperglutamatergia identified in both cocaine overdose victims and rhesus monkeys self-administering cocaine [31, 85]. Interestingly, the study identified several proteins that complement/supplement the results of the study in cocaine overdose victims, including proteins involved in cell structure, synaptic plasticity/signal transduction, metabolism, and mitochondrial function. Specifically, glial fibrillary acidic protein, syntaxin binding protein 3, protein kinase C isoform, adenylate kinase isoenzyme 5, and mitochondria-related proteins were increased in monkeys self-administering cocaine while beta-soluble *N*-ethylmaleimide-sensitive factor attachment protein and neural and non-neural enolase were decreased. In addition to determination of overall protein abundance, the study also explored the "functional" proteome of the accumbens, in this case by evaluating the expression of phosphorylated proteins. Of the identified spots on the gel, 15 phosphoproteins were positively identified, including increased levels of gamma-aminobutyric acid-A receptor-associated protein 1, 14-3-3 gamma protein, glutathione s-transferase, and brain type aldolase and decreased levels of beta-actin, Rab GDP dissociation inhibitor, guanine deaminase, peroxiredoxin 2 isoform b, and several mitochondrial proteins. Results from this study complement previous studies of cocaine-induced biochemical alterations in cocaine overdose victims using an animal model that closely recapitulates the human condition. The findings suggest a coordinated dysregulation of proteins related to cell structure, signaling, metabolism, and mitochondrial function that likely indicate long-term compromised cellular function. The reversal or attenuation of these biochemical alterations are important targets for addressing the neuropathology associated with drug abuse.

Proteomic Analysis of Alcohol

Similar to cocaine, the majority of proteomic analyses for alcohol abuse have been conducted in human post-mortem tissue, and the research has been guided largely by previous studies detailing significant changes in brain morphology, such as cortical and subcortical atrophy. Alcohol-induced changes in cortical and subcortical structure volumes have been correlated with both white and gray matter damage, and overall brain shrinkage in alcoholism is largely attributable to cortical white matter loss [8, 25]. Thus, in one of the first published proteomic studies of the effects of alcohol in the human brain, Matsumato and colleagues compared the proteomic profile of white matter in the dorsolateral prefrontal cortex between controls, uncomplicated alcoholics (>80 g of ethanol/day, no post-mortem evidence of cirrhosis or Wernicke-Korsakoff syndrome), alcoholics complicated with hepatic cirrhosis (>80 g of ethanol consumed per day, post-mortem confirmation of hepatic cirrhosis and no post-mortem evidence of Wernicke-Korsakoff syndrome), reformed alcoholic (>120 g of beer/day for 10 years, abstained last 14 years, no post-mortem evidence of cirrhosis or Wernicke-Korsakoff syndrome). The elegant experimental design addresses multiple comparisons simultaneously, including the effects of alcoholism in the human brain (controls vs. uncomplicated alcoholics), peripheral versus centrally mediated effects on protein alterations (uncomplicated alcoholics vs. alcoholics complicated with hepatic cirrhosis), and the transient or permanent nature of alcoholism on brain protein changes (uncomplicated alcoholics vs. reformed alcoholics). Following dissection of the dorsolateral prefrontal cortex, crude protein homogenate was isolated from each subject and separated using two-dimensional gel electrophoresis followed by protein identification using matrix-assisted laser desorption ionization time-of-flight mass spectrometry. The study found 60 protein spots that were differentially expressed between controls and alcoholics, of which

18 were positively identified, representing 11 proteins including proteins involved in cell structure and metabolism, with the most interesting finding being that thiamine deficiency may be related to alcohol-induced brain damage to this region. Interestingly, NADH2 dehydrogenase and fructose-biphosphate aldolase C were the only two proteins that were differentially expressed between the uncomplicated and complicated alcoholics.

Complementary proteomic analyses have also been conducted in the genu [38] and splenium [39] of the corpus callosum—a structure the volume of which is decreased in alcoholics [26]. The corpus callosum is of particular interest given that it is the major white matter structure connecting the total cerebral hemispheres, allowing exchange of sensory, motor, and cognitive information. Using similar cohorts and proteomic approaches, two regions of the corpus callosum were assessed—the genu and splenium. In the splenium, 43 proteins were found to be differentially expressed between alcoholics and controls, with 26 proteins present in the complicated alcoholic group that were involved in oxidative stress, lipid peroxidation, and apoptosis networks. The prevalence of protein alterations in the complicated alcoholic group suggests a potential relationship with liver dysfunction and cirrhosis. Similarly, 50 identified proteins were differentially expressed in alcoholics in the genu of the corpus callosum, with seven proteins unique to the uncomplicated alcoholic group and 28 unique to the complicated alcoholic group. Differentially expressed proteins were categorized as cytoskeletal, metabolic, oxidative stress related, calcium regulation, and signaling proteins. Comparative analysis between the three studies indicated significant region-specific protein expression in different regions of white matter (corpus callosum genu, corpus callosum splenium, and dorsolateral prefrontal cortex), suggesting that there are regional differences in their susceptibility to the effects of chronic alcohol.

In addition to determining potential protein correlates of regional white matter alterations induced by alcohol, separate studies have explored alcohol-induced alterations in the hippocampus of human post-mortem tissue [52] and in the nucleus accumbens and amygdala of a rodent model of chronic alcohol intake [5]. These regions are known to be sensitive to the effects of alcohol with changes in the functional integrity that affect short-term and spatial memory and reward circuitry. Both studies utilized standard two-dimensional gel electrophoresis approaches and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry analysis. In the human post-mortem study, crude protein homogenates from the hippocampus were compared between uncomplicated alcoholics and controls. Seventeen proteins were identified that were differentially expressed between the groups—proteins involved in metabolism, signaling, and oxidative stress. Comparison with other data from this group emphasizes the regional specificity of alcohol-induced changes and provides a framework for determining the biochemical mechanisms of alcohol-induced neuropathology.

In addition to the use of human post-mortem tissue to understand the effects of alcohol, the field has benefited by the use of well characterized rodent models that exhibit varying degrees of alcohol consumption. As the aforementioned studies in humans have provided exceptional insight into the pathology associated with chronic alcohol intake, the continuum of alcohol abuse and alcoholism includes biochemical changes in regions associated with the rewarding effects of alcohol—for example, the nucleus accumbens and amygdala. Using the inbred alcohol-preferring rat line, Bell and colleagues compared the effects of alcohol access (continuous, multiple scheduled access, and ethanol naïve) on the expression of proteins obtained from crude protein homogenates. Data revealed proteins in the accumbens and amygdala that changed in the same direction in the continuous and multiple scheduled access groups, suggesting that these proteins were altered as a function of alcohol consumption. In addition, numerous proteins were found to be differentially expressed based on brain region and on exposure to alcohol. The amygdala appeared to

be more sensitive to the cellular stress-related effects of chronic alcohol, whereas protein identifications in the accumbens reflected alterations in synaptic and cytoskeletal activity, which led the authors to suggest increased neuronal function. Examination of the differentially expressed proteins identified in this study in other behavioral models and at various times along the alcohol exposure continuum is warranted.

Conclusions

The advent of proteomics technologies provides a unique opportunity to discover and explore biochemical substrates and consequences associated with abused substances. Results from rodent, non-human primate, and human post-mortem studies indicate significant impairments in neuronal function and plasticity in several brain regions. To date the majority of studies have utilized rodents to model human cocaine intake; however, growing evidence indicates the need to refine rodent and non-human primate models to better recapitulate human drug intake and associated neuropathologies. As in other psychiatric and neurological illnesses, researchers should identify the molecular pathologies associated with cocaine addiction in humans and attempt to recapitulate such biological alterations in animal models.

Understanding the coordinated involvement of multiple proteins with chronic cocaine and alcohol addiction provides insight into the molecular basis of drug dependence in general and may offer novel targets for pharmacotherapeutic intervention. Although significant advances have been made in the identification of neurochemical and neurobiological substrates involved in the behavioral effects of abused drugs, the relationship between these effects and resultant alterations in protein expression remains in its infancy, and the application of this information to the development of treatment strategies has not been fruitful for several reasons. One explanation is that studies in the areas of neurobehavioral pharmacology and molecular biology have proceeded in relative isolation of each other. To date, there have been few published studies combining models of self-administration with proteomic approaches. Other possible explanations include: (1) the inappropriate use of experimental models, (2) reliance on non-neuronal systems or neuronal tissue not directly involved in the reinforcing effects of the drug, and (3) the lack of definable neural substrates at the cellular or biochemical level. The combination of appropriate behavioral models of drug reinforcement, specific neurobiological systems, and state-of-the-art molecular techniques will provide the most pertinent data for understanding the molecular basis of drug reinforcement and for potentially establishing novel targets for treatment.

A more detailed understanding of the molecular and biochemical cascades in specific neuronal populations and the interactions between well-defined neuronal populations within discrete brain regions could lead to a greater knowledge of the basic neurobiological processes involved in drug reinforcement. Future efforts investigating the biological basis of drug reinforcement should be directed at specific cellular targets in brain regions considered to be involved in drug reinforcement, and should focus on cortical influence on behavior—structures that are best studied in human post-mortem tissue and in non-human primate models. The integration of basic neuroscience and behavior offers the most productive avenue for delineating the complexity of the neurobiological underpinnings of drug reinforcement and the subsequent development of effective pharmacotherapies to treat addiction.

Part IV
Clinical Aspects of Alcohol and Drug Addiction

Alcohol: Clinical Aspects

Introduction

Alcohol is both the oldest and the most widely used psychoactive substance in the world. The use of alcohol is a part of most cultures worldwide, and it is recognized that there are both positive and negative aspects of alcohol consumption. Positive aspects might include the stimulation of appetite, aiding in sleep, and reduction in the incidence of heart disease. The negative aspects include poor judgment, liver disease, hypertension, memory problems, and even death. Of course, as with all drugs, there is a risk of addiction to alcohol, which exacerbates the negative aspects of alcohol use and leads to its own sequelae of complications and disorders. The National Institute on Alcohol Abuse and Alcoholism notes that "men who drink 5 or more standard drinks in a day (or more than 14 per week) and women who drink 4 or more in a day (or more than 7 per week) are at increased risk for alcohol-related problems" [75].

There are six levels of alcohol use: abstention, experimentation, social or recreational use, habituation, abuse, and, finally, addiction. Abstention is non-use. Experimentation is the use of alcohol for curiosity and without any subsequent drug-seeking behavior. Social or recreational use of alcohol involves sporadic infrequent drinking without any real pattern. Habituation involves drinking with an established pattern, but without any major negative consequences. Abuse of alcohol is the continuation of drinking despite negative consequences.

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_17,

Finally, addiction to alcohol involves a compulsion to drink, an inability to stop drinking, and the progression of major life dysfunction with continued use [48].

In the United States, the per-capita consumption of alcohol from beer, wine, and spirits combined in 2006 was 2.27 gallons. This value had risen from 2.23 gallons in 2005, a 1.8% increase. Essentially, since 1999 there has been a general increase in per-capita consumption of alcohol [76].

Alcohol dependence is a significant cause of morbidity and mortality in the United States and worldwide. The World Health Organization reports that about 140 million people throughout the world suffer from alcohol dependence [43]. Worldwide, alcohol causes 1.8 million deaths per annum. Eight million people in the United States are dependent on alcohol [37, 60]. Mortality rates follow drinking levels. A European study of 25 countries found that a rise of 1 liter per capita in alcohol intake was associated with a 1% rise in all causes of morbidity [45]. In Europe, men between the ages of 15 and 29 years have a 1 in 3 to 1 in 4 chance of dying as a result of alcohol [60]. The global economic burden of alcohol was estimated to be in the range of $210–665 billion in 2002 [3].

In the United States, more than 50% of adults have a close family member who is dependent on alcohol [20]. More than 25% of youths under the age of 18 years are aware of a relative who is dependent on alcohol [43]. Alcohol dependence runs in families [5, 16, 67].

The burden of the alcohol dependence disease is not equal across all regions. The disease impact of alcohol dependence is greatest in regions where the per-capita consumption is highest, such as Latin America, as compared with the Middle East. Additionally, other factors, such as increasing economic growth, have raised the risk of alcohol dependence in Europe [84].

Alcohol consumption increases the risk of harm or death in the context of the operation of heavy machinery, fires, falls, and water activities. In the United States, approximately 40% of all traffic fatalities are alcohol related [14]. Trauma and aggressive behavior are associated highly with alcohol consumption less than 6 h prior to the event.

Alcohol-Related Disorders

Alcohol is associated with many physical and mental disorders. Perhaps the most well-documented physical disorder is alcohol-related liver disease. Alcohol-induced fatty liver disease and obesity are both associated with progression to cirrhosis [13, 21]. In the United States, more than 900,000 individuals have cirrhosis; about 33% of these cases are attributed to excessive alcohol consumption. Typically, the development of cirrhosis requires the consumption of at least 80 g of ethanol daily for 10–20 years [61]. Additionally, the presence of hepatitis C virus in the context of alcohol dependence is associated with increased rates of cirrhosis [88, 91]. Women have an increased incidence of liver cirrhosis due to a greater level of alcohol consumption than men; however, there also might be increased susceptibility due to female gender [18, 80]. Globally, esophageal cancers, head and neck cancers, and liver cancers are of great concern, and are associated with alcohol abuse or dependence [10].

Individuals with mental illness are susceptible to alcohol abuse and dependence. This, in part, may be due to attempts to self-medicate anxiety, mania, or depression. Drinking alcohol in excess tends to worsen underlying psychiatric illness. Excessive use of alcohol is associated with a poorer chance of recovery from anxiety and depressive disorders [44]. Bipolar disorders and other impulse control disorders are associated with high rates of alcohol dependence. Dually diagnosed individuals have a poorer prognosis than those with just one of these disorders [23, 97]. Drinking more than 29 drinks per week can double the risk of a psychiatric disorder. Dementing illnesses, such as Alzheimer's or multi-infarct dementia, can be worsened or be caused by alcohol, and the relationship between the two can be difficult to determine [90]. Alcohol abuse and dependence are common

in individuals with schizophrenia and worsen symptoms of the disease [30, 34, 59]. Individuals with mental illness tend to underreport their use of alcohol [96].

Age of Onset of Drinking Behavior

The age of onset of drinking has a significant role in outcomes. An individual who starts drinking before the age of 15 years is approximately 4 times more likely to develop alcohol dependence, and this rate increases the earlier the onset of drinking [25]. Data collected from the 2005 National Survey on Drug Use and Health found that the mean age of the initiation of alcohol use among 12–20 year olds was 14 years [76]. Furthermore, according to the Monitoring the Future survey in 2004, 33.9% of eighth graders reported recreational use of alcohol within the past year [76]. The risk of developing alcohol dependence and a more relapsing illness is greater in adolescents compared with adults [46]. Notably, between 20 and 30% of early alcohol drinkers progress to heavy drinking in adulthood [32, 38]. Children who drink often have behavioral problems, especially conduct disorders [28, 51]. Frequently, adolescents, much like adults, are self-medicating for anxiety and depression [56, 87].

Alcohol dependence is a heterogeneous disorder and consists of subtypes, each with "varying degrees of biological and psychosocial antecedents" [6, 16, 52, 92]. The relationship between biological vulnerability, the environment, and their interactions in the development of alcohol dependence is the subject of active research [55]. Current evidence suggests that alcoholism is 50–60% determined genetically in both men and women [27]. The term "psychiatric pharmacogenetics" has now entered the alcohol literature. Its purpose is to use genetic testing to predict, on an individual level, which treatment will be efficacious [41].

Contrary to conventional wisdom, there are a number of studies showing that alcohol dependence is not always a chronic and progressive disease. This assertion is based on longitudinal studies and national surveys. It appears that those who develop alcohol dependence in middle age have the most stability in terms of the disease. In this population, alcoholism can be a chronic remitting disease [38, 39, 100, 102, 103]. In contrast, individuals who develop alcoholism over the age of 50 years will often decrease their drinking as they age. Interestingly, alcohol dependence in those over 65 years of age continues to increase in the United States.

Recently, the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions analyzed recovery rates of alcohol-dependent adults over a 1-year period. This population tended to be middle-aged, white males who were well educated (60% college educated); thus the generalizability is limited. More than half of the 4,422 adults had experienced the onset of alcohol dependence between the ages of 18 and 24, and only 25% had ever received any treatment for alcohol problems. At 1 year, 35.9% were fully recovered (17.7% low-risk drinkers plus 18.2% abstainers), 25% were still dependent, 27.3% were in partial remission, and 11.8% were "asymptomatic drinkers". Only 25% of the group had ever received any type of treatment [20].

Ethnicity, Gender, Place of Residence, and Religion Affect Alcohol Consumption

Ethnicity is a complex and multifaceted construct, and often the terms used by demographers do not reflect the different subgroups. For example, Korean Americans and Chinese Americans are both considered as "Asian", but drinking patterns are quite distinct between these two groups. A study conducted in 2004 found a lower rate of alcohol dependence in Chinese-American college students (5%) as compared with Korean-American college students (13%)

[29]. First-generation Mexicans and native-born Mexicans behave differently in their drinking patterns [12, 35]. Whites have the highest consumption levels, followed by Latinos and, then, Blacks. There is considerable ethnic disparity in the progression of drinking behavior. White men peak first (18–25 years), followed by Hispanic and Black men, with peak ages between 26 and 30 years. Although levels of drinking tend to be low among native-born Latinos, acculturation stress increases alcohol abuse and dependence with migration and first-generation populations [9, 12]. Ethnicity and socioeconomic status are also tied to the level of drinking [36].

Currently, women have nearly the same rates of alcohol dependence as men. This is in contrast with 1940, when men were more than twice as likely to be alcohol dependent. Interestingly, women often have a more severe disease course—perhaps due to reduced access to care, a greater time period before seeking treatment, or both.

Despite common misperceptions, the extent of drinking among Native Americans varies tremendously by tribe. The proportion of Native Americans who reported being current drinkers ranged from a low of 30% to a high of 84%. This wide range of reported drinking behavior is indicative of considerable variance between Native American tribes' alcohol use. Furthermore, it has been reported that Northern reservations have a higher incidence of hospital admittance for an alcohol-related medical problem than Southern reservations (111/1,000 versus 11/1,000, respectively) [99]. On some Native American reservations, high quantities of alcohol are consumed per episode, but the frequency of binge drinking is low [78].

Location also matters. Urban and suburban dwellers have higher rates of dependence compared with their rural counterparts. Drinking styles also differ.

Religion appears to be an important determinant for drinking [68]. Jews, Episcopalians, and Baptists living in rural areas show low rates of alcohol dependence compared with the general population.

Clinical Picture

Alcoholism can present in a multitude of ways, and at times its clinical effects can be subtle. Whilst there is no typical clinical pattern for an individual's progression from excessive drinking to alcohol dependence, there are certain themes that prevail. These are based on the pathophysiology of alcohol.

An early manifestation of excessive drinking is intoxication. This can begin with one's peers or by the influence of an older individual or family member. Some individuals note stress, depressed mood, or negative affect as a driving force, although at times it is elation. For others, there is an urge to drink, or "craving". Although the concept of craving appears simple, the craving literature has found it difficult to define with consensus. When alcohol consumption leads to repeated bouts of intoxication and becomes a fixed pattern of behavior, the likelihood of alcohol-related problems increases.

As the body adapts to excessive alcohol consumption, tolerance develops. With tolerance, an increasingly greater amount of alcohol consumption is needed to obtain the same physiologic effects. This can manifest as worsening grades or sick days among college students and workers and, for both, an increase in stress within interpersonal relationships, often characterized by greater irritability and moodiness. Furthermore, driving while under the influence of alcohol becomes more likely, and can lead to legal complications as well as morbidity and mortality to drivers, passengers, and other bystanders.

Heavy drinking can lead to blackouts, a failure to recall the events around the intoxication, due to the brain's inability to process and lay down the memory in the hippocampus.

Hangovers, which are associated with headaches and nausea, can manifest the next morning after a bout of heavy drinking. Often, as duties and responsibilities lapse, attention to hygiene can wane, and the chronic drinker's demeanor and behavior change. Memory lapses or forgetfulness may become more evident. Also, the chronic excessive drinker may report

guilt, remorse, and self-loathing after consuming alcohol and might conceal his or her drinking in order to avoid dealing with others. Such individuals tend to minimize the severity of their drinking behavior and its impact on others.

When drinking is being concealed, social isolation tends to occur, and to block or dampen guilt and anxiety, "relief drinking" can happen. Relief drinking may serve not only to temper these feelings but also to reduce transiently the resulting insomnia. Relief drinking might also ameliorate temporarily withdrawal symptoms upon drinking cessation (often starting within a few hours), which are the consequence of the sympathetic nervous system hyperactivity. These symptoms can include tremulousness and anxiety, and can proceed to a spectrum of serious withdrawal patterns, including delirium tremens. Despite any painful consequences such as loss of relationships, employment, legal entanglements, and physical and psychological complications, drinking can become the individual's sole goal. The physical features of the disease are described below.

Signs and Symptoms

Cardiovascular System

While it has been consistently shown that light-to-moderate drinking reduces the risk of coronary artery disease, there still remain severe risks to the cardiovascular system for people who are heavy alcohol drinkers [57, 64, 83, 85]. Cardiovascular conditions that may result from heavy drinking include hypertension, cardiac arrhythmias, and dilated cardiomyopathy.

The relationship between hypertension and heavy alcohol use has been known for more than three decades. While a mechanism has yet to be elucidated, several clinical studies have confirmed this relationship [54, 58, 65]. Clinicians in all fields of medicine should be aware that hypertension can be the result of heavy and chronic alcohol consumption.

The incidence of cardiac arrhythmias following excessive alcohol consumption is commonly known as "holiday heart phenomenon" following the observation that supraventricular arrhythmias in alcoholics most often occur on Mondays or between Christmas and New Year's Day [31]. While the direct cause of arrhythmias following heavy drinking is not explicitly known, it has been suggested that it could be due to myocardial damage, vagal reflexes, electrolyte or metabolic effects, or changes in conduction and refractory periods. Regardless of the root cause, the incidence of cardiac arrhythmias doubles for heavy drinkers compared with light drinkers [17].

Dilated cardiomyopathy is characterized by an enlarged heart with weakened contraction. Sustained heavy alcohol use is thought to be a major contributing factor to dilated cardiomyopathy [53]. Whilst the prevalence of alcohol-induced dilated cardiomyopathy is not fully known, it is estimated to be less than those who have alcohol-related liver cirrhosis [24]. The clinical picture may initially involve non-specific electrocardiographic findings and possible rhythm disturbances but may progress to congestive heart failure, chronic rhythm disturbances, and even death [7, 82].

Gastrointestinal System

Excessive alcohol consumption can cause gastroesophageal reflux disease, gastritis, or ulcers in the lining of the stomach. These can manifest as a burning in the throat or stomach or complaints of dark stools (i.e., melena). In individuals who present with a long history of gastroesophageal reflux disease, there is an increased incidence of Barrett's esophagus. Barrett's esophagus, a metaplastic conversion of the mucosa of the lower esophagus, is a well-known precursor lesion for esophageal cancer.

Chronic excessive alcohol consumption can cause varices, both gastric and esophageal. When varices rupture, often during severe retching, the individual may present with bright red blood. Bleeding varices are life-threatening

medical emergencies. Mallory-Weiss tears from esophageal varices often require monitoring in intensive care settings due to their risk for rebleeding with a high rate of blood loss.

Hepatic System

Chronic excessive alcohol consumption is associated with an increased risk for the development of liver disease. In the United States, 2 million people have alcoholic liver disease, ranging in severity from fatty liver to alcoholic hepatitis and end-stage cirrhosis [72].

Fatty liver is the accumulation of fatty acids in the liver. The pathogenesis of fatty liver is due to the overproduction of protonated nicotinamide adenine dinucleotide from alcohol dehydrogenase, which, in turn, leads to the inhibition of fatty acid oxidation, the citric acid cycle, and gluconeogenesis [62]. It is the inhibition of fatty acid oxidation, as well as an increased synthesis of triglycerides, followed by the inhibition of the secretion of lipoprotein from the liver, which all contribute to fatty liver [93].

Alcoholic hepatitis causes inflammation of the liver along with areas of fibrosis and necrosis. In the United States, approximately 10–35% of heavy drinkers develop alcoholic hepatitis. It can take months to years to develop this condition, and the only method to arrest its progress is through abstinence. Nevertheless, even with the cessation of alcohol consumption, the resulting scarring of the liver and any other collateral damage remain [69]. The mortality rate in individuals with alcoholic hepatitis is 15–20%, and even despite abstinence, many cases progress to cirrhosis [79].

Cirrhosis is characterized by progressive scarring of the liver due to the toxic effects of excessive alcohol use and alcohol's metabolites. Cirrhosis, the most advanced form of alcoholic liver disease, is the leading cause of death among alcoholics. Approximately 10,000 to 24,000 Americans die each year from cirrhosis due to excessive alcohol use [22]. Individuals with a diagnosis of both alcoholic hepatitis and cirrhosis have a death rate of more than 60% over a 4-year period. Most individuals die within the first 12 months of receiving the diagnosis [72]. Whilst the progression of cirrhosis might be halted by abstinence, cirrhosis is very difficult to treat, and the damage to the liver cannot be reversed.

Endocrine System

Pancreatitis, both acute and chronic, is another complication of excessive alcohol use. Pancreatic insufficiency or malabsorption presents with gray, foul-smelling stools that float. Pancreatitis typically manifests with pain in the center of the abdomen that radiates to the back. Pancreatitis ranges from an uncomfortable but stable condition to a medical emergency, depending on the severity of the event. Individuals with chronic pancreatitis may have calcifications that can be seen on a plain radiographic film.

Diabetes, both Type I and Type II, can be a consequence of excessive alcohol use. The development of Type I diabetes is rare and due to almost complete destruction of the pancreas. Type II diabetes is more common and due to weight gain from carbohydrate ingestion. Hypogonadism and osteoporosis are other complications. Thyroid disease also can be a sequela of excessive alcohol use, abuse, or dependence.

Rheumatic and Immune System

Chronic excessive alcohol consumption has been linked with an increase in illness and death from infectious diseases. Due to alcohol's immunosuppressive effects, there is an increased susceptibility to bacterial pneumonia, pulmonary tuberculosis, and hepatitis C. There is even some speculation that chronic excessive alcohol users are at increased risk for HIV infection due to lowered immune response, and those with HIV

may have a quicker progression from HIV to full-blown AIDS [72].

Gout is a common complication of chronic excessive alcohol consumption. Podagra (pain in the big toe) is a typical complaint. Alcohol use appears to mitigate certain autoimmune conditions such as systemic lupus erythematosis and rheumatoid arthritis.

Hematologic/Hematopoietic System

Anemias, both macrocytic and microcytic, are possible. Macrocytic anemia can be due to folate or vitamin B_{12} deficiency. An increased mean corpuscular volume can reflect macrocytic anemia. Of note, an increased mean corpuscular volume can also be a result of liver disease when the lipid bilayers that hold the red cell do not form correctly. When liver disease is severe, platelets can be destroyed or can sequester in an enlarged spleen. Microcytic anemias are related to active bleeding or blood loss and should prompt evaluation for a gastrointestinal disorder or lesion. Sideroblastic anemia can also occur.

Central Nervous System

The brain is sensitive to alcohol's toxic effects. Areas that are particularly sensitive include the hippocampus and the cerebellum, which can result in memory deficits and dementias as well as abnormal gaits and intention tremors. Rarely, central pontine myelinolysis can occur. These central nervous system deficits will be discussed in detail below.

Peripheral Neurologic System

Changes in position and vibration sense occur after prolonged excessive alcohol use and are due to vitamin B_{12} or folate deficiencies, or both. Myopathy can be a rare manifestation of alcohol dependence.

Integumentary System (Skin)

Psoriasis vulgaris, acne rosacea, and erythropoietic protoporphyria are all common skin conditions associated with excessive alcohol use. With liver disease, spider nevi, telangiectasias, palmar erythema (reddened palms), spider angiomas, and hepatic porphyrias, particularly porphyria cutanea tarda (bullous erosions, blistering, crusting lesions, and scarred healing with hyperpigmentation or depigmentation on the face, the side of the neck, and the back of the hands), might be found.

Nutritional Status

Low levels of potassium, magnesium, and phosphorus are common among individuals with severe alcohol dependence. Hypophosphatemia and hypomagnesemia also can be complications of severe nutritional deficiency. A refeeding syndrome that can lead to diaphragmatic paralysis and respiratory failure can occur. On many blood chemistries, magnesium and phosphorus are not part of the panel. Therefore, it is prudent to check these electrolytes in an alcohol-dependent individual who appears nutritionally compromised. Low levels of potassium can cause additional medical complications (particularly cardiovascular) if not replaced; however, this can be difficult to achieve in the setting of low magnesium. Therefore, magnesium and potassium need to be replenished simultaneously. As noted previously, thiamine replacement is also often required.

Oncology

An increasing number of cancers are being associated with excessive alcohol use or dependence.

Traditionally, alcohol-related cancers include oropharyngeal, esophageal, gastric, pancreatic, and rectal cancers. In women, alcohol abuse has been reported to contribute to the etiology of breast cancer.

Fetal Development

The consumption of alcohol during pregnancy has been linked with poor birth outcomes, the potential for long-term developmental disabilities, and the manifestation of fetal alcohol spectrum disorder, which includes fetal alcohol syndrome [2]. In 2004, it was estimated that a half-million women in the United States reported drinking alcohol during pregnancy. Nearly 1 in 5 of these women admitted to binge drinking. The resulting prevalence of American women drinking alcohol during pregnancy is 13% [33].

It has been estimated that the annual cost of care for those diagnosed with fetal alcohol spectrum disorders is $3.6 billion and that the lifetime cost for a single individual is $2.9 million [63]. These numbers are staggering considering that maternal alcohol use during pregnancy is one of the leading causes of preventable birth defects and developmental disabilities in the United States [40]. The health care community continues to emphasize prevention and stresses abstinence from alcohol for women who are pregnant or considering becoming pregnant. Research into the clinical management of persons diagnosed with fetal alcohol spectrum disorders is still emerging, but human studies using behavioral intervention are encouraging.

The clinical manifestations of fetal alcohol exposure fall under the classification of fetal alcohol spectrum disorders. Fetal alcohol spectrum disorders can be further subdivided into four categorical syndromes: (1) fetal alcohol syndrome; (2) partial fetal alcohol syndrome; (3) alcohol-related neurodevelopmental disorder; and (4) alcohol-related birth defects [8]. Approximately 1–4.8 of every 1,000 children born in the United States have fetal alcohol syndrome, and nearly 1 in 100 children are born with fetal alcohol spectrum disorders [89]. A clinical diagnosis of fetal alcohol syndrome requires alcohol exposure, a recognizable facial pattern that includes short palpebral fissures (<10th percentile), thin upper vermilion lip, and smooth philtrum, evidence of growth retardation or malformation, and evidence of neurocognitive defects. Fetal alcohol syndrome newborns may exhibit irritability, tremors, hypotonia, and even withdrawal symptoms. Partial fetal alcohol syndrome is diagnosed when there is confirmation of alcohol consumption during pregnancy and, while not all the features of fetal alcohol syndrome are present, neurocognitive and some craniofacial features are present. Children diagnosed with alcohol-related neurodevelopmental disorder do not typically have the growth retardation or facial features characteristic of fetal alcohol syndrome, but the resulting neurocognitive defects are more pronounced. A diagnosis of alcohol-related birth defect requires some of the facial features characteristic of fetal alcohol syndrome, but it is the behavioral features or structural abnormalities that are more prominent [70].

In addition to the physical impairments inflicted by alcohol, there is a spectrum of cognitive problems that children diagnosed with fetal alcohol spectrum disorders exhibit. These problems include difficulties with hyperactivity, sustained and focused attention, cognitive flexibility, learning and memory, and social understanding [50]. Aside from cognitive deficits, these children can also exhibit psychological and behavioral difficulties such as psychiatric problems, inappropriate sexual behavior, and alcohol and/or drug abuse [98]. In fact, 90% of those diagnosed with fetal alcohol spectrum disorders have some form of diagnosable psychiatric disorder ranging from attention deficit disorder to depression to schizophrenia. Fifty percent have been confined in either a mental health or criminal justice institution [63].

Although perinatal exposure to alcohol is known to be detrimental to fetal development, there is some debate as to whether it is ethanol or its metabolite acetaldehyde that causes the

developmental abnormalities found in fetal alcohol syndrome. Acetaldehyde is 10 times more teratogenic than alcohol [81]. However, this differential in teratogenicity is, perhaps, countered by the fact that blood ethanol concentration is 10 times higher than acetaldehyde in the typical person.

Acetaldehyde levels in excess of 35 μg can cause damage to a fetus, but acetaldehyde is rapidly metabolized by the placenta, and, after the third month of pregnancy, no acetaldehyde is detectable in the fetus [77]. The placenta is, however, permeable to ethanol, and the fetus does not have ethanol dehydrogenase, the enzyme required to break down ethanol. It is, therefore, reasonable to propose that an hour or two following alcohol ingestion, the ethanol concentration in the mother's blood may be falling while the ethanol concentration of the fetus may be rising [49]. Although it is not clear whether it is alcohol itself or its metabolite acetaldehyde that is responsible for the developmental abnormalities found in fetal alcohol spectrum disorders, the physical findings in fetal alcohol syndrome do point to an interesting fact: it is not the disruption of developing tissues, but rather the reduction in the number of cells and the subsequent cell migration abnormalities, particularly of the central nervous system, that causes the anomalies found in fetal alcohol syndrome.

Psychological and Psychiatric Complications of Alcohol

Individual differences in human physiology cause varying physical manifestations of the effects of both acute and long-term use of alcohol. Alcohol affects almost all organ systems through the natural progression of the disease. These are characterized as acute, chronic, and withdrawal effects.

Acute Effects

The acute effects of alcohol ingestion can be progressively tracked using the concentration of alcohol in a person's blood, or blood alcohol concentration. The unit of measurement for blood alcohol concentration is weight by volume, such as milligrams per deciliter, but can also be expressed as a percentage, such as 5% alcohol by volume [1]. The acute effects of alcohol consumption follow the typical dose-response relationship characteristic of all drugs in that the bigger the dose, the bigger the effect [72]. The typical progressive effects of alcohol intoxication in relation to blood alcohol concentration are illustrated in Table 1 [73, 74]; however, there is considerable personal variation.

The metabolism of alcohol occurs at a rate of about 1 ounce of pure alcohol (2 drinks) eliminated from the body every 3 h. Following alcohol consumption, it takes about 15–20 min for alcohol to reach the brain and cause impairment. The maximum blood alcohol concentration is reached 30–90 min following the ingestion of alcohol [71].

It is generally accepted that the consumption of a standard serving of alcohol (14 g, or 17.74 ml ethanol content) will increase the average person's blood alcohol concentration by 0.02–0.05%. The average person's blood alcohol concentration decreases approximately 0.015% per hour following complete cessation of alcohol intake. A blood alcohol concentration of 0.20% represents very serious intoxication. A blood alcohol concentration ranging between 0.35 and 0.40% could be potentially fatal alcohol poisoning. The accepted LD_{50} for alcohol—i.e., the dose that is lethal for 50% of the adult human population—is 0.40% [74].

Besides the well-known acute effects of alcohol consumption such as lowered inhibitions, impaired ability to drive, slowed reaction time, slurred speech, and blackouts, some rare complications can occur. These include alcohol-induced psychotic disorder, central pontine myelinolysis, and acute alcoholic myopathy.

Alcohol-induced psychotic disorder or alcohol hallucinosis occurs most often in the context of drinking but can also occur in the presence of withdrawal. It is characterized by the acute onset of visual and auditory hallucinations

Table 1 The progressive effects of alcohol

Blood alcohol concentration	Changes in behavior	Activity impairment
0.01–0.05	Relaxation	Impaired alertness
	Feeling of well-being	Impaired judgment
	Loss of shyness	Minor impairment of memory
	Loss of inhibitions	Minor impairment of reasoning
	Exaggerated behaviors	
0.06–0.10	Feeling of euphoria	Impaired coordination
	Feeling of pleasure	Impaired balance
	Numbness of feelings	Impaired speech
	Nausea and sleepiness	Impaired vision
		Slow reaction time
0.11–0.20	Anger	Impaired reasoning
	Mood swings	Impaired depth perception
	Feeling of sadness	Inappropriate social behavior
	Confusion	Impairment of motor coordination
	Feeling of restlessness	Slurred speech
	Nausea and vomiting	Severely impaired judgment
	Disorientation	Severe memory impairment
		Blackouts
0.21–0.30	Aggression	Loss of balance
	Depression	Loss of temperature regulation
	Stupor	Loss of consciousness
	Reduced sensations	May be difficult to awaken
	Nausea and vomiting	
0.31–0.40	Unconsciousness	Loss of bladder control
	Coma	Difficulty breathing
	Death possible	Slowed heart rate
0.41 and greater	Death

and often includes delusions of a persecutory nature. These hallucinations and delusions usually resolve within 48 h although in some cases they can last much longer.

Central pontine myelinolysis is a rare disorder that is most often found in individuals who abuse alcohol. This disorder typically evolves over days to weeks, and the individual presents with mental confusion along with dysarthria, mutism, dysphagia, conjugate gaze palsies, and facial and neck weakness. Chronic hyponatremia seems to be a precipitating factor in the development of central pontine myelinolysis. Characteristic of the complication is bilaterally symmetrical focal destruction of white matter in the ventral pons. Approximately 10% of individuals display extrapontine lesions in the thalamus, basal ganglia, cerebellum, and cerebral white matter. As the name of the disorder implies, these lesions are typified by a loss of myelin [26]. With proper support, individuals diagnosed with this condition typically regain some or all function after a few weeks [11].

Acute alcoholic myopathy is a severe and life-threatening disorder that typically presents following several days of binge drinking [42]. Individuals typically present with pain, tenderness, cramps, proximal weakness, and swelling of the muscles, which can lead to cardiac arrhythmias. Further complications of acute alcoholic myopathy include hyperkalemia, renal failure, and even death. Following abstinence, recovery takes from a few days to weeks.

Chronic Effects

Although the physical effects of chronic alcohol abuse or dependence are well characterized, the psychological and psychiatric consequences are

less familiar. Such chronic complications from chronic alcohol abuse or dependence include Wernicke's encephalopathy, Korsakoff's psychosis, alcoholic neuropathy, chronic alcoholic myopathy, and alcoholic dementia.

Wernicke's encephalopathy is caused by thiamin (vitamin B_1) deficiency and is usually diagnosed by a triad of symptoms: ataxia, oculomotor abnormalities, and global confusion [86, 104]. Wernicke's encephalopathy, however, is not just a condition of alcoholics but is found in people who are malnourished due to persistent vomiting, are experiencing starvation, or are undergoing renal dialysis. Gait ataxia is a prominent symptom, as are nystagmus and bilateral rectus palsies. The global confusion is characterized by sleepiness, disorientation, and inattention. Treatment (i.e., vitamin B_1 supplements) can correct most or all of the disturbances, but if left untreated, the mortality rate is 10–20%. Individuals surviving Wernicke's encephalopathy, however, tend to acquire Korsakoff's psychosis [4, 63].

Korsakoff's psychosis is a chronic amnesic disorder that can occur in individuals who have had Wernicke's encephalopathy. Like Wernicke's encephalopathy, Korsakoff's psychosis is the result of thiamin deficiency. It is manifested by retrograde and anterograde amnesia, the latter caused by an inability to lay down new memories. While immediate recall remains intact, short-term memory is impaired. Individuals are unaware of their memory deficits, and confabulation is common. The most probable cause of the memory deficits is lesions in the dorsal medial nuclei of the thalamus [94]. While 20% of individuals recover completely over several months with vitamin B_1 supplements, approximately 25% never recover and subsequently require long-term care [98].

Alcoholic neuropathy is the most commonly reported neurologic complication in people addicted to alcohol. These individuals present with paresthesias, pain, and weakness. These individuals also can have reduced pain and reduced temperature sensations. Typically, there is axonal degeneration and demyelination, possibly due to a neurotoxic effect of ethanol on the peripheral nerves [15, 66]. While recovery is possible, it requires total abstinence and may take months.

The development of chronic alcoholic myopathy manifests as a painless syndrome wherein the individual has muscle weakness. The severity of the myopathy is related directly to the amount of alcohol consumed [101]. It is thought that chronic alcoholic myopathy is the result of the toxicity of ethanol and its metabolites, such as acetaldehyde, as opposed to nutritional deficiencies [1, 50, 95]. Individuals typically improve a few months after the discontinuation of alcohol.

The diagnostic criteria for alcoholic dementia remain controversial. There are currently no acceptable criteria available to diagnose definite alcohol-related dementia. There do exist, however, criteria for diagnosing probable alcohol-related dementia. These criteria include: (1) a clinical diagnosis of dementia at least 60 days after alcohol exposure and (2) significant alcohol use as defined by 35 or more standard drinks/week for men and 28 or more standard drinks/week for women for 5 years or longer. Furthermore, the onset of dementia must fall within a 3-year period of significant alcohol use [47]. The neuropathic changes that usually accompany individuals diagnosed with alcoholic dementia include cortical atrophy, the loss of cortical neurons, and enlargement of the lateral ventricles [19]. The cognitive function of these individuals tends to improve after a few months of abstinence. Even the neuroimaging of these individuals reveals decreased ventricle dilation following a few months of abstinence [71].

Conclusions

Alcohol-related disorders are an important global health problem. Not only is there a significant economic burden, but the negative personal effects of excessive alcohol consumption may be both physically and psychologically devastating. Many factors including age of onset, ethnicity, gender, place of residence, and religion must all be considered in regard to the

clinical picture of alcohol use and abuse. The clinical picture of alcohol is different for everyone, but there are consistent themes based on the pathophysiology of alcohol. Intoxication, blackouts, and hangovers are all typical clinical manifestations of excessive alcohol use. While these manifestations may be readily apparent, other signs and symptoms may remain subtle, especially at the onset of excessive alcohol consumption. Many organ systems may be negatively affected by alcohol consumption. Alcohol-related liver disease, holiday heart phenomenon, gastroesophageal reflux disease, and anemia may all result from the prolonged use of alcohol, especially in excessive amounts. Furthermore, the excessive consumption of alcohol not only harms the individual who is drinking but may also have serious physical effects on the developing fetus. The psychological and psychiatric picture of alcohol consumption can be divided into acute and chronic effects. The acute effects of alcohol consumption, such as a loss of inhibitions and feelings of pleasure and euphoria, are well known, and these well-known effects entice individuals to consume alcoholic beverages. Finally, the continued excessive use of alcoholic beverages may result in severe chronic psychological and psychiatric effects such as Wernicke's encephalopathy or Korsakoff's psychosis.

Introduction

The effects of cocaine on the nervous system have been studied for over 100 years. Early observers noted that among the symptoms produced by frequent cocaine use, one of the most prominent was cocaine craving [40]. In time, this craving for cocaine develops into a disorder termed cocaine dependence. Cocaine dependence is a chronic disorder characterized by compulsive drug seeking, frequent relapses, and continued drug use despite negative consequences [24, 32, 44]. On a personal level, the disease is associated with devastating consequences including loss of employment, disruption of marriage and family stability, risk of imprisonment,

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_18,

and associated health risks such as viral hepatitis and HIV [19, 39]. On a societal level, costs associated with cocaine addiction include increases in violent crime, increased prevalence of bloodborne and sexually transmitted infections, and a soaring population of incarcerated addicts [33]. Data from 2006 indicate that there were 2.4 million current cocaine users aged 12 or older [118]. In this chapter, we review the definitions and diagnostic criteria for the various cocaine-related disorders as well as the current understanding of the molecular biological basis for these disorders and current approaches to treatment.

Historical Aspects

Cocaine is a naturally occurring substance derived from the leaves of the Erythrooxylum coca plant. Its use is thought to have originated over 5,000 years ago in religious ceremonies among the ancient civilizations of South America, but its use was increased greatly following the conquest of South America by the Spanish, who valued its effects in decreasing appetite and increasing stamina in the slaves who worked in the silver mines [43, 57, 122]. The first chemical purification of cocaine was achieved by Albert Niemann in 1860, and shortly thereafter it was incorporated into a variety of patent medicines and "tonics", including the original recipe for Coca-Cola, which was marketed as a temperance drink, "offering the virtues of coca, without the vices of alcohol" [43]. Its use was promoted by several prominent figures of the time, perhaps most notably by Sigmund Freud [43, 57]. Growing concern about the potential toxicity of cocaine led to the passage of the Harrison Narcotics Tax Act in 1914. However, cocaine continued to be sold over the counter in the United States in a variety of forms until 1916.

Sex and Gender Differences

A variety of studies over the past decade have shown that the responses of men and women to cocaine differ markedly in several important aspects [37, 82, 92]. These differences extend to all phases of the addictive process including induction, maintenance, relapse, and response to treatment. Compared with men, women have been reported to initiate cocaine use at later ages, but progress more rapidly from first use to dependence, a phenomenon termed "telescoping" [126]. Women have also been reported to experience decreased subjective effects of cocaine, including both positive ("feel high") and negative ("paranoid/suspicious", "heart racing/pounding") effects [116]. This phenomenon may be explained partly by the lower peak blood levels of cocaine observed in women after administration of the same dose of cocaine [73], although other studies have reported an increase in negative "nervousness" effects among women [67]. Cocaine-dependent women also have been reported to differ from their male counterparts in their subjective [2] and physiological [35] responses to stress, factors which may place them at increased risk for stress-induced relapse after an initial period of sobriety [37]. This is consistent with recent findings that severity of childhood trauma is predictive of cocaine relapse outcomes in women but not men [54]. Cocaine-dependent women also have been reported to have a higher pattern of psychiatric, medical, social/family, and employment problems than men [82]. Finally, cocaine-dependent men and women appear to differ in their response to different forms of treatment for cocaine dependence, with men, but not women, showing decreased rates of relapse following treatment with disulfiram [89]. Whilst progesterone was found to decrease the effects of smoked cocaine in women, this was not the case in men [30]. These findings highlight the need to consider individual factors including gender when discussing both the pathophysiology of and approaches to the treatment of cocaine dependence and abuse.

Pregnancy and Effects of Prenatal Exposure

The increasing prevalence in recent years of cocaine use among women of child-bearing age has significance not only for the women

themselves but for the potential consequences to children exposed *in utero*. The pathophysiology of cocaine's effects on the developing nervous system has been conceptualized as occurring along three inter-related pathways [68]. The first of these are the direct neurochemical effects of cocaine on the developing nervous system; the second are sequelae related to the vasoconstrictive effects of cocaine on both the fetal and placental vessels. Finally, and perhaps most insidious, are the epigenetic changes that may be induced by cocaine's effects on the developing brain, leading to long-term changes in both reward and stress-related circuits in the brain. A meta-analysis published in 2001 [38] of studies carried out on children who had been exposed to cocaine *in utero* suggested that after controlling for confounders, including prenatal exposure to tobacco, marijuana, or alcohol and the quality of the child's environment, there was no consistent negative association between prenatal cocaine exposure and physical growth, developmental test scores, or receptive or expressive language. However, studies using animal models of *in utero* cocaine exposure suggest that there may be latent differences in neurocircuitry that are not revealed until the offspring are exposed to various stressors in adulthood [12]. Moreover, neuroimaging studies of adolescents who were exposed prenatally to cocaine confirm the presence of subtle differences in brain activation [26]. These differences in brain function may interact with various environmental factors to increase the risk for a variety of adverse outcomes including the development of cocaine dependence. Additional effects of cocaine during pregnancy and development are discussed in Chapter "Alcohol and Drugs of Abuse in Pregnant Women: Effects on the Fetus and Newborn, Mode of Action, and Maternal Treatment".

Youth

In 2008, 1.8% of 8th graders, 3.0% of 10th graders, and 4.4% of 12th graders had used cocaine in the past year [84]. All of these numbers represent a decrease from the previous year's figures, suggesting that efforts aimed at primary prevention are having some effect. However, given the devastating consequences associated with cocaine abuse and dependence, they are certainly not cause for complacency. Results from the 2006 National Survey on Drug Use and Health [118] show that in 2006, there were 977,000 persons aged 12 or older who had used cocaine for the first time within the past 12 months; this averages to approximately 2,700 initiates per day. While these numbers may have declined somewhat in the past 2–3 years, this still represents a terrible loss to the affected individuals, their families, and their communities.

Criminality

Studies conducted in the 1990s suggested that the arrival of crack cocaine in urban centers in the United States and elsewhere was associated with a significant increase in the rates of a variety of types of crime [4, 45]. Concerns about the relationship between cocaine use and criminality have resurfaced at the end of the first decade of the twenty first century in connection with the drug wars currently taking place along Mexico's northern border.

Broadly speaking, the relationship between cocaine use and criminality can be considered in (at least) two complementary ways. The first is the relationship between cocaine use and criminality on the local level by users and small-scale dealers of cocaine. (Frequently these groups overlap.) The second is the relationship between the illegal sale of cocaine and criminality on the national or international scale. On the individual level, cocaine use and dependence clearly increase the likelihood of engaging in other criminal activity including prostitution, theft, and violent crime [19, 55]. Conversely, successful treatment of substance dependence is associated with decreased likelihood of reoffending among substance abusers in the criminal justice system [83]. On the national and international scale, the funds provided to international criminal organizations through the sale of illegal

drugs and the violence perpetrated by these organizations can undermine the stability of entire nations and regions. These findings highlight the need for new approaches to treatment for cocaine-abusing individuals in the criminal justice system, as well as improved national and international efforts to direct treatment to those in need.

Cocaine Dependence

Definition/Diagnostic Criteria

Cocaine dependence can be conceptualized in a number of different ways. As defined by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*, Text Revision [1], the diagnosis of cocaine dependence is based on the same criteria used to diagnose dependence on other drugs of abuse. These include the presence of three or more of the following within the past year:

1) tolerance, defined by either
    a. a need for increased amounts of the substance to achieve intoxication or the desired effect, or
    b. markedly diminished effect with continued use of the same amount of the substance,
2) withdrawal, manifested by either
    a. characteristic withdrawal syndrome for the substance, or
    b. the same (or a closely related) substance being taken to relieve or avoid withdrawal symptoms,
3) the substance is taken in larger amounts or over a longer period than was intended,
4) a persistent desire for, or unsuccessful efforts to cut down or control, substance use,
5) a great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects,
6) important social, occupational, or recreational activities are given up or reduced because of substance use, and
7) substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., continued cocaine use despite recognition of cocaine-induced depression. . .) (adapted from the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*, Text Revision [1]).

Note that this definition does not require the presence of physiological dependence, although the presence of physiological dependence may contribute to making the diagnosis (i.e., criterion 1 or 2 above). Rather, as conceptualized in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision, the diagnosis of cocaine dependence is made based primarily on the pattern of maladaptive behavior associated with its use.

Physiological dependence on cocaine is characterized by tolerance (criterion 1 above) and the occurrence of specific withdrawal symptoms when use is stopped. Symptoms of cocaine withdrawal include cocaine craving, depressed mood, sleep disturbance, appetite disturbance, and increased anxiety [6, 7, 20, 115]. These symptoms have been incorporated into the current diagnostic criteria for cocaine withdrawal (discussed below), and standardized instruments have been developed for rating the severity of these symptoms [63].

Neurobiology

Development of cocaine dependence is thought to be due to long-term consequences of repeated cocaine use in several areas of the brain, particularly those related to the processing of reward-related information and executive control of behavior [31, 62, 87, 88]. Molecular changes that occur following the chronic administration

of cocaine include changes in both the dopamine and glutamate signaling pathways. Chronic administration of cocaine increases the level of tyrosine hydroxylase, the rate-limiting enzymes in dopamine synthesis in the ventral tegmental area, and the glutamate receptor GluR1. These effects are mediated, at least in part, by the transcription factor cyclic AMP response element binding protein [87]. Up-regulation of cyclic AMP response element binding protein appears to increase the activity of negative feedback loops in the brain associated with tolerance and dependence. Another transcription factor that is induced by chronic cocaine exposure, ΔFosB, appears to contribute to sensitization (increased behavioral response to the same dose of a drug following repeated administration) [13].

Studies in animals show that the effects of cocaine use on the brain can be extremely long lasting and, in some cases, can continue to increase during a period of abstinence such that the abstinent user—far from being "back to normal" after a brief or even a prolonged period of abstinence—may be even more sensitive to drug-related cues than someone who is actively using [104]. In addition to the changes in brain chemistry described above, long-term exposure to cocaine can cause structural changes in the brain—particularly by increasing the number of dendritic branches and the density of spines in a part of the brain called the nucleus accumbens [96]. The nucleus accumbens is part of the limbic system that regulates our response to natural rewards such as food or sex. Dendrites, specifically dendritic spines, are the specialized parts of brain cells that receive input from other cells and other brain regions. Changes in the number and structure of dendritic branches in the nucleus accumbens may account for some of the extremely long-lasting changes in brain function seen in cocaine addiction [62, 86]. With this in mind, treatment strategies for cocaine dependence must focus on long-term treatment outcomes and the development of strategies for preventing or minimizing the impact of relapses over the lifetime of the cocaine-dependent individual.

Treatment Approaches

Pharmacological Treatments for Cocaine Dependence

Strategies for treating cocaine dependence include both pharmacological treatments (reviewed in [25, 64, 117]) and non-pharmacological treatments [28]. There are several promising medications for the treatment of cocaine dependence. These include GABAergic, dopaminergic, glutaminergic, and serotonergic medications, and even cocaine vaccines [64, 117]. Details of the effects of these medications are described in Chapter "Pharmacotherapy of Cocaine Addiction".

Self-Help Treatments for Cocaine Dependence

Non-pharmacological treatments for cocaine dependence include a variety of individual psychotherapies [21, 98], group therapies [123], and 12-step programs such as Narcotics Anonymous. Not surprisingly perhaps, the primary determinant of outcome for most such psychosocial treatments appears to be length of retention in treatment, with better outcomes generally reported by those treated 90 days or longer in both residential and outpatient settings [108]. These findings reinforce the need to focus on long-term outcomes and relapse prevention as the primary goal of treatments (both pharmacological and psychosocial) for cocaine dependence. Specific psychotherapeutic approaches to the treatment of cocaine dependence are discussed in more detail in the section below on craving and relapse.

Cocaine Abuse

Definition/Diagnostic Criteria

Cocaine abuse is defined by the same criteria used to define other substance abuse disorders

[1]. These include "a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) or the following occurring within a 12-month period:

1. recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
2. recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
3. recurrent substance-related legal problems (e.g., arrest for substance-related disorderly conduct)
4. continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)" [1].

Compared with cocaine dependence, cocaine abuse is characterized by less frequent and less intense use, and the degree of social disruption is generally less severe, with an episodic—rather than a continuous—pattern of problematic use, neglect of responsibilities, and interpersonal conflict related to substance use [1]. However, it should be clear from the symptoms listed above that cocaine abuse and dependence occur along a continuum, with abuse often progressing to full dependence in months to years [93, 103].

Neurobiology

Cocaine abuse represents an earlier stage along the continuum from recreational use to dependence. It has been proposed that whilst changes in dopamine signaling are most important in the transition from recreational use to abuse (initiation of addiction), the transition from abuse to dependence (end-stage addiction) is due to changes in glutaminergic signaling from the anterior cingulate and orbitofrontal cortex to the nucleus accumbens [62]. These changes serve to decrease the value of natural rewards and to diminish cognitive control over drug seeking.

Treatment Approaches

Treatments for cocaine abuse are similar to those for cocaine dependence and include both pharmacological and psychosocial interventions. Promising pharmacological treatments for cocaine dependence and abuse are detailed in Chapter "Pharmacotherapy of Cocaine Addiction". Self-help (see above) and other non-pharmacological treatments (see below) are detailed within this chapter. Generally, compared with cocaine-dependent individuals, cocaine abusers present with less severe problems and tend to have better outcomes [108]. Nevertheless, the majority of cocaine users (75%) meet the criteria for both abuse and dependence. In most cases (57%), the criteria for abuse and dependence occur within the same year, and in a small percentage of cases (17%), the criteria for abuse are met only after the physiological criteria for dependence are already present [94]. Thus, the finding that a person meets the diagnostic criteria for abuse but not dependence should by no means be a cause for complacency.

Cocaine Intoxication

Definition/Diagnostic Criteria

Acute cocaine intoxication is typically characterized by a "high" feeling and stimulant effects including euphoria, increased pulse and blood pressure, and psychomotor activation. It also can

include any of the following: alertness, anger, anxiety, belligerence, cognitive impairment, gregariousness, grandiosity, hyperactivity, hypervigilance, impaired judgment, impaired social and occupational functioning, interpersonal sensitivity, mood lability, restlessness, stereotyped and repetitive behavior, increased talkativeness, and tension. With chronic intoxication, there also can be depressant effects such as social withdrawal, sadness, bradycardia, decreased blood pressure, and decreased psychomotor activity. Both acute and chronic intoxication are associated with impaired social and occupational function. Severe intoxication is associated with a number of medical complications including seizures, cardiac arrhythmias, hyperpyrexia, and vasoconstriction leading to increased risk for myocardial infarction, stroke, and even death.

Diagnostic criteria for cocaine intoxication include:

a. Recent use of cocaine.
b. A clinically significant maladaptive behavioral or psychological change (described above) that develops during or shortly after cocaine use.
c. Two (or more) of the following physical symptoms: (1) tachycardia or bradycardia, (2) pupillary dilation, (3) altered blood pressure (elevated or lowered), (4) chills or perspiration, (5) nausea or vomiting, (6) evidence of weight loss, (7) psychomotor agitation or retardation, (8) muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias, and (9) confusion, seizures, dyskinesias, dystonias, or coma.
d. The symptoms observed are not due to a general medical condition or better accounted for by another mental disorder [1].

Neurobiology

Cocaine, administered by any of the commonly used routes including snorting, smoking, and intravenous injection, enters the bloodstream and crosses the blood-brain barrier rapidly. While cocaine inhibits reuptake of all three monoamine neurotransmitters (dopamine, norepinephrine, and serotonin), both the acute effects of cocaine and the long-term changes responsible for the development of cocaine dependence are thought to be related primarily to its effects on dopamine signaling [88]. The neurotransmitter dopamine is synthesized in a small number of specialized dopamine-producing (dopaminergic) cells in the brain, and serves to regulate a number of important physiological processes. In particular, dopaminergic signaling in the limbic system, including the ventral tegmental area (which produces dopamine) and the nucleus accumbens (one of the main sites of dopamine's actions), functions to signal the presence of naturally occurring rewards. Cocaine-induced increases in dopamine activity within the nucleus accumbens have been associated with the "high" felt after its ingestion [53, 88]. In addition to its effects on the brain, cocaine can have direct effects on the circulatory system, leading to increased blood pressure and risk for myocardial infarction and stroke [5, 58, 65, 121].

Treatment Approaches

There are no specific treatments for cocaine intoxication, and in most cases acute cocaine intoxication can be managed with supportive care. Benzodiazepines are considered first-line treatment for agitation associated with acute cocaine intoxication. Typical antipsychotic medications (e.g., perphenazine and haloperidol) can be used for treatment of paranoia or psychosis associated with cocaine intoxication; however, these should be used with caution because of the possibility of acute hyperthermia syndromes associated with acute cocaine intoxication, which may be confused with neuroleptic malignant syndrome [50]. Cardiac or neurological symptoms associated with severe intoxication may require referral to an intensive care unit. Pregnant women will require additional monitoring since vasoconstriction associated with cocaine intoxication may lead to premature labor.

Given the chronic, relapsing nature of cocaine abuse and dependence, it is important to focus, as soon as possible, on planning for long-term treatment and relapse prevention. In most cases, referral to residential or other long-term treatment modalities can be made even prior to the resolution of the acute symptoms associated with cocaine intoxication.

Cocaine Withdrawal

Definition/Diagnostic Criteria

Withdrawal from cocaine occurs after cessation or reduction of heavy and prolonged cocaine use and is characterized by dysphoric mood and two or more of the following:

A. fatigue
B. vivid, unpleasant dreams
C. insomnia or hypersomnia
D. increased appetite
E. psychomotor retardation or agitation.

These symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning to be diagnosed as cocaine withdrawal [1]. In some cases, cocaine withdrawal is associated with a profound depression, and suicidal ideation and actions can occur.

Neurobiology

Cocaine withdrawal is thought to occur as the result of long-term adaptations in brain physiology and functioning caused by prolonged exposure to cocaine. Such adaptations are generally homeostatic in nature [66]. That is to say, they oppose the acute effects of cocaine and enable the brain to function as well as possible despite the greatly increased dopamine signaling induced by cocaine. The synaptic architecture and signaling properties of a number of brain regions, including the limbic system, frontal cortex, and amygdala, are reconfigured such that functioning in the presence of cocaine becomes the new "normal". The abrupt withdrawal or reduction of cocaine intake is perceived as a state of dopamine deficiency, and triggers the occurrence of the symptoms described above, as well as an intense desire to resume cocaine use in order to restore what is now perceived as a normal level of functioning. Molecular changes associated with the development of cocaine withdrawal include the accumulation of the transcription factor ΔFosB, increased cyclic AMP-cyclic AMP response element binding protein signaling in the medium spiny neurons of the nucleus accumbens, increases in tyrosine hydroxylase (the rate-limiting enzyme in dopamine synthesis), and increased neurotrophin and cyclic AMP response element binding protein signaling in the ventral tegmental area, where the dopaminergic projections to the nucleus accumbens originate. These changes have the net effect of decreasing basal dopamine signaling but increasing the cocaine-stimulated release of dopamine, and thus reduce the body's ability to respond to rewards other than cocaine [77, 87, 88]. Importantly, while the acute phase of cocaine withdrawal typically resolves within several days, some of the neuroadaptations induced by prolonged exposure to cocaine may persist for months or even longer, resulting in a heightened sensitivity to both cocaine and cocaine-associated cues [74, 104]. Thus, the resolution of acute withdrawal symptoms does not imply that the person is no longer dependent on cocaine.

Treatment Approaches

There are no specific treatments for cocaine withdrawal, and in most cases acute cocaine withdrawal can be managed with supportive care (see also Chapter "Pharmacotherapy of Cocaine Addiction"). Mood changes including depression, irritability, anhedonia, emotional lability,

and disturbances in attention and concentration are common. In some instances, cocaine withdrawal can be associated with a profound depressive state, and suicidal ideation and actions are not infrequent. In these cases, hospitalization to prevent self-harm may be necessary. As noted above, resolution of acute withdrawal symptoms should not be construed as implying that the person is no longer dependent on cocaine. Therefore, as soon as possible, the focus of treatment should shift to planning for long-term treatment. Ideally, this should include referral to residential or other long-term treatment modalities with a focus on relapse prevention.

Cocaine Craving and Relapse

Definition/Diagnostic Criteria

Cocaine craving and relapse are not specific diagnoses but are associated with all cocaine-related disorders. As discussed above, prolonged use of cocaine results in an intense desire to consume more cocaine. This effect has been noted for over 100 years [40] and is one reason why cocaine dependence is so difficult to treat. Relapse refers to the resumption of drug use after a period of abstinence. However, defining relapse in cocaine users is complex since many users frequently engage in binge and other styles of periodic use, such that short intervals of abstinence are the rule even among current users [46]. Factors associated with increased risk for relapse include current levels of cocaine craving, exposure to stress or drug-related cues, and history of childhood abuse [54, 90, 110].

Neurobiology

As discussed above, prolonged exposure to cocaine or other drugs of abuse produces homeostatic changes in the brain, such that it is no longer able to function normally in the absence of the abused drug [66]. Changes in glutaminergic signaling from the anterior cingulate and orbitofrontal cortex to the nucleus accumbens may be important in the transition from abuse to dependence (end-stage addiction) [61, 62]. Animal studies suggest roles for the basolateral amygdala in cue-primed reinstatement, the ventral tegmental area in drug-primed reinstatement, and adrenergic innervation of the extended amygdala in stress-primed reinstatement [61]. All three forms of priming may converge on the anterior cingulate cortex and have a final common output through the core of the nucleus accumbens. Neuroimaging studies also support a role for the projections from the anterior cingulate and orbitofrontal cortex to the nucleus accumbens in drug addiction [15, 44, 62].

Parallel evidence from human laboratory and relapse outcome studies also substantiates preclinical evidence of neuroadaptations in brain stress and reward pathways that are associated with increased stress and drug cue-induced drug craving, anxiety, and dysfunctional physiological and neuroendocrine responses in treatment-engaged, cocaine-dependent individuals as compared with healthy social drinkers [36, 95, 109]. Stress and cue-induced cocaine craving and neuroendocrine responses have been shown to predict cocaine relapse outcomes [94, 109]. Brain imaging studies of stress and drug cue-induced cocaine craving show specific positive association within the dorsal striatum regions [111, 112], while inhibitory control deficits show decreased activity in the prefrontal and anterior cingulate regions in cocaine-dependent individuals [69].

Treatment Approaches

Treatments for cocaine craving and relapse are at the heart of all treatments for cocaine dependence and abuse. These include both pharmacological treatments, which are detailed in Chapter "Pharmacotherapy of Cocaine Addiction", and non-pharmacological treatments, which are described below.

Other Non-Pharmacological Approaches

Apart from the self-help treatments described above, other psychosocial approaches to the treatment of cocaine craving and relapse include contingency management, relapse prevention, general cognitive behavior therapy, and treatments combining cognitive behavior therapy and contingency management [28]. Contingency management interventions are based on principles of operant conditioning and offer monetary and/or non-monetary rewards that are contingent on negative toxicology screens, indicating abstinence from drug use [48]. This approach has been evaluated in several controlled trials [47, 59, 105–107] and has shown consistent, if modest, effects in reducing relapse (reviewed in [28]). Potential barriers to more widespread use of this approach include costs associated with monetary incentives and frequent drug testing as well as social prohibitions against paying drug users for "good behavior". However, some studies have found that contingency management approaches using prizes worth from $1 to $100 can achieve short-term abstinence with a lower per-client cost [91].

Relapse prevention is an alternative approach that focuses on identifying high-risk situations for relapse to drug use and avoiding or managing these situations by rehearsing alternative responses. Several studies have evaluated the effectiveness of relapse prevention techniques in cocaine-dependent subjects with mixed results. A 1991 study by Carroll et al. [10] that compared relapse prevention therapy with interpersonal psychotherapy found no significant main effect for treatment. However, among the subgroup of more severe users, subjects who received relapse prevention therapy were significantly more likely to achieve abstinence (54% vs. 9%) and to be classified as recovered (54% vs. 0%) than those who received interpersonal psychotherapy, while among the less severely addicted group, there was no difference between the two treatments. A 1994 study by the same research group comparing relapse prevention therapy with pharmacological treatment using the antidepressant imipramine or a combination of relapse prevention therapy plus desipramine found no significant effects on outcome for either relapse prevention therapy or medication. However, a 1-year follow-up study showed evidence of significant continuing improvement among the group who had gotten relapse prevention therapy [11]. Another study comparing relapse prevention therapy with 12-step programs in a group of 110 treatment-seeking subjects found no difference between the two treatments [125]. Thus, the available evidence is limited and does not strongly support relapse prevention therapy over other approaches to treating cocaine craving and relapse.

Cocaine Intoxication-Induced Delirium

Definition/Diagnostic Criteria

Cocaine intoxication-induced delirium refers to an acute disturbance in consciousness and cognition that occurs during cocaine intoxication—and is in excess of the cognitive disturbances usually associated with cocaine intoxication—and when the symptoms are sufficiently severe to warrant independent clinical attention. Diagnostic criteria for cocaine intoxication-induced delirium are identical to those for other substance-induced deliriums and include:

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, or language disturbance) or the development of a perceptual disturbance that is not better accounted for by a pre-existing, established, or evolving dementia.

C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
D. Evidence from the history, physical examination, or laboratory findings that: (1) these symptoms developed during the course of cocaine intoxication, and/or (2) cocaine use is etiologically related to the disturbance in consciousness [1].

Neurobiology

The precise molecular biological basis of cocaine intoxication-induced delirium is currently unknown. However, post-mortem studies of individuals with cocaine intoxication-induced delirium or chronic cocaine abusers have shown reduced levels of the mRNA encoding the dopamine transporter [14, 70] and the transcription factor NURR1 [3], which regulates the expression of the dopamine transporter. These changes would be expected to raise extracellular levels of dopamine in the brain and thus interfere with the normal modulatory roles of dopamine on a variety of signaling mechanisms throughout the brain.

Treatment Approaches

There is no specific treatment of cocaine intoxication-induced delirium, and in most cases the delirium can be managed with supportive care. However, such individuals will require more intensive monitoring than those with typical cocaine intoxication, due to the elevated risk for cocaine-induced rhabdomyolysis [99]. Hyperthermia in individuals with cocaine intoxication can be a sign of impending rhabdomyolysis. This condition must be recognized early to prevent secondary renal failure. Treatment of rhabdomyolysis focuses on ensuring adequate urine output and, possibly, alkalization of the urine. Dialysis may be necessary in extreme cases [52]. One study found that 24% of patients presenting to the emergency room for acute cocaine-related disorders had some degree of rhabdomyolysis, which in many cases was not apparent from the clinical history or physical examination, thereby making laboratory assessment—including measurement of serum creatinine phosphokinase and urinary myoglobin—an essential part of the evaluation and treatment of such individuals [124]. Cardiac monitoring also should be considered given the risk of cocaine-induced arrhythmias, vasoconstriction, and myocardial infarction [27].

Cocaine-Induced Psychotic Disorder

Definition/Diagnostic Criteria

Cocaine-induced psychotic disorder refers to the presence of psychotic symptoms in excess of those typically seen in individuals with cocaine intoxication or withdrawal. These can include delusions, hallucinations, or both. Delusions may be of any type but typically are paranoid and/or grandiose in nature. Diagnostic criteria for cocaine-induced psychotic disorder are the same as those used to diagnose other substance-induced psychotic disorders, and include:

a. Prominent hallucinations or delusions. Note: Do not include hallucinations if the person has insight that they are substance induced.
b. Evidence from the history, physical examination, or laboratory findings that: (1) these symptoms developed during the course of cocaine intoxication or withdrawal, and/or (2) cocaine use is etiologically related to the development of psychotic symptoms.
c. The disturbance is not better accounted for by a psychotic disorder that is not substance induced. Evidence that the symptoms are better accounted for by a primary psychotic disorder that is not substance induced might include the following:
    i. psychotic symptoms that precede the onset of cocaine use;

ii. psychotic symptoms that persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication,
iii. other evidence that suggests the existence of an independent non-substance-induced psychotic disorder (e.g., a history of recurrent non-substance-related episodes).

d. The disturbance does not occur exclusively during the course of a delirium [1].

There are two subtypes of cocaine-induced psychotic disorder: (1) "with delusions" if delusions are the predominant symptom and (2) "with hallucinations" if hallucinations are the predominant symptom.

Neurobiology

The precise molecular biological basis of cocaine-induced psychotic disorder is currently unknown. However, there is evidence for a genetic vulnerability to the development of psychotic symptoms in individuals who abuse cocaine. In particular, genetic variants associated with low plasma levels of dopamine beta-hydroxylase, an enzyme that converts dopamine to norepinephrine and thus affects the balance between these two neurotransmitters in the brain, have been associated with increased risk for cocaine-induced psychotic symptoms [22, 60]. Individuals with lower levels of dopamine beta-hydroxylase would be expected to have a higher ratio of dopamine to norepinephrine, and thus be more sensitive to drugs such as cocaine that lead to unbalanced dopamine signaling in the brain.

Treatment Approaches

There is no specific treatment of cocaine-induced psychosis, and in most cases the psychotic symptoms will resolve within a few days after cessation of cocaine use. Benzodiazepines can be used for individuals who are agitated. Care must taken in using neuroleptics to treat cocaine-induced psychosis because most antipsychotic medications will increase the QTc interval and may increase the risk for cocaine-associated cardiac arrhythmias [127].

Cocaine-Induced Anxiety Disorder

Definition/Diagnostic Criteria

Cocaine-induced anxiety disorder can occur during either cocaine intoxication or cocaine withdrawal. Like other substance-induced anxiety disorders, cocaine-induced anxiety disorder is distinguished from a primary anxiety disorder by the fact that a substance is judged to be etiologically related to the symptoms. Diagnostic criteria for cocaine-induced anxiety disorder are the same as those for other substance-induced anxiety disorders and include:

a. The presence of prominent anxiety, panic attacks, or obsessions or compulsions.
b. Evidence from the history, physical examination, or laboratory findings that: (1) these symptoms developed during the course of cocaine intoxication or withdrawal, and/or (2) cocaine use is etiologically related to the development of psychotic symptoms.
c. The disturbance is not better accounted for by an anxiety disorder that is not substance induced. Evidence that the symptoms are better accounted for by an anxiety disorder that is not substance induced might include:

- anxiety symptoms that precede the onset of cocaine use;
- anxiety symptoms that persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication, or
- other evidence that suggests the existence of an independent non-substance-induced anxiety disorder (e.g., a history of recurrent non-substance-related episodes).

Neurobiology

While the precise molecular biological basis of cocaine-induced anxiety disorder is unknown, it has been suggested that the development of cocaine-induced anxiety or panic symptoms can be explained in terms of limbic-neuronal hyperexcitability induced by cocaine through a kindling mechanism [71].

Treatment Approaches

There is no specific treatment of cocaine-induced anxiety disorder, and in some cases these symptoms will resolve within a few days after cessation of cocaine use. In cases where the symptoms do not resolve following cessation of cocaine use, treatment of cocaine-induced anxiety disorder is usually similar to treatment for a primary anxiety disorder such as generalized anxiety disorder, phobias, panic disorder, or obsessive-compulsive disorder. It has been suggested that clonazepam and/or carbamazepine may be more effective in the treatment of cocaine-induced panic symptoms than shorter-acting benzodiazepines such as alprazolam, possibly because of their greater anticonvulsant properties [71]. Of note, antidepressants, particularly tricyclic antidepressants, have been reported to be ineffective in the treatment of cocaine-induced panic symptoms. Indeed, one study found that 60% of individuals with cocaine-induced panic symptoms experienced a worsening of their symptoms when treated with tricyclic antidepressants [72].

Cocaine-Induced Mood Disorder

Definition/Diagnostic Criteria

Cocaine-induced mood disorder refers to a prominent and persistent disturbance in mood that is judged to be due to the direct physiological effects of cocaine. Diagnostic criteria for cocaine-induced mood disorders are the same as for other substance-induced mood disorders and include:

a. A prominent and persistent disturbance in mood predominates in the clinical picture and is characterized by either (or both) of the following: (1) depressed mood or markedly diminished interest or pleasure in all, or almost all, activities, or (2) elevated, expansive, or irritable mood.
b. Evidence from the history, physical examination, or laboratory findings that: (1) these symptoms developed during the course of cocaine intoxication or withdrawal, and/or (2) cocaine use is etiologically related to the development of psychotic symptoms.
c. The disturbance is not better accounted for by a mood disorder that is not substance induced.
d. The disturbance does not occur exclusively during the course of a delirium [1].

Neurobiology

The neurobiological mechanisms underlying the development of cocaine dependence and mood disorders share a number of similarities [8, 76]. These include a prolonged activation of the hypothalamic-pituitary-adrenal axis and overexpression of the neuropeptide corticotropin-releasing factor [42]. There is abundant evidence from both animal [29, 100] and human [110, 113] studies showing that stress and the associated increase in hypothalamic-pituitary-adrenal activity can trigger relapse to cocaine use. Conversely, prolonged elevation of hypothalamic-pituitary-adrenal activity as a result of chronic cocaine use may result in a negative affective state, which provides a powerful motivational force for the continuation of drug self-administration [66]. Treatments that target this heightened hypothalamic-pituitary-adrenal activity may thus represent important potential treatments for both mood [49, 85] and substance abuse [101] disorders.

Treatment Approaches

Mood disorders that are directly attributable to cocaine can be difficult to distinguish from the frequent case of comorbid cocaine abuse or dependence with a "primary" mood disorder, either major depression or bipolar disorder. By definition, substance-induced mood disorders arise only in association with intoxication or withdrawal states, whereas primary mood disorders may precede the onset of substance use or may occur during times of sustained abstinence. However, in many cases, both cocaine use and mood symptoms are long-standing, and it may be difficult to identify significant periods of time when either was absent. In addition, because the withdrawal state for cocaine can be relatively protracted, mood symptoms can persist in an intense form for several weeks after the cessation of cocaine use. Features that would suggest a primary mood disorder include: (1) persistence of mood symptoms for a substantial period of time (i.e., a month or more) after cessation of cocaine use, (2) the development of mood symptoms that are substantially in excess of what would be expected given the amount or the duration of cocaine use, or (3) a history of prior recurrent primary episodes of mood disorder [1].

Both cocaine-induced and primary mood disorders require clinical attention, especially when symptoms have been persistent and severe prior to treatment. The preponderance of evidence—from both randomized clinical trials that prospectively targeted both depression and cocaine dependence and randomized clinical trials in which a post hoc analyses demonstrated efficacy in the subgroup of cocaine abusers with comorbid depression—appears to support the use of antidepressant medication in those with comorbid major depression and cocaine dependence (reviewed in [97, 119]). In general, selective serotonin reuptake inhibitors appear to work poorly in dually diagnosed individuals (e.g., [18, 102]), whereas positive studies have used agents such as desipramine [9, 41] or bupropion [75] that are more activating.

Cocaine-Induced Sexual Dysfunction

Definition/Diagnostic Criteria

Cocaine-induced sexual dysfunction refers to a clinically significant sexual dysfunction resulting in marked distress or interpersonal difficulty that is judged to be explained fully by the direct physiological effects of cocaine. Subtypes may include cocaine-induced sexual dysfunction with: (1) impaired desire, (2) impaired arousal, (3) impaired orgasm, and (4) sexual pain [1].

Neurobiology

Acute administration of cocaine is associated with an increase in sexual drive, an effect that may be due to increased secretion of luteinizing hormone [23, 79]. However, chronic cocaine use induces a number of neuroendocrine abnormalities, including alterations in levels of prolactin secretion [17, 78] (hypothesized to occur as a result of increased dopamine depletion in the tubulo-infundibular tract [16, 23]). Elevated levels of prolactin would be expected to inhibit pituitary gonadotropin secretion [80], which may contribute to the development of cocaine-induced sexual dysfunction in some people.

Treatment Approaches

Since by definition cocaine-induced sexual dysfunction is explained fully by the direct physiological effects of cocaine, the primary focus of treatment should be on cessation of cocaine use. Expected improvements in sexual functioning may become a motivating factor to seek treatment for some cocaine-dependent subjects. When sexual function does not return to normal following a prolonged period of abstinence (i.e., 1 month or more), consideration should be

given to the possibility that the person has a primary sexual dysfunction. Contributing psychological factors such as possible comorbid major depression or anxiety disorders also should be taken into consideration. Phosphodiesterase-5 inhibitors (sildenafil, tadalafil, or vardenafil) are commonly prescribed. However, some studies suggest that these drugs are taken more commonly to enhance sexual experience than to treat erectile dysfunction [51], and may contribute to unsafe sex practices [34] and the consequent risk for infection among active cocaine users as well as the risk for adverse cardiac events [56, 114]. Thus, it is important to take a careful sexual history and discuss openly the associated risks and benefits before prescribing these medications.

Cocaine-Induced Sleep Disorder

Definition/Diagnostic Criteria

Cocaine-induced sleep disorder refers to a prominent disturbance in sleep that is sufficiently severe to warrant independent clinical attention, is judged to be due to the direct physiological effects of cocaine, and does not occur exclusively during the course of a delirium. Subtypes may include insomnia type, hypersomnia type, parasomnia type (which includes a variety of sleep-related disorders such as confusional arousals, sleepwalking (somnambulism), and sleep terrors (night terrors)), or mixed type (if more than one sleep disturbance is present and none predominates) [1]. The onset of the sleep disorder can occur either during intoxication or during withdrawal. The diagnosis of cocaine-induced sleep disorder is made only when the symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning and the symptoms are in excess of those usually associated with cocaine intoxication or withdrawal. Typically, cocaine intoxication produces insomnia, while cocaine withdrawal is associated with hypersomnia.

Neurobiology

In addition to changes in the total number of hours slept, chronic cocaine use is associated with significant changes in sleep architecture and deficits in sleep-related cognitive performance (e.g., sleep-dependent learning) [81, 120]. It has been suggested that this may be due to alterations in gamma-aminobutyric acid (GABA) signaling that are the result of adaptation to repeated overstimulation of monoaminergic pathways [81]. Interestingly, while self-reports of sleep quality typically improve following cocaine abstinence, polysomnographic studies have shown that changes in sleep architecture and sleep-related cognitive performance do not improve, at least over the first 3 weeks of abstinence, suggesting that there may be long-lasting deficits in sleep quality that occur as a result of chronic cocaine use and are not necessarily appreciated by the individuals themselves.

Treatment Approaches

Alterations in sleep architecture that occur during prolonged withdrawal from cocaine (reviewed in [81]) include an initial suppression of rapid-eye-movement sleep, followed after about 3 days by a rebound in rapid-eye-movement sleep and an increase in total hours of sleep. After 2.5 weeks of abstinence from cocaine, users have sleep architecture similar to individuals with chronic insomnia—i.e., increased sleep latency, decreased sleep efficiency (the percentage of time spent asleep while in bed), and decreased total hours of sleep. These findings suggest that agents such as tiagabine that improve slow-wave sleep and possibly deficits in sleep-related cognitive performance may be more beneficial than benzodiazepines, which extend sleep by promoting stage 2 sleep [81]. Several of the GABAergic medications that are being tested for treatment of cocaine dependence (topiramate, baclofen,

tiagabine, and vigabatrin) also may be helpful in treating cocaine-induced sleep disorders.

Summary

In sum, cocaine-use-related disorders are associated with severe physical disability (particularly increased risk of cardiovascular disease and cerebrovascular accidents), mental problems ranging from precipitating major psychosis to sleep disorders, and death. Cocaine taking, therefore, is an important cause of preventable morbidity and mortality in the United States and globally. Associated problems of cocaine use such as violent crime and enhancing the spread of HIV/AIDS have a major societal impact. Prevention and education programs, especially among youth, appear to diminish the incidence of cocaine use. Over the last two decades, there has been an explosion of neuroscientific knowledge, and the pharmacogenetic basis of cocaine dependence is being elucidated. In the absence of Food and Drug Administration—approved medications to treat cocaine-related disorders, clinical experience and early results from clinical studies have guided the use of agents to ameliorate these conditions. Presently, self-help and non-pharmacological approaches remain an important component of treatments for cocaine-related disorders.

Epidemiology

Cigarette smoking is the principal cause of premature death and disability in the United States. In 2006 about 438,000 deaths in the United States were caused by cigarette smoking [42]. According to a recent report published by the International Agency for Research on Cancer, tobacco smoking is causally linked to 13 different types of neoplastic disease [95]. However, despite education about the health hazards of smoking and other tobacco control efforts, many smokers continue to encounter extreme difficulty quitting and staying tobacco free long-term.

The latest annual National Survey on Drug Use and Health [164] (covering 20 million non-institutionalized United States residents age 12 years or older) reported that tobacco use has declined in recent years, from the highest rate of 42% in 1965 to the lowest reported rate of 28.6% in 2007. However, in 2007 nearly 42% of the 18–25 year-olds reported using cigarettes in the previous month, a much larger percentage than the 8% who reported using an illicit drug or the 6.9% who were classified as heavy alcohol users.

Surveys with different methodologies and definitions of smoking have produced varying rates of smoking prevalence. For example, the National Health Interview Survey [42] conducted in 2007 reported that 19.8% of the United States population were "current smokers," through rates were substantially higher among those with less than a high school education. Overall, 39.8% of current smokers made at least one quit attempt of at least 24 h in the previous year. The 2008 University of Michigan Monitoring the Future survey found that smoking in the last month among 8th, 10th, and 12th graders was 22.1, 34.6, and 46.2%, respectively [98]. The above numbers highlight the magnitude of the problem with smoking and nicotine dependence, in particular when compared

with the lower prevalence of other substances of dependence.

The difficulty in overcoming nicotine dependence is illustrated by the poor success rates among smokers who try to quit. The majority of smokers (~70%) report an interest in quitting, and around 42% have attempted to quit in the previous year. However, fewer than 6% of smokers are abstinent at 1 month after their quit date and fewer than 2% are abstinent 1 year after quitting when they do not receive assistance in smoking cessation [178]. The difficulty in maintaining abstinence is strongly related to affective and cognitive dysfunction, which may persist in some smokers for some time after the initial cessation, as well as post-cessation cigarette cravings [104].

The health consequences associated with smoking tobacco are substantial and life-threatening (see Fig. 1). Reportedly, smoking was the primary causal factor for 30% of all cancer deaths and 80% of deaths related to chronic obstructive pulmonary disease [41]. According to the Center for Disease Control [41] cigarette smoking or exposure to tobacco smoke resulted in 443,000 premature deaths/year and 5.1 million years of potential life lost from 2000 to 2004. The three leading causes of smoking attributable deaths were lung cancer, ischemic heart disease, and chronic obstructive

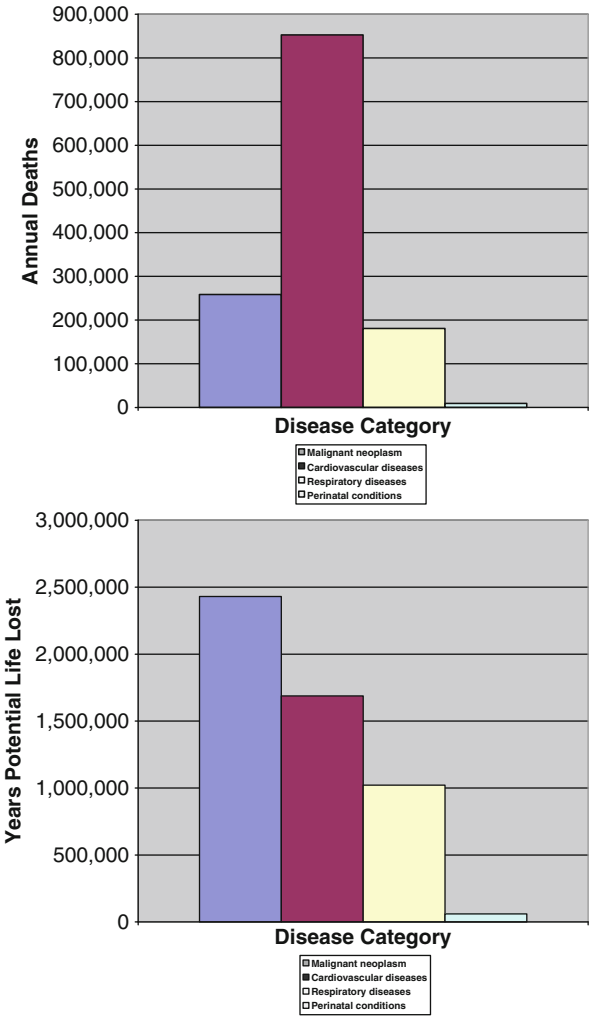

Fig. 1 Smoking-attributed annual deaths and years of potential life lost for the years of 2000–2004 [43]

pulmonary disease. Additionally, an estimated 776 infant deaths attributed to smoking during pregnancy occurred annually from 2000 to 2004. Despite the fact that cigarette use has declined substantially since the 1960s, the number of smoking-related deaths has remained relatively unchanged [43].

Biological, Behavioral, and Cognitive Aspects of Nicotine Dependence

The Reward Pathway

Among the more than 4,000 components of tobacco smoke, 60 or more are known carcinogens [84]. The most studied component of tobacco smoke is nicotine. It is the major psychoactive ingredient in tobacco smoke and the component most associated with tobacco dependence [14]. Like many drugs associated with abuse and dependence, nicotine stimulates a rapid increase in dopamine in the nucleus accumbens and the ventral tegmental area, typically within 10 s after ingestion [135, 136, 143]. Under normal circumstances, the nucleus accumbens and ventral tegmental area are also activated by food, social affiliation, and sexual activity, all of which are linked to survival. The key component of the reward pathway within the mesocorticolimbic system is the neurotransmitter dopamine, whose pathways project from the nucleus accumbens and ventral tegmental area to the prefrontal cortex, the amygdala, and the olfactory tubercle (see Fig. 2). Other neurotransmitter systems such as the gamma-aminobutyric acid system, the glutamate system, and the cholinergic system from those and other areas of the brain are believed to be involved in the activation of the reward pathway, while dopamine appears to be the final common neurotransmitter of this pathway [119].

Nicotine affects the reward pathway by more than one mechanism. In animal studies, dopamine antagonists or the destruction of dopaminergic neurons in the nucleus accumbens results in a decrease of nicotine self-administration in laboratory animals [61]. Nicotine receptors, a sub-type of muscarinic cholinergic receptors are present throughout the central nervous system and exert varying effects

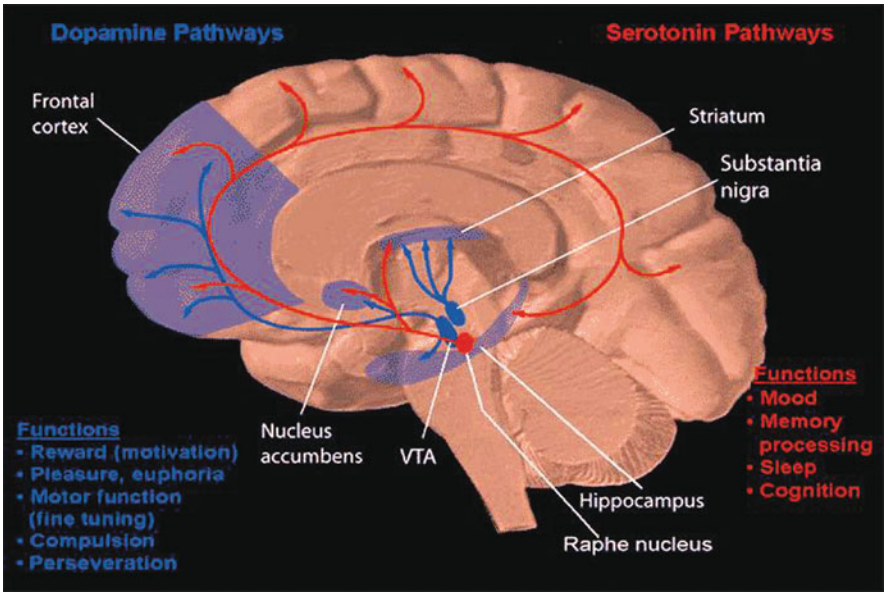

Fig. 2 The reward pathway with projections to the frontal and prefrontal cortex [131]. VTA = ventral tegmental area

(excitatory, inhibitory, or modulatory) depending on their location in the brain. In turn these receptors have an impact on the activity of several neurotransmitters, including dopamine, norepinephrine, serotonin, glutamate, and gamma-aminobutyric acid, and of endogenous opioid peptides. Prior research has focused primarily on dopamine as main determinant of nicotine and other drug addiction [38, 95, 135, 147], but most recently the emphasis is shifting to include most if not all the other major neurotransmitter systems in the brain [181]. Finally, cannabinoid-1 receptors also seem to be involved in nicotine dependence and the activation of dopaminergic neurons in the mesocorticolimbic system [51, 111] highlighting once more the importance of broadening the horizon and scope of our research efforts to include other systems in addition to dopamine and the reward pathway.

Neuronal Adaptation

Most if not all substances of abuse and dependence initially produce desirable and pleasant effects. However, not everyone who uses these substances goes on to abuse them, and not all substance abusers become dependent. Genetic, environmental, and cultural factors may all interact to predispose some individuals to substance abuse and dependence.

The pleasurable sensation produced by reward pathway activation is associated with acute substance use; repeated administration of nicotine over months or years is likely to lead to increased tolerance and withdrawal in the absence of nicotine. Tolerance and withdrawal are the physiologic hallmarks of dependence, and they may be related to neuroadaptive effects occurring within the brain [15]. Interestingly, the chronic use of drugs of abuse appears to cause a generalized decrease in dopaminergic neurotransmission, likely in response to the intermittent yet repetitive increases in dopamine induced by the frequent use of such drugs [180]. Drugs of abuse also increase levels of corticotropin-releasing factor, which is associated with the activation of central stress pathways. In vivo animal studies utilizing microdialysis during withdrawal from ethanol, cocaine, nicotine, or tetrahydrocannabinol showed an increase in extracellular corticotropin-releasing factor [109]. Of interest, the direct injection of a corticotropin-releasing factor antagonist into the amygdala reversed some of the symptoms of withdrawal (i.e., anxiogenic behaviors) [137].

Two neuroadaptive models have been used to explain how changes in reward function are associated with the development of substance dependence: sensitization and counter adaptation. The sensitization model [150] postulates that there is an increased desire for the drug, without necessarily a corresponding increase in pleasure, following intermittent but repeated administration of a drug. This is in contrast to or despite the tolerance to a drug, which would occur later or after continuous exposure to the drug. Sensitization can be thought of as the increase in "wanting" a drug after intermittent but repeated use and can facilitate the transition from occasional use to chronic use and tolerance [149].

The counter adaptation model postulates that the initial positive feelings of reward resulting from the use of a drug are followed by an opposing rather than synchronous development of tolerance that is manifested by the appearance of withdrawal associated with the lack of the substance [175]. Since tolerance takes longer to dissipate than the positive rewarding effects, a cycle of escalating drug use may follow after each cessation and consequent withdrawal. When the neurotransmitter system of the reward pathway is over-activated through escalating drug use, the system may not be able to maintain an increasingly pleasurable response to the drug. This is evidenced in microdialysis experiments that have documented decreases in dopaminergic and serotonergic transmission in the nucleus accumbens after chronic and escalating use [170]. The increase in corticotropin-releasing factor and concomitant decrease in neuropeptide Y during substance withdrawal (including nicotine) are associated with increases in anxiety [154]. In turn during withdrawal the activation of

norepinephrine pathways stimulates additional corticotropin-releasing factor release, possibly resulting in an amplification of arousal and stress and even neurotoxic effects if this amplification of arousal and stress are long-lasting [154].

Other models of nicotine addiction have been proposed, based on mechanisms associated with cognitive control and reinforcement learning [55], particularly the negative reinforcement associated with the reduction in negative affect that may follow smoking after a period of abstinence (withdrawal) [8]. These models are discussed in detail later in this chapter.

Cognitive Impairment

While much of the focus of previous research on nicotine addiction has been related to its effects on reward processes and mesolimbic dopamine neurotransmisssion [38, 95, 135, 143, 147], a growing body of literature suggests that nicotine's noradrenergic and dopaminergic effects on attention, information processing, and affective regulation, elsewhere in the limbic system, may be of considerable importance in understanding the maintenance of dependence. Neurological deficits common to attention and substance use disorders, such as impaired performance, lack of motivation, decreased working memory, and impaired executive function have been well documented [187] in both children and adults [9, 13, 63, 155, 166]. Current lines of investigation suggest that overlapping interrelated brain areas are responsible for explaining the attentional and executive impairments common to the two disorders [44, 68]. The involvement of two areas in particular, the prefrontal cortex and anterior cingulate cortex, highlight the commonalities between drug dependence and attentional disorders, including nicotine and neurophysiological deficits related to cognitive dysfunction.

The prefrontal cortex regulates goal directed behavior, thought, and affect by using working memory to provide representational knowledge about past or future events and integrating this information into a plan for action or to exercise inhibitory control over inappropriate actions or thoughts. In attentional/cognitive disorders these processes are impaired and manifested in symptoms that involve poor attention, planning, impulse control, and monitoring of one's behavior. Studies indicate that the right prefrontal cortex in humans is particularly important in the inhibition of activity (i.e., Stop or Go-No Go tasks) [5]. The orbital and ventral prefrontal cortex may also have a similar inhibitory effect in the affective domain, thus permitting appropriate social behaviors [163, 173]. In attention deficit/hyperactivity disorder for example, the anterior cingulate cortex has been implicated in the regulation of the motivational aspects of attention as well as in the regulation of response selection and inhibition [187]. Thus, researchers have begun to characterize attention deficit/hyperactivity disorder as a disorder with deficits in inhibitory processes involving frontal cortical structures [9]. Notably, there is a significant relationship between a history of attention deficit/hyperactivity disorder and smoking [108]. If a person must mentally manipulate information and make a response, the anterior cingulate cortex (with its connections to the prefrontal cortex) becomes active [134]. This area becomes particularly active in tasks where inhibitory control or divided attention is necessary [148].

The importance of the inhibitory role of these structures in drug dependence has also been highlighted by several researchers. Drug-addicted individuals, including smokers, continue to use drugs even when faced with negative consequences and diminished reward, suggesting an apparent loss of control [149]. The failure to regulate (i.e., inhibit) this drive points to a dysfunction within the prefrontal cortex [181] and related areas, including the anterior cingulate and orbitofrontal cortices [120]. As shown in Fig. 3, the resulting persistence of the behavior is not necessarily due to continued reinforcement by the drug (mesolimbic dopamine) but rather to the enhanced saliency of the drug and drug cues that have been firmly established (learned) in memory during the acquisition of dependence.

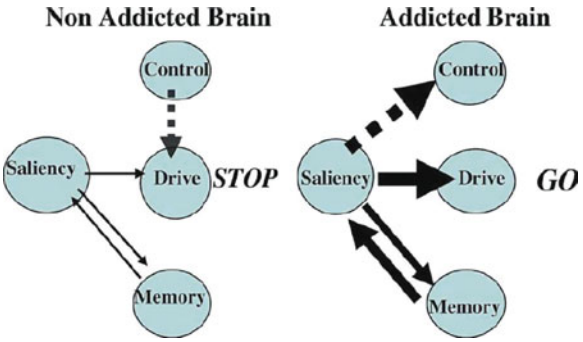

Fig. 3 Addiction model proposed based on results from brain imaging studies documenting abnormalities in brain circuits that involve saliency/reward, motivation/drive, memory/conditioning, and control/disinhibition. These circuits interact with one another and change as a function of experience and context. During addiction, the enhanced saliency value of the drug in the reward, motivation, and memory circuits overcomes the inhibitory control exerted by the prefrontal cortex. A positive feedback loop initiated by consumption of the drug and perpetuated by the enhanced activation of the motivation/drive and memory circuits results in compulsive drug seeking and taking. Reprinted from Volkow et al. [181], with permission from Elsevier

During maintenance of drug dependence these "super salient" drug-related cues, including self-administration, overcome the inhibitory control of the prefrontal cortex that might normally extinguish a response with decreasing hedonistic properties.

Preclinical studies suggest that the impairment in prefrontal cortex function may be related to significant dendritic branching and spine density resulting from repeated drug administration [151], thus amplifying the signal of salient events. Moreover, abstinence from the drug significantly reduces the efficiency of the prefrontal cortex to process information in working memory, thereby interfering with its regulatory function [189]. Such effects might be mediated by the negative affect associated with nicotine withdrawal, and when present, reduce the probability that a smoker may exercise an appropriate coping response and increase the probability of relapse [8, 189]. There is EEG evidence supporting persistent frontal lobe dysfunction among smokers using tasks related to working memory (P300). Neuhaus and colleagues [132] found a hypoactivation of the anterior cingulate, orbitofrontal, and prefrontal cortices among both current and former smokers compared with "never" smokers, suggesting that the dysfunctional activation patterns found in smokers may not completely remit after quitting; a fact that may increase their vulnerability to relapse.

A recent model by Curtin and colleagues [55] attempts to address the conditions under which cognitive control mechanisms affect the processing of motivationally relevant information (i.e., smoking cues) and the execution of situation appropriate behavior. The model holds that once dependence is established, drug use motivation is frequently driven by implicit processes that are largely automatic and outside of the user's awareness. These implicit processes are developed and maintained by negative and positive reinforcement learning. In the case of negative reinforcement, internal states associated with negative affect or drug withdrawal can engage motivational systems and drug use behavior in an attempt to ameliorate these aversive states. With positive reinforcement, environmental cues and positive mood states previously associated with rewarding drug effects can increase approach motivation. The model postulates that these learned associations trigger subcortical, "bottom-up" processes that can influence drug-seeking behavior implicitly by engaging appetitive or avoidance motivational systems. Thus, the drug user may frequently engage in drug use behaviors for reasons that are outside of conscious awareness.

While the Curtin et al. [55] model holds that drug sensitization is largely maintained by the implicit influence of learned associations on motivation, the authors also speculate about circumstances in which drug use comes under explicit or cognitive control. Cognitive control can be defined as the effortful application of attentional resources to meaningful information and tasks [24]. Cognitive control is crucial to learning as it is activated when an organism encounters unexpected outcomes, unfavorable outcomes, or response errors [88]. In this model, cognitive control is important because it is elicited during response conflict, which can occur when the user attempts to regulate the craving and drug-seeking behaviors that result from exposure to conditioned cues. Ultimately, cognitive control is what allows a drug user to engage in less well learned alternatives to drug-seeking behavior when drug craving and approach motivation are activated. However, it is during instances of response conflict and engagement of cognitive control mechanisms, that drug craving will be most acutely experienced by the drug user. If there are clear processing deficits engendered in the management of response conflict (also pertinent to error monitoring in the anterior cingulate cortex), behavioral resistance to the increased craving is also diminished.

Nicotine and Negative Affect

One of the most fundamental aspects of nicotine dependence involves its neuroregulatory function on mood. The relationship of negative affect with the maintenance and cessation of smoking behavior plays a prominent role in current theories of nicotine dependence [8]. In such model, it is theorized that individuals addicted to a substance learn to detect internal cues that negative affect is approaching as drug levels fall within the body. In order to prevent the onset of these negative feelings, the addicted person self-administers the drug, though often this process proceeds without conscious awareness. The longer the individual is without the drug, the more likely these negative feelings are to enter conscious awareness, providing direct reinforcement that taking the drug relieves negative affect (see Fig. 4). This relationship has driven the development of new pharmacological [47, 81, 93] and behavioral [33, 81] approaches to treatment. The experience of negative affect is a significant contributor to the risk of relapse and reports of negative affect reduction are cited by many smokers as an important reason to smoke. Improving the understanding of the psychobiological and genetic mechanisms associated with the modulation of mood by nicotine will help us better understand the mechanisms of nicotine dependence and the relationship between these mechanisms and treatment success.

The term "negative affect" refers to a composite index of many negative mood states, including feelings of depression, dysphoria, irritability, nervousness, etc., and is usually measured by Likert type scales such as the Positive and Negative Affect Scale [183], the Profile of Mood States [123], or other similar adjective checklists [156]. Research on the relationship between negative affect and smoking behavior has included evaluation of the effects of a past history of major depression, which may serve as a marker for vulnerability to future depressed mood, and evaluation of the effects of pre and post-cessation negative affect. A significant shared familial risk of depression and smoking has been identified for heavy and non-heavy nicotine-dependent smokers [96], and a history of major depression [1] has been associated with an increased prevalence of smoking [28, 29, 74, 103], nicotine dependence [28], and greater nicotine withdrawal severity. Some studies have found an inverse relationship between major depression history and quitting success [4, 25, 35, 73, 74, 80, 186] but these findings have not been uniform [30, 72, 87, 126, 133].

Negative affect following a quit attempt has been related to treatment failure and relapse across a variety of treatment modalities [23, 35, 104]. Indeed, the presence of negative affect following cessation has been found to characterize over 50% of all smoking lapses, with 19% of

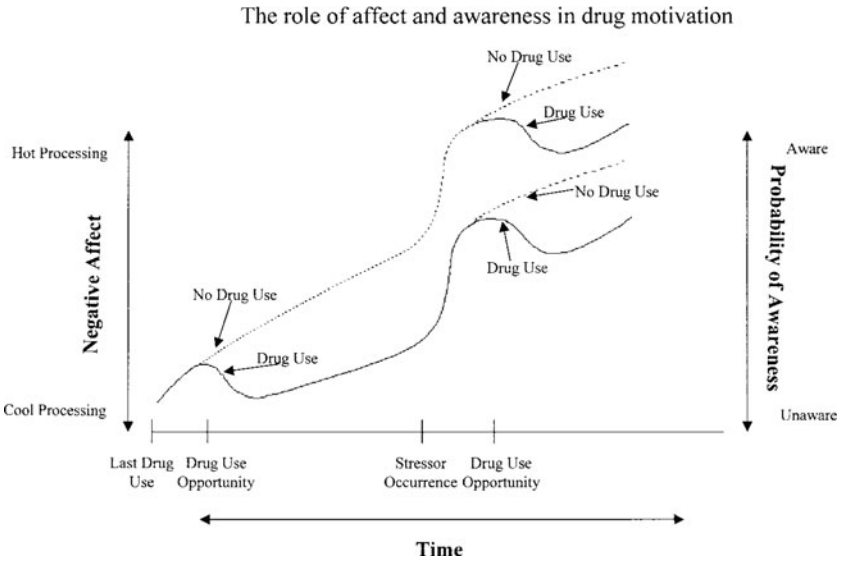

Fig. 4 Affective processing model of negative reinforcement in addiction. The *horizontal axis* represents time since last drug use, and the *vertical axis* represents intensity of the affective response. Affect increases in direct proportion to the amount of time since last drug use. As affect grows, the probability of the affect being consciously available grows as well. Also, as the affect escalates, information processing begins to be dominated by the hot system rather than the cool system. If the drug is used optimally, nascent negative affect will be quelled before it becomes available to consciousness. If drug use is impeded at this point, however, affect may become conscious, and the addicted individual may be aware that negative affect decreases following renewed drug use. Negative affect spurred by exteroceptive stressors can become conscious as well and may be relieved by drug use. Reprinted from Baker et al. [8]

all lapses occurring under conditions of extreme negative mood [156]. Negative affect appears to be the component of nicotine withdrawal that most profoundly influences relapse and the trajectory of nicotine withdrawal symptoms [104, 140, 141]. The expectation that nicotine will produce desirable emotional consequences [185] has also been shown to inversely predict cessation success. In addition to post-cessation negative affect, pre-cessation levels of negative affect [45, 72, 104, 106, 107] have been shown to predict cessation outcome.

When a smoker quits using tobacco, the above biological, cognitive, and behavioral aspects of dependence may increase the risk of relapse. However, many factors are associated with an increased risk for relapse after quitting smoking, including the availability of cigarettes, an increase in psychological stressors and a triggering of conditioning factors (cues). Visual cues can be seeing people smoking or going to a location where one used to smoke or obtain cigarettes. Such factors may trigger residual adaptational changes that occurred in the brain during the period of nicotine consumption and subsequent addiction.

Genetics

Heritability

Recent family, twin, and molecular genetic studies provide compelling evidence of a role for genetic factors governing smoking initiation, continuation and cessation, with estimated heritability rates ranging from 47 to 76% for initiation and 62% for persistence [37, 113, 112, 142, 152, 160]. The concordance rates for smoking, not smoking, and quitting are higher for monozygotic than for dizygotic twins, and the concordance rates for smoking in 82 pairs of identical twins reared apart were 79%. A meta-analysis of data from 8 studies revealed an

estimated heritability rate of 60% for smoking. For the maintenance of dependent smoking behavior, the percent of genetic contribution is about 70% [172]. Three linkage studies of smoking behavior [16, 62, 162] suggest that alleles that influence smoking behavior occur in only a small proportion of families.

Genome-Wide Association Studies of Nicotine Dependence

Recent genome-wide association studies related to nicotine dependence have been published. Uhl et al. [176] used 520,000 single nucleotide polymorphisms using a DNA pooling approach. They prepared pools of DNA from nicotine-dependent European-American smoking cessation trial participants and control individuals. Because in the DNA pooling technique individual genotypes are not available, they compared genotypes from the entire group of nicotine-dependent research participants to genotypes from European-American research volunteers free from any substantial lifetime use of any addictive substance. They performed analyses using smokers versus non-smokers and successful versus non-successful quitters and identified several genes of interest.

A study by Berrettini and colleagues [18] examined nicotine dependence using genome-wide association data from proprietary databases established to study cardiovascular and other common diseases. In this study, nicotine dependence was studied using a single indicator: cigarettes per day where cases were defined as smokers consuming $\geq$25 cigarettes per day and controls were noted as consuming <5 cigarettes per day. Their initial analysis identified a significant relationship (p=0.0006) between a single nucleotide polymorphism in the CHRNA3 region, rs6495308, though the p-value fell below the 10^{-7} expected for genome-wide analysis. Nevertheless, in a replication sample, another single nucleotide polymorphism in this same region, rs1317286, did meet the expected p-value for a relationship with cigarettes per day.

Bierut et al. [19] performed a genome-wide association on 1,050 nicotine-dependent individuals and 879 non-dependent smokers. This was a two-stage study in which DNA pooling was used in the first stage of analyses and 31,960 single nucleotide polymorphisms were selected and genotyped in the nicotine-dependent cases and non-dependent controls. They identified 35 single nucleotide polymorphisms with p-values less than 10^{-6}, however, none of these single nucleotide polymorphisms maintained significance after correcting for multiple testing. However, this study did identify several candidate genes. In a follow-up study, Bierut et al. [20] used data from the Collaborative Study on the Genetics of Alcoholism and contrasted smokers who consumed over 20 cigarettes per day with those who smoked >100 cigarettes in their lifetime but never more than 10 cigarettes per day. The results showed the non-synonymous coding single nucleotide polymorphism of the CHRNA5 gene, rs16969968 (p=0.007), was associated with habitual smoking. Other single nucleotide polymorphisms in this region that were highly correlated with rs16969968 included rs2036527, rs17486278, rs1051730, and rs17487223 (r^2>0.79). A second independent finding noted by these authors in this gene cluster, was an association with rs578776, for which a low correlation with rs16969968 (r^2<0.15) was observed.

There have been 3 recent genome-wide association studies which have identified gene variants in a region on the long arm of chromosome 15 (15q24/15q25.1) as significant contributors to the risk of lung cancer, as well as nicotine dependence. The region of interest encompasses the nicotinic acetylcholine receptor subunit genes CHRNA3, CHRNA5 and CHRNB4, and involves several single nucleotide polymorphisms in strong linkage disequilibrium with each other. These include rs1051730 [3, 89, 167] and rs8034191 [3, 89]. In the case control study by Amos et al. [3] and in a further analysis of these and other data by Spitz and colleagues [161], a significant relationship was noted for gene variants in this region (the "A" variant for rs1051730 in this analysis) associated with lung cancer, nicotine

dependence, and smoking quantity indices in cases and controls, as well as earlier age of smoking initiation and time to first cigarette in controls. A non-significant trend was also noted for an inverse relationship between the adverse allele and duration of cessation. Thorgeirsson and colleagues [167] also found a significant relationship between risk of lung cancer and peripheral artery disease and the "T" variant (TT TG GG) of rs1051730. A significant association was also found between the adverse allele likelihood of being a former smoker and as with the previous study; associations were also noted between the minor allele and smoking quantity, Fagerström Test for Nicotine Dependence scores and symptoms of nicotine dependence from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition. Interestingly, the genome-wide association study by Hung and colleagues [92] also noted a significant risk of lung cancer and the variant alleles of rs1051730 and rs8034191 but unlike the other two genome-wide association studies for lung cancer, these authors did not note an association with nicotine dependence: a finding which is at variance with several recent studies of nicotine dependence not involving cancer patients. For example, the rs1051730 single nucleotide polymorphism is in strong linkage disequilibrium (correlated) with the CHRNA5 single nucleotide polymorphism, rs16969968, for which the "A" variant has been shown to increase the risk of nicotine dependence in the studies noted above [20, 153]. This single nucleotide polymorphism also has an r^2 of 0.18 and 0.90 with rs6495308 and rs1317286, respectively, which are two single nucleotide polymorphisms in this CHRNA3-A5 region that have been shown to predict cigarettes per day in heavy smokers in the genome-wide association study by Berrettini and colleagues [18]. Further, in the Thorgeirsson et al. [167] study, the relationship of rs1051730 with Fagerström Test for Nicotine Dependence scores or symptoms on the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, was at a level similar to that observed in a candidate gene study using low frequency smokers as controls [153].

Candidate Gene Studies for Nicotine Dependence

An examination of the literature in this area shows that over 60 unique genes have been noted in candidate gene studies of nicotine dependence. Several reviews have been published in this area [39, 117, 118, 127–129] with most concluding that small sample size and replicability pose significant issues in interpreting these results. Additionally, the limited characterization of the phenotype (i.e., simple classification as a smoker or not) may further restrict the information that can be obtained from these studies. Most of the candidate genes studied to date fall into two categories: Nicotine metabolism and central nervous system receptor or neurontransmitter function. These include all the major single nucleotide polymorphisms that have been researched in the smoking literature related to dopamine pathways and nicotinic receptors—for example, DRD2, DOPA, ANKK1, DAT, COMT, CHRNA4, and CHRNB2 (see [70, 89, 94, 153, 191]).

Genome-Wide Studies Predicting Nicotine Cessation Treatment Outcome

Uhl and colleagues [177] recently conducted a genome-wide association study examining successful vs. unsuccessful quitters across three clinical trials: one using nicotine replacement (results from this sample were also previously published by this group [176]); and two using bupropion, in mixed racial samples. The combined sample for all three trials totaled 540 individuals with individual trial samples 266 and 150 for the two bupropion trials and 124 in the nicotine replacement therapy trials. This group of investigators used a DNA pooling strategy and Monte Carlo simulation analysis of gene frequencies to identify single nucleotide polymorphisms that differentiated abstainers and non-abstainers, as well as those that were specific to nicotine replacement therapy or bupropion. In total, they noted several thousand single

nucleotide polymorphisms with nominal significance covering over 100 genes, involved in numerous biological processes ranging from cell adhesion, transcription regulation, intracellular signaling, cell structure and unknown function. While intriguing and suggestive of a pharmacogenetic effect the results from this study are difficult to interpret given the sheer number of "hits" and the complex biological processes involved. Clearly, much more information is needed taking a more traditional approach to genome-wide association techniques to examine both predictors of abstinence and pharmacogenetic effects of smoking cessation medications.

Candidate Gene Studies Predicting Treatment Outcome

There have been a handful of candidate studies examining genetic predictors of nicotine replacement therapy and bupropion. Like the candidate gene studies on nicotine dependence, most of these studies have focused on markers in the dopamine pathway, given the importance of the dopaminergic neurotransmission in nicotine reinforcement. For example, several polymorphisms in the D2 receptor gene (DRD2), including C957T, -141Cins/del and Taq1A (ANKK1), C32806T and a VNTR in the DRD4 (C-521T) have been shown to predict cessation outcome to nicotine replacement therapy [60, 99, 116, 190]. Others have identified genes associated with opioid or serotonergic pathways [58, 115]. With the exception of the study by David et al. [60] most have predicted only end of treatment success. Similarly, many of these same markers (Taq1A, –141Cins/del) [17, 58, 59, 116, 165] and others (COMT, CYP2B6, DAT) [57, 114] have been associated with successful treatment by bupropion, as well as another antidepressant, venlafaxine [46, 47]. One recent candidate gene study took a systems approach to identifying single nucleotide polymorphisms associated with smoking cessation using bupropion [52]. This study involved a population of 217 and 195 smokers receiving bupropion or placebo, respectively. Using a systems-based candidate gene approach this study identified polymorphisms (rs2072661 and rs2072660) within the β_2 nicotinic acetylcholine receptor (CHRNB2) which showed significant association with abstinence rates at end of treatment and at 6-month follow-up in a placebo-controlled trial of bupropion for smoking cessation. The association with the two single nucleotide polymorphisms was very high (r^2=0.96). These effects were independent of treatment but there was some indication that abstinence might be modulated by bupropion. For example, there was a substantial increase in relapse rates for those individuals carrying the minor allele after treatment was discontinued. Subsequent analyses of rs2072661 showed a significant relationship with time to relapse at the 6-month follow-up period and modulation of withdrawal symptoms at the target quit date.

Diagnosis

Nicotine is reported to be among the most addictive of abused substances, especially when consumed through smoking tobacco. After prolonged smoking, the user develops nicotine tolerance and exhibits withdrawal symptoms when nicotine is absent, these are two physiological symptoms of dependence (addiction). Further, nicotine may be responsible for other criteria for dependence: loss of control over smoking (e.g., not being able to reduce or stop smoking; or smoking more than intended), compulsive use (e.g., spending more time using the substance or giving up important events to use the substance), and continued smoking despite adverse consequences (e.g., heart attack, emphysema or cancer). The presence of any three or more of those criteria for at least a year satisfies the definition of "dependence" (classically known as addiction), according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition [1] (see Table 1).

A traditional method of assessing nicotine dependence has been the Fagerström Test for Nicotine Dependence, which measures physiological dependence (tolerance and withdrawal)

Table 1 *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria for substance dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by *three* (or more) of the following, occurring at any time in the same 12-month period:

(1) Tolerance, as defined by either of the following:
   (a) A need for markedly increased amounts of the substance to achieve intoxication or desired effect
   (b) Markedly diminished effect with continued use of the same amount of the substance
(2) Withdrawal, as manifested by either of the following:
   (a) The characteristic withdrawal syndrome for the substance
   (b) The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
(3) The substance is often taken in larger amounts or over a longer period than was intended
(4) There is a persistent desire or unsuccessful efforts to cut down or control substance use
(5) a great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use of the substance (e.g., chain-smoking), or recover from its effects
(6) Important social, occupational, or recreational activities are given up or reduced because of substance use
(7) The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

Specify if:
– With Physiological Dependence: evidence of tolerance or withdrawal (i.e., either Item 1 or 2 is present)
– Without Physiological Dependence: no evidence of tolerance or withdrawal (i.e. neither Item 1 nor 2 is present)

reliably well (the first item of the scale in particular; see Table 2), but does not reliably measure some of the other dimensions of nicotine dependence (especially the behavioral ones). Most research studies have used the total Fagerström Test for Nicotine Dependence score of equal to or greater than 4 as a cutoff to include people in; as a synonymous of physiological dependence to nicotine [138, 146]. The Wisconsin Inventory of Nicotine Dependence [144] is

a more recently developed multi-dimensional scale of nicotine dependence. It is more comprehensive in scope than the Fagerström Test for Nicotine Dependence and includes measures of cognitive enhancement, negative reinforcement, positive reinforcement, automaticity, affiliative attachment, loss of control, behavioral choice/amelioration, craving, cue exposure/associative processes, social/environmental goals, taste/sensory processes, weight control, and tolerance.

Smoking and Psychiatric Comorbidities

There is substantial evidence to suggest that smoking is closely linked with several psychiatric comorbidities, suggesting shared biological pathways between nicotine dependence and these psychiatric conditions. For example, current smoking rates among those with no mental illness, lifetime mental illness, and past-month mental illness has been reported as 22.5, 34.8, and 41.0%, respectively. Remarkably, smokers with a mental disorder in the past month reportedly consumed 44.3% of all cigarettes smoked in this nationally representative sample [110]. Several studies have demonstrated a positive relationship between alcohol, substance abuse and other psychiatric disorders and smoking [10, 22, 31, 54, 74, 82, 110, 188]. For example, the lifetime prevalence rate of alcohol dependence or drug abuse is estimated at 23–30% among adult smokers [11, 26]. Among non-dependent and dependent current smokers, lifetime rates of mood and anxiety disorders have been reported as 12–26.7%, and 33.5–46.5%, respectively [26]. Similarly, as shown in Table 1, among tobacco-dependent smokers, 12-month prevalence of any mood or anxiety disorder was 21–22%, respectively, [79]. There is also an elevated risk of first onset of major depression, panic disorder, and generalized anxiety disorder among smokers [27, 30, 32, 97, 103]. In the area of cognitive dysfunction, odds ratios comparing "ever" with "never" smokers were positively related to the number of attention deficit/hyperactivity disorder symptoms. Among those reporting regular smoking over their lifetime, an inverse relationship between number of attention deficit/hyperactivity disorder symptoms and age of onset, and a positive relationship between symptoms and number of cigarettes smoked, has also been observed [108].

Treatment

The United States Department of Health and Human Services, in concert with other public health agencies, has provided general guidelines for the treatment of tobacco use and dependence. The guidelines were initially published in 1996 (summarizing 3,000 publications), updated in 2000 (adding 2,000 publications), and further updated in 2008, when information was added from about 2,700 newer publications and 10 key recommendations were included [69] (Table 3).

The chance for recovery from nicotine dependence is maximized when a comprehensive biological, psychological, and social (biopsychosocial) assessment is done. Such assessments, which should account for the smoker's motivation for change, can guide both psychosocial therapy and pharmacologic treatment. Pharmacologic treatments are used as adjunctive to psychosocial therapy. When psychosocial and medication treatments are provided in concert the odds of quitting smoking are doubled. However, medication alone can often alleviate some of the effects of nicotine withdrawal, decrease cravings for tobacco use, and decrease the risk of relapse.

Non–nicotine-based medications such as sustained-release "bupropion-SR" (Zyban or Wellbutrin-SR) and varenicline (Chantix) have been shown to reduce cravings and nicotine withdrawal symptoms when used as aids to quitting smoking. Bupropion-SR and varenicline are first-line therapies for tobacco dependence, while nortriptyline (Pamelor) and clonidine (Catapres) are considered second-line (see Table 4).

Table 3 Ten key guideline recommendations

The overarching goal of these recommendations is that clinicians strongly recommend the use of effective tobacco dependence counseling and medication treatments to their patients who use tobacco, and that health systems, insurers, and purchasers assist clinicians in making such effective treatments available.

1. Tobacco dependence is a chronic disease that often requires repeated intervention and multiple attempts to quit. Effective treatments exist, however, that can significantly increase rates of long-term abstinence.
2. It is essential that clinicians and health care delivery systems consistently identify and document tobacco use status and treat every tobacco user seen in a health care setting.
3. Tobacco dependence treatments are effective across a broad range of populations. Clinicians should encourage every patient willing to make a quit attempt to use the counseling treatments and medications recommended in this guideline.
4. Brief tobacco dependence treatment is effective. Clinicians should offer every patient who uses tobacco at least the brief treatments shown to be effective in this guideline.
5. Individual, group, and telephone counseling are effective, and their effectiveness increases with treatment intensity. Two components of counseling are especially effective, and clinicians should use these when counseling patients making a quit attempt:
   - Practical counseling (problem solving/skills training)
   - Social support delivered as part of treatment
6. Numerous effective medications are available for tobacco dependence, and clinicians should encourage their use by all patients attempting to quit smoking—except when medically contraindicated or with specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, and adolescents).
   - Seven first-line medications (5 nicotine and 2 non-nicotine) reliably increase long-term smoking abstinence rates: Bupropion SR, Nicotine gum, Nicotine inhaler, Nicotine lozenge, Nicotine nasal spray, Nicotine patch, Varenicline
   - Clinicians also should consider the use of certain combinations of medications identified as effective in this guideline.
7. Counseling and medication are effective when used by themselves for treating tobacco dependence. The combination of counseling and medication, however, is more effective than either alone. Thus, clinicians should encourage all individuals making a quit attempt to use both counseling and medication.
8. Telephone quit line counseling is effective with diverse populations and has broad reach. Therefore, both clinicians and health care delivery systems should ensure patient access to quit lines and promote quit line use.
9. If a tobacco user currently is unwilling to make a quit attempt, clinicians should use the motivational treatments shown in this guideline to be effective in increasing future quit attempts.
10. Tobacco dependence treatments are both clinically effective and highly cost-effective relative to interventions for other clinical disorders. Providing coverage for these treatments increases quit rates. Insurers and purchasers should ensure that all insurance plans include the counseling and medication identified as effective in this guideline as covered benefits.

Table 4 Food and drug administration—approved dosage and prescription availability for pharmacologic agents for smoking cessation

Cessation agent	Dosage	Label indication and use	Availability in United States	OR of efficacy (95% CI)
Nicotine gum	2 and 4 mg	2 mg ≤25 cig/day and 4 mg ≥25 cig/day; one piece every 1–2 h for weeks 1–6, one every 2–4 h for weeks 7–9, and one every 4–8 h for weeks 10–12	OTC; traditional, mint, and orange flavors, generic available	1.66(1.52–1.81)[a]
Nicotine patch	21, 14, and 7 mg	≥10 cig/day: 21 mg for 6 weeks, then 14 mg for 2 weeks; then 7 mg for 2 weeks, ≤10 cig/day: 14 mg for 6 weeks, then 7 mg for 2 weeks	OTC; clear and skin color; generic available	1.81(1.63–2.02)[a]
Nicotine nasal spray	10 mg/mL, 0.5 mg/squirt	2 squirts (one dose) per hour, minimum 8 doses/day, maximum 40 doses/day; recommended up to 3 months	Prescription only, 100 mg/bottle; no generic	2.35(1.63–3.38)[a]
Nicotine oral inhaler	10 mg/cartridge, 4 mg delivered	6–16 cartridges/day up to 12 weeks, then gradual reduction for another 12 weeks; usually individualized	Prescription only, 168 cartridges/box; no generic	2.14(1.44–3.18)[a]
Nicotine lozenges	2 and 4 mg	If first cig is ≤30 min after waking, use 4-mg lozenge; if ≥30 min, use 2-mg lozenge; use one every 1–2 h for 6 weeks, then one every 2–4 h for 3 weeks, then one every 4–8 h for 3 weeks; minimum 8 lozenges/day, maximum 20 lozenges/day	OTC; mint and cherry flavors; no generic	2.05(1.62–2.59)[a]
Bupropion-SR	100 and 150 mg	150 mg every morning for 3 days, then 150 mg twice daily; recommended for 3 months	Prescription available; generic available	1.94(1.72–2.19)[b]
Varenicline	0.5 and 1 mg	0.5 mg every morning for 3 days, then 0.5 mg twice daily for 4 days, then 1 mg twice daily up to 3 months; if successful may extend another 3 months	Prescription only; no generic	3.09(1.95–4.91)[c]; 2.66(1.72–4.11)[d]

[a]Odds ratio/comparative efficacy for nicotine replacement therapies with control (placebo), as reviewed by Silagy et al. [157]

[b]Odds ratio for overall bupropion-SR efficacy, as reviewed by Hughes et al. [91]

[c]Odds ratio for varenicline efficacy compared with placebo by Gonzales et al. [76]

[d]Odds ratio for varenicline efficacy compared with placebo by Jorenby et al. [101]

Pharmacologic agents for nicotine dependence may be grouped into three categories: nicotine agonists (i.e., nicotine replacement therapies), nicotine antagonists (bupropion and mecamylamine), and nicotine partial agonists (cytisine and varenicline).

Nicotine Agonists

Nicotine replacement therapies were the first pharmacologic treatments to be offered for smoking cessation. The quit rate among smokers who take a nicotine replacement therapy is double that of smokers who do not [102]. Some nicotine replacement therapies are available by prescription only, and some are available over the counter. The United States Food and Drug Administration has approved the following nicotine replacement therapies for smoking cessation: polacrilex gum (over the counter); patches (16- or-24 h; by prescription and over the counter); nasal spray (by prescription only); buccal inhaler (by prescription only); flavored gum (over the counter); and lozenges (over the counter). Table 2 provides more detailed information on nicotine replacement therapies.

In a recent review on nicotine replacement therapies, Silagy et al. [157] identified 123 trials on nicotine replacement therapies, 103 of which involved a comparison between a nicotine replacement therapy and a control (placebo) or a non-nicotine replacement therapy control. The Silagy group reported that the overall odds ratio for abstinence with nicotine replacement therapies compared with control (placebo) was 1.77 (95% confidence interval, 1.66–1.88). In addition, they reported that combinations of nicotine replacement therapies were more effective than any nicotine replacement therapy alone, and they offered the following conclusions: (1) 8 weeks of patch therapy is as effective as longer courses of patch therapy, and there is no evidence that tapering therapy is better than abruptly ending therapy; (2) wearing a patch only during waking hours (16 h/day) is as effective as wearing a patch for 24 h/day; (3) gum may be offered on a fixed-dose or as-needed basis; (4) highly dependent smokers (e.g., those who need to smoke within 30 min of waking) and those who have been unable to quit with 2-mg gum can be offered 4-mg gum, and (5) the effectiveness of nicotine replacement therapies appears to be largely independent of the intensity of psychosocial therapeutic support provided to the smoker. Lastly, the review stated that practitioners should give the client brief advice on how to quit and an overview of ways to improve the effectiveness of treatment.

Two considerations in offering combined nicotine replacement therapies are the client's previous success with a nicotine replacement therapy and the extent of nicotine dependence. If someone has had prior success quitting on one type of nicotine replacement therapy, using the same product again is recommended, assuming that the person is interested in nicotine replacement therapies instead of non–nicotine-based medications. Client education and management of expectations are key aspects of the clinical visit before treatment begins. This is especially true for combination approaches, such as the simultaneous use of two nicotine replacement therapies or of bupropion and a nicotine replacement therapy. Clients may hesitate to use such combinations since all nicotine replacement therapy labels still have a warning against combining nicotine replacement therapies as well as against continuing to smoke after starting a nicotine replacement therapy. To note, both the combination of nicotine replacement therapies and using nicotine replacement therapies with concurrent smoking are deemed safe by more recent research [67]. Results from several studies demonstrate the safety of combining nicotine replacement therapies; other studies have explicitly used nicotine replacement therapies (gums, inhalers, or patches) even if participants continued to smoke. Using nicotine replacement therapies in this way have helped reduce the number of cigarettes smoked each day by as much as 50% in participants who were not motivated to quit. Those studies pointed out a lack of significant nicotine toxicity or major adverse events [21, 65, 184].

Nicotine Antagonists

Bupropion

The Food and Drug Administration approved bupropion-SR (Amfebutamone) for the treatment of tobacco dependence in 1991 under the new trade name Zyban. Bupropion-SR therapy is typically started 1–2 weeks before the planned quit date at a dosage of 150 mg per day for 3–7 days. The dosage should then be increased to 300 mg/day (divided into two doses). Bupropion-SR was originally approved as an antidepressant it is considered an atypical antidepressant because it does not have a clearly known mechanism of action. Its pharmacodynamic properties include inhibition of norepinephrine reuptake and a modest inhibition of dopamine reuptake [6]. These properties are thought to contribute to bupropion-SR's antidepressant and antismoking action. In addition, recent studies [158] have suggested that bupropion-SR acts as a non-competitive antagonist on high-affinity (alpha4beta2) subnicotinic acethylcoline receptors. One of bupropion-SR's metabolites, (2S, 3S)-hydroxybupropion, has been hypothesized to be an even more powerful antagonist at alpha4beta2 nicotine receptors than bupropion-SR itself. Therefore, (2S,3S)-hydroxybupropion may also reduce nicotine reward, withdrawal symptoms, and cravings [56].

Bupropion-SR is contraindicated in individuals with a family history or personal history of seizure and in those who have ever had a significant head trauma that resulted in a loss of consciousness for more than 10 min. Patients with anxiety, insomnia, dry mouth, or tremors may experience a worsening of these symptoms with bupropion-SR. In those with elevated liver enzyme levels, bupropion-SR metabolites may accumulate and lead to toxicity.

Hughes et al. [91] analyzed the efficacy data on bupropion-SR as the sole therapy in a recent meta-analysis of 31 clinical trials that included more than 10,000 smokers. The meta-analysis found that individuals taking bupropion-SR were twice as likely as those taking a placebo to achieve long-term tobacco abstinence (odds ratio = 1.94; 95% confidence interval, 1.72–2.19). Bupropion-SR also has been shown to be effective in several special clinical populations such as schizophrenic [66] or depressed [34] individuals, veterans [12], smokers with post-traumatic stress disorder [85] and in primary care settings [130].

The addition of a nicotine replacement therapy to bupropion-SR therapy is believed to produce immediate relief from nicotine withdrawal, at least in the immediate post-cessation period. However, a large controlled trial showed that the combination of bupropion and one form of nicotine replacement therapy (the patch) was more effective than the either alone at the end of treatment; but it was not more effective than bupropion-SR alone at the one year follow-up [100]. Bupropion-SR can offer unique advantages for smokers who also have depression or attention deficit/hyperactivity disorder because it may alleviate some of the comorbid symptoms. It may also be an advantageous treatment choice in individuals who are overweight or afraid of gaining weight after they quit smoking as it seems to help in attenuating the weight gain associated with smoking cessation [125]. Bupropion seems to have a subtle but important positive effect on sexual dysfunction, especially if the dysfunction is related to the use of serotonin reuptake inhibitors [49].

Although other antidepressants and anxiolytics have not generally been found efficacious for smoking cessation [91], bupropion's antidepressant actions may make it a particularly attractive choice for smokers vulnerable to negative affect or among those with some level of affective and/or cognitive impairment. For example, in one study relative to placebo, bupropion has been shown to be effective among smokers with a history of depression [159], although absolute cessation rates among depression history positive and negative smokers may not differ [91]. Apart from smoking, bupropion has long been indicated for the treatment of depression, and recent studies have shown additional benefits including prevention of the recurrence and

improved efficacy for depressed individuals with concomitant anxiety (see Clayton [48]), as well as a favorable outcome for the treatment of cocaine addiction when combined with behavioral treatment [145]. Direct tests of bupropion with depressed smokers have not been carried out since those with concurrent depression are typically excluded from smoking cessation pharmaceutical trials. Similarly, given concerns about bupropion's seizure potential during alcohol withdrawal, it has not been directly used in the treatment of smokers with alcohol use disorders; (although other antidepressants with similar noradrenergic properties have shown efficacy in the treatment of depressed alcoholics (see Torrens et al. [171]).

Mecamylamine

Mecamylamine, a nicotine receptor antagonist, is used as an experimental therapy for smoking cessation. The addition of mecamylamine was shown in preclinical and clinical studies to increase the efficacy of nicotine patch therapy from 27.5–29% to 47.5–58%. However, a more recent multi-site controlled study reported that the increase in efficacy was not statistically significant [75].

Mecamylamine produces unpleasant side effects, such as postganglionic effects (e.g., orthostatic hypotension) and strong anticholinergic effects (e.g., dry mouth and constipation), which have limited its use to either clinical or laboratory research settings.

Nicotine Partial Agonists

Varenicline

Varenicline (trade name Chantix) is the first pharmaceutically designed compound with partial agonist effects at nicotine receptors to become available in the market. Varenicline is a selective partial agonist that stimulates the alpha4beta2 nicotine cholinergic receptors and consequently stimulates dopamine release in the nucleus accumbens, though to a lesser extent (40–60% less) than nicotine itself. By binding to nicotine receptors throughout its relatively long half-life (24 h), varenicline displays antagonistic properties as well. As it prevents the full stimulation of the receptors that ensues when nicotine is co-administered [50]. Because of these properties, varenicline may provide relief from withdrawal symptoms (an agonist effect) while blocking the rewarding effects of nicotine (an antagonist effect) [168]. Animal studies also have shown that varenicline acts as a full agonist of the alpha-7 nicotine cholinergic receptor. Though this property has no clear benefit for smoking cessation [124], it may have benefits for individuals with chronic mental disorders (e.g., schizophrenia).

Clinical trials have shown varenicline to be more effective than bupropion-SR or placebo for smoking cessation with a resulting odds ratio of 3–1 compared to placebo (Table 4). Two randomized double-blind clinical trials have compared varenicline (2 mg), bupropion (300 mg), and placebo. One showed overall continuous abstinence rates from the end of treatment through 1 year of 21.9, 16.1, and 8.4%, respectively [76]; and the other, 23, 14.6, and 10.3% [101]. In all these comparisons, continuous abstinence rates were significantly higher for varenicline than for bupropion or placebo even at 1 year follow-up with medication. In a combined analysis of the two trials, varenicline resulted in significantly higher continuous abstinence rates at 1 year than either placebo or bupropion (all p-values < 0.05) [77]. In this pooled analysis, varenicline nearly tripled the odds of quitting smoking compared with placebo even when using continued abstinence as a measure during the last 4 weeks of medication treatment (odds ratio $= 3.09$; 95% confidence interval, 1.95–4.91; $p < 0.001$). An additional 12 weeks of varenicline therapy (a total of 24 weeks) was given to those who abstained from smoking at some point during the first 3 months of varenicline therapy. After re-randomization to varenicline or placebo in a double blind design, the carbon monoxide-confirmed continuous

abstinence rate was significantly higher for the varenicline group than for the placebo group for weeks 13–24 (70.5% vs. 49.6%; odds ratio [OR], 2.48; 95% confidence interval [CI], 1.95–3.16; $p < 0.001$) as well as for weeks 13–52 (43.6% vs. 36.9%; OR, 1.34; 95% CI, 1.06–1.69; $p = 0.02$) [169]. Furthermore, those who received varenicline reported significantly less cravings and diminished withdrawal symptoms throughout the trial [36].

The most common adverse effects of varenicline are nausea, which occurs in up to 30% of individuals (approximately twice the rate of nausea as in those taking a placebo), flatulence, and abnormal dreams. Recently, the Food and Drug Administration (FDA) has received a large amount of reports indicating increased depressive symptoms, occurrence or increase in suicidal ideation, and difficulty with coordination. The FDA have requested from the manufacturer further analysis of existing data and prospective studies to clarify the relationship to the medication and the magnitude of such occurrences. It is currently recommended that individuals stop the medication and advise their health care provider immediately if they develop changes in behavior or any of the above symptoms [179]. For many patients, the prospect of using varenicline, a new option, seems to motivate them to quit smoking, especially for those who have not succeeded with older smoking cessation medications. It is possible that combining varenicline with bupropion-SR would provide better smoking cessation efficacy, although two trials are under way no data on this combination have been published.

Cytisine

Cytisine (also known as Tabex) is a nicotine-like alkaloid derived from the plant species *Laburnum anagyroides*. Little was known about cytisine in the United States until the fall of the Soviet Union in the 1990s. Most studies of cytisine for smoking cessation were open-label trials and the controlled studies were not done so rigorously. Further, most of the studies were from Bulgaria and none were published in the English-language literature, making it difficult for investigators in the United States to form a definitive scientific opinion on the efficacy of cytisine for smoking cessation [174]. A recent review and meta-analysis of two double-blind, placebo-controlled studies of cytisine (Tabex) reported a pooled odds ratio for smoking cessation of 1.83 (95% confidence interval, 1.12–2.99) at 3 and 6 months, while another double-blind, placebo-controlled trial resulted in an odds ratio of 1.77 (95% confidence interval, 1.29–2.43) at 2 years of follow-up [64].

Other Medications

Clonidine, a second-line pharmacotherapy, has exhibited modest efficacy in smoking cessation trials. Its superiority to placebo has been reported in two meta-analyses that included a total of 13 placebo-controlled clinical trials, with odds ratios of quitting smoking of 2.4 (1.7–3.28 95% confidence interval) and 2.0 (1.3–3.0 95% confidence interval) [53, 78].

Several tricyclic antidepressants, which inhibit the reuptake of norepinephrine and serotonin, such as nortriptyline (a second line pharmacotherapy), might facilitate smoking cessation either alone or in combination with behavioral treatment. There are 6 well-designed, controlled studies showing nortriptyline's effects on smoking cessation with an odds ratio of 2.1 compared to placebo [90]. However, tricyclic antidepressants have significant disadvantages, including anticholinergic burden, cardiac side effects, and potential for lethal overdose.

Other potentially useful medications that are not Food and Drug Administration approved at this time for smoking cessation include [71]: (1) rimonabant (Acomplia®), a cannabinoid-1 receptor blocker, (2) Quitpack® (a combination of mecamylamine plus bupropion-SR) and (3) topiramate (Topamax®).

A novel treatment approach currently under development is active immunization against nicotine via vaccination. The proposed mechanism of action is inducing the formation of

antibodies against nicotine, which binds nicotine in the blood stream and consequently prevents it from crossing the blood-brain barrier [86]. This would prevent the direct and active effects of nicotine on the acetylcholine nicotinic receptors in the brain, potentially attenuating its effect [139] on the reward pathway, thought to be central in developing nicotine addiction. Since nicotine is a small non-immunogenic molecule it must be bound to a carrier protein in order for the immune system to detect and form antibodies against it [7]. Candidate nicotine vaccines have been developed using different antigens [86], they are in different stages of testing [121] and include: (a) NicQb (by Cytos Biotechnology): A virus-like particle nicotine conjugate, inducing specific antibodies of the immunoglobulin G isotype (long-term response, i.e., antibodies) but not immunoglobulin E isotype (immediate reaction, i.e., allergy response) [122]; (b) NicVAX (by Nabi Pharmaceuticals): A detoxified pseudomonas aeruginosa r-exoprotein A [182]; (c) Ta-Nic (by Celtic Pharma): A cholera toxin-B subunit as a carrier protein for nicotine [40, 137]; (d); and a newer NicAb (being developed at University of Minnesota) based on a bivalent antigen mix: detoxified pseudomonas aeruginosa r-exoprotein A plus a keyhole limpet hemocyanin, resulting in an enhanced antibody response [105]. Clinical testing for these products is in various stages of development at this time.

Non-pharmacologic Treatments

Behavioral treatment delivered by a variety of clinicians (e.g., physicians, psychologists, nurses, pharmacists, and dentists) has been shown to increase abstinence rates when "the five A's" are applied [69]: (1) Ask if they smoke; (2) Advise them to quit; (3) Assess motivation for change; (4) Assist if they are willing to change; (5) Arrange for follow-up.

More than 100 studies have validated the use of multimodal behavioral therapies (includes a combination of approaches such as supportive, cognitive behavioral, and motivational techniques) for smoking cessation, either alone or in combination with pharmacologic therapies. Multimodal behavioral therapies without pharmacologic agents achieve double the quit rates compared with controls that come for research visits, with 6-month efficacy ranges between 20 and 25%. While more intensive treatments usually translate into higher abstinence rates, not every smoker requires the same amount of intervention.

Summary

Long term tobacco use, usually resulting in nicotine dependence, is the leading cause of preventable disease and death in the United States and worldwide. Nicotine addiction activates the reward pathway and consequently the prefrontal cortex in a similar way to other addictions. Familial traits and genetics are responsible for as much as 60% of the variance for nicotine dependence, several single nucleotide polymorphisms and specific chromosomes have been implicated. Smoking cigarettes is a very fast and effective tool for nicotine delivery and nicotine dependence is a multifaceted syndrome consisting of biological, behavioral, and cognitive components. After a cessation attempt the emerging negative affect (anxiety, depression, irritability, etc.) has been found to correlate with relapse to smoking. Therefore, the treatment of nicotine dependence often requires an integrated approach that includes behavioral and motivational therapy in addition to medication. The diagnosis of nicotine dependence is usually made clinically, however there are several scales that can be used to quantify the level of dependence, such as the Fagerström Test for Nicotine Dependence and the Wisconsin Inventory of Nicotine Dependence. After more than two decades of research and development, health professionals can now turn to an arsenal of efficacious pharmacotherapies to treat smoking cessation. These agents often double the odds for quitting over placebo and in some cases almost triple the odds of quitting over those of placebo. Indeed, many smokers have benefited from these treatments and quit successfully.

However, despite these advances, many smokers relapse and unfortunately the long-term abstinence rates among smokers who are interested in quitting smoking remain low despite the best efforts and pharmacological treatment.

Introduction

Marijuana (also referred to as cannabis) is a drug that is derived from the flowers, stems, leaves, and seeds of the hemp plant (*Cannabis sativa*). The need for public health awareness and evidence-based clinical care for marijuana use and its disorders remains a major health care priority in the United States and beyond. Indeed, marijuana has been the most widely used illicit substance in the United States for the past 30 consecutive years [66], with approximately 25 million people in the United States (8.6% of the population) having used marijuana in the past year [67]. An estimated 10% of persons who have ever used marijuana will become daily users [64]. Lifetime marijuana dependence is estimated at 4% of the general population, a rate that is the highest of any illicit drug [3, 4]. These rates of marijuana use, abuse, and dependence in the United States represent a significant public health concern considering that several well-documented negative consequences have been associated with daily or weekly drug use (e.g., increased risk of severe medical disease, increased risk taking behavior, and clinically significant life impairment) [9, 81, 109].

The overarching aim of the present chapter is to provide an overview of marijuana use and its disorders. The chapter is organized into seven sections. First, we describe the prevalence of marijuana use and its disorders. Second, we clarify the nature of marijuana use in terms of its pharmacokinetics and acute intoxication features. In the third section, we describe the

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_20,

classification of marijuana use and its disorders using the current diagnostic nomenclature. Fourth, we describe the motivational bases for use of the drug. In the fifth section, we provide a synopsis of some problems associated with marijuana use and its disorders, including health problems, social problems, and psychological disturbances. Sixth, we provide a summary of the scientific work focused on marijuana, the reasons for its use, and users' relative success in quitting. In the final section, we describe some practically oriented clinical issues for primary care medical practitioners to consider in terms of the recognition and treatment of marijuana use and its disorders.

Prevalence

Marijuana has been the most widely used illicit substance for 30 consecutive years in the United States [65], with approximately 25 million people in the United States (8.6% of the population) having used marijuana in the past year [67]. An estimated 10% of persons who have ever used marijuana will become daily users [64]. Lifetime marijuana dependence is estimated at 4% of the general population, a rate that is the highest of any illicit drug [3, 4]. Rates of conditional dependence, defined as the risk for developing dependence among those who have ever used the drug, indicate that marijuana is associated with a high rate of dependence potential [4]. For example, the relative risk of experiencing marijuana dependence given use of the drug in the past year is estimated to be 7% among adults, which is only slightly lower than that for cocaine (12%) and greater than that observed for alcohol (5%) [69]. Furthermore, greater levels of use are related to an increased risk for dependence. Studies suggest that the rate of dependence is 20%-30% among those persons using marijuana on a regular (weekly) basis [49]. Moreover, marijuana use problems have increased in certain parts of the world, with 35% of adult marijuana users in the United States currently meeting criteria for marijuana abuse or dependence, compared with 30% 10 years earlier, representing an increase of approximately 730,000 individuals [26].

Of special relevance to clinical practitioners, many treatment and community studies have examined prevalence rates of marijuana use among different samples suffering from a variety of medical and psychological problems. For example, one study found that among those seeking treatment for psychosis, approximately 23% currently used marijuana, with about half of that group currently "misusing" the drug [47]. This study examined the "misuse" of marijuana rather than abuse or dependence. As a result, the precise percentage of those abusing or dependent on marijuana in this study is not known. Another community-based study found that approximately 16% of those with spinal cord injury used marijuana [117]. Other work found that marijuana use accounted for as much as 25% of the primary drug problems of individuals seeking residential drug treatment [38]. Similarly, among adolescents seeking outpatient services for marijuana abuse or dependence, approximately 38% reported suffering from depression and 29% reported acute levels of anxiety [37]. These studies suggest that marijuana use: (1) may be overrepresented among certain "vulnerable" populations and (2) is a primary clinical concern.

Nature of Marijuana Use: Pharmacokinetics and Acute Intoxication Features

Pharmacokinetics

Marijuana can be consumed via smoking (e.g., hand-rolled cigarettes, water pipes, non-water pipes) or ingestion (e.g., mixed into foods or used in the process of brewing tea). Marijuana shares some qualities with tobacco in that it is composed principally of plant material, often is used via smoking routes (e.g., pipes, joints), and contains a myriad of chemical compounds. Unlike tobacco, however, the active

agents in marijuana are cannabinoids (unique to the marijuana plant). There are at least 60 different cannabinoids in marijuana, although the pharmacokinetics of the vast majority of these compounds is largely unknown [6]. Of these, the most well-known, and arguably important, cannabinoid is tetrahydrocannabinol, which is believed to be the most potent psychoactive agent in the cannabinoid plant [110]. The tetrahydrocannabinol content of plants from a range of sources and strains varies dramatically [86]. With a focus on improved plant breeding and improved growing techniques, the tetrahydrocannabinol content of marijuana has increased dramatically in a short period of time. As one illustrative example, tetrahydrocannabinol content from a typical marijuana cigarette (joint) in the 1960s was 10 mg, whereas estimates suggest that it currently is around 1 g (or 150–200 mg) [6]. Given that marijuana effects are dose dependent (i.e., greater amount or potency yields greater effect) [110], the significantly increased potency of marijuana available in the current time period relative to the past is a major public health concern and is important to understanding the current and historical prevalence rates of use, abuse, and dependence.

Since the discovery of a cannabinoid receptor within the brain in the late 1980s, researchers have been able to explicate the process by which tetrahydrocannabinol acts on the brain. Currently, there is evidence of three potential cannabinoid receptors, only one of which is located within the brain (the cannabinoid-1 receptor) [110]. When tetrahydrocannabinol is inhaled into the body via marijuana smoking, it passes from the lungs into the bloodstream [56]. Once in the blood, tetrahydrocannabinol attaches to cannabinoid receptors, such as the cannabinoid-1 receptor, adding to or reducing the naturally occurring endogenous ligands for these receptors (e.g., anandamide) [36]. The cannabinoid-1 receptor, in particular, has been found to mediate both neurochemical and behavioral properties of these cannabinoids including tolerance [110]. It also is noteworthy that tetrahydrocannabinol and other cannabinoids move rapidly into fat and other bodily tissues but are relatively slowly released from these tissues back into the bloodstream [61]. Eventually, cannabinoids are cleared from the body via urine and fecal matter [110].

Acute Intoxication Features

In general, marijuana consumption produces a mild, relatively short period of intoxication (being "high"). More specifically, marijuana can produce a range of acute psychosensory experiences including perceptual distortions (e.g., hallucinogenic properties), relaxation, anxiety, acute paranoia, inhibition, and so on [63]. Periods of intoxication depend on use patterns and potency, but tend to last for at least a few hours [21, 87, 91]. Marijuana intoxication also impairs cognitive and psychomotor performance with complex, demanding tasks [50, 98]. There is a dose-dependent relation between marijuana use and psychomotor and cognitive impairment, with higher doses being associated with more impairment for more demanding tasks [6, 50]. Although cognitive impairment for hours after using marijuana is a well-replicated phenomenon in laboratory studies [98], there has been consistent debate about the permanent cognitive effects of using marijuana [6]. Some recent work suggests that individuals who have used marijuana over long periods of time demonstrate impaired performance on a variety of neuropsychological tests (e.g., attention, memory, and processing complex information) even when not acutely intoxicated [51]. These negative cognitive effects appear to be present months and even years after successful cessation [98]. Overall, pre-existing cognitive deficits or disease may be exacerbated or complicated by regular marijuana use.

Classification of Marijuana Use and Its Disorders

The current diagnostic criteria for problematic patterns of marijuana use, according to the *Diagnostic and Statistical Manual of Mental*

Table 1 Criteria for marijuana abuse

A. A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:
   1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home.
   2. Recurrent substance use in situations in which it is physically hazardous.
   3. Recurrent substance-related legal problems.
   4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance.

B. The symptoms have never met the criteria for marijuana dependence.

Table 2 Criteria for marijuana dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period [2]:

1. Tolerance, as defined by either of the following:
   (a) a need for markedly increased amounts of the substance to achieve intoxication or desired effect
   (b) markedly diminished effect with continued use of the same amount of the substance
2. Withdrawal, as manifested by either of the following:
   (a) the characteristic withdrawal syndrome for the substance
   (b) the same (or closely related) substance is taken to relieve or avoid withdrawal symptoms
3. The substance is often taken in larger amounts or over a longer period than was intended.
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use.
5. A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects.
6. Important social, occupational, or recreational activities are given up or reduced because of substance use.
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.

Disorders, 4th edition, include abuse and dependence [2] (see Tables 1 and 2 for the diagnostic criteria for marijuana abuse and marijuana dependence, respectively). Marijuana abuse is a pattern of marijuana use that includes significant and unpleasant consequences associated with frequent use. This pattern needs to have occurred within a 12-month period. Some of the consequences associated with marijuana abuse include multiple legal problems, repeated use in physically hazardous situations, and recurrent social and interpersonal problems as a result of use. What differentiates substance abuse from dependence is that abuse only includes harmful consequences of frequent use, whereas dependence indicates compulsive use, tolerance, or withdrawal [2]. As with diagnosis of other substance use disorders, it is also important to note that marijuana abuse cannot be diagnosed if marijuana dependence criteria are met. This important distinction highlights the putative more severe nature of marijuana dependence.

There are relatively few empirical data, however, pertaining to the validity of distinguishing among marijuana use, abuse, and dependence [48]. Moreover, for a long period of time, scholars did not uniformly endorse or support a marijuana dependence syndrome [16]. Current research has partially laid these earlier questions to rest in that heavy users of the drug tend to report problems controlling their use, despite noted negative consequences, and experience withdrawal and other adverse symptoms when discontinuing use (see [51] for a review). In fact, the best estimates suggest that approximately 1 out of every 10 individuals who use the drug become dependent on it at some point in the future [4], a pattern of data consistent with alcohol use problems, but markedly lower than that found with tobacco [4].

To date, researchers have employed standardized interviews to index marijuana diagnoses in a manner identical to those for other types of substances (e.g., alcohol, tobacco). At the

same time, in contrast to the relatively recent emerging perspective that classification of marijuana along the nosological lines of use, abuse, and dependence is the optimal and most accurate approach [16], it has been more common historically to denote marijuana use variability by asking respondents to indicate their level of use (e.g., frequency) over a specified period of time [33]. From this perspective, having participants specify the frequency, and perhaps quantity, of marijuana use also can be a common assessment method [24]. Collectively, then, deciding upon whether nosological classification and/or a use-oriented assessment protocol (i.e., volume and frequency) is indicated may depend on the specific clinical need or research question being posed and the theoretical basis for it.

Motivational Bases of Marijuana Use

Researchers and clinicians also have increasingly found merit in applying motivational models to understand and clinically intervene with marijuana use and its disorders. This work has built from the motivational study of alcohol [28, 31, 106, 107] and tobacco [62, 88, 90, 120] use. At the most basic level, such an approach recognizes that there are a number of distinct motives for using marijuana that can vary both between and within individuals [27]. That is, two individuals may use marijuana for different reasons, and one individual may use for multiple types of reasons. Motivational models predict that distinct motives may theoretically be related to particular types of problems [27]. For example, specific motives may play unique roles in various aspects of use (e.g., addictive use, withdrawal symptoms, craving) or problems related to use (e.g., psychological disturbances, risk-taking behavior). Thus, enhancing efforts to explicate marijuana use motives empirically will presumably facilitate, as it has for alcohol and tobacco use [27, 88], the nature of marijuana use and its disorders as well as linkages between marijuana use and its clinically important correlates.

Recognizing the practical importance of theoretically delineating and empirically measuring marijuana use motives, Simons and colleagues developed the Marijuana Motives Measure [96, 97]. Studies have evaluated the factor structure of the Marijuana Motives Measure: one focused on young adults in the United States ($n = 161$ [97]); one focused on young adults and adolescents in France ($n = 114$ [22]), and the most recent one focused on young adult marijuana users in the United States ($n = 227$ [122]). Using a combination of exploratory factor analytic and confirmatory factor analytic approaches, the Marijuana Motives Measure demonstrated a multidimensional measurement model across extant work—specifically, a five-factor solution denoting Enhancement, Conformity, Expansion, Coping, and Social motives for marijuana use, each with satisfactory levels of internal consistency [22, 97, 122].

Existing motivation-oriented work on marijuana is important in terms of informing the understanding of how and why marijuana use may be related to certain patterns of substance use and psychological problems. For example, greater levels of Coping, Enhancement, Social, and Expansion motives for marijuana use have each been found to be concurrently significantly associated with frequency of past-30-days marijuana use [10, 22, 96, 97]. These associations between motives for use and frequency of use do not appear to be attributable to other alternative factors such as amount of time being a marijuana user or other types of concurrent substance use [10]. However, the exact directional relation between marijuana motives and patterns of marijuana use remains underexplored. For example, it is not known whether specific marijuana motives explain variance in marijuana use patterns when controlling for the shared variance with other motives (e.g., the explanatory value of coping motives when controlling for shared variance with other marijuana use motives). Still, it is noteworthy that other work suggests that specific motives may be relevant to the understanding of psychological vulnerability. For example, coping motives for marijuana use, but not other motives, have been significantly predictive of

negative affect, anxious arousal, and anhedonic depressive symptoms [83]. These types of findings may have important theoretical implications for a better understanding of previous research linking marijuana use to affect-based psychological vulnerability.

Negative Correlates of Marijuana Use and Its Disorders

Historically, marijuana has been viewed by some as a "less severe" or "soft" drug [100]. In contrast, scientific study has provided a corpus of empirical evidence that marijuana use and its disorders are associated with a number of clinically significant problems [68]. Indeed, there are several empirically documented negative consequences of frequent or problematic marijuana use (typically defined as weekly or daily use). These negative effects are evident in physical, social, interpersonal, and, more recently, psychological realms. In this section of the chapter, we describe some examples of work pertaining to possible negative correlates of marijuana use.

Health-Related Problems

Perhaps the foremost negative effect linked to various types of marijuana use is its impact on physiological processes, particularly the cardiovascular and pulmonary systems. On the one hand, as would be expected, many of these effects are similar to those typically found with tobacco. On the other hand, due to the potentially greater level of carcinogenic properties of marijuana relative to tobacco [99], among certain subpopulations of users (e.g., those using marijuana more frequently), the negative medical effects of this drug are, perhaps, even more clinically noteworthy. For example, frequent marijuana use is associated with increased risk of severe respiratory illnesses, especially chronic bronchitis [9]. Other work has shown that when compared with individuals who do not use marijuana or tobacco, or with tobacco smokers who have no marijuana use history, the lung function of those who use marijuana regularly is significantly poorer [41].

There also has been a series of important large-scale prospective studies documenting the negative effects of marijuana over time on pulmonary functioning (e.g., [94, 111, 112]). Though the results across investigations are not fully consistent, they converge on the observation that greater duration of marijuana use is related to increased bronchitis symptoms (e.g., coughing, wheezing [111]). There also are studies of the relations between marijuana use and cancer. Most investigations suggest that there is an increased risk of lung cancer among more frequent users of the drug [20]. Controlled studies of these cancer-related negative effects of marijuana use, however, are largely underrepresented in the literature. In addition to the increased risk for lung cancer, it is noteworthy that some research suggests that marijuana use may be related to impaired immune system functioning, but these investigations, again, have not been consistently replicated [25, 58, 71]. Upon close inspection of these studies, it becomes clear that some of the inconsistencies of these investigations may be related to problems in the measurement of marijuana use and individual differences in use. A similar set of issues is evident for linkages between marijuana use and impaired reproductive effects. Non-human research suggests that heavier marijuana use is related to impaired reproduction capacity [51], but controlled evidence among humans is currently lacking [20].

It should be noted that although the vast majority of research has focused on elucidating putative negative health consequences or correlates of marijuana use, there has been scientific and clinical interest in possible health benefits of the drug. Namely, marijuana has been suggested to improve certain disease symptoms (e.g., by decreasing eye pressure, involuntary movement, and perceived pain) and to stimulate appetite [57, 58]. Although this body of work is complicated, the strongest evidence of possible health

benefits for marijuana use appears to be focused on increasing appetite, decreasing nausea and vomiting, preventing systemic weight loss, and possibly improving pain tolerance [58].

Social Problems

In addition to the potential risk of a number of negative physical consequences, adverse social consequences related to certain types of marijuana use have been reported (e.g., frequent users such as those who use on a daily or weekly basis). Lynskey and Hall [78], for example, reviewed evidence suggesting that marijuana use was a contributing factor to impaired educational attainment, and others have found that marijuana use leads to reduced workplace productivity [74], as well as impaired judgment within hours after marijuana use (e.g., among airline pilots [75]). In all of these studies, a consistent pattern emerges: the greater the amount of use (measured in frequency of use or severity of use), the greater the impairment. The specific mechanism(s) underlying these use-related effects are as yet theoretically and empirically unspecified.

As another example, marijuana use has been shown to be related to other social problems. For example, one cross-sectional study found that those who are dependent on marijuana compared with those who are not demonstrate greater levels of clinically significant impairment in life activities (e.g., work or school performance [103]). Additionally, quantity of marijuana use and acute intoxication have been related to general risk-taking behavior and impaired judgment. For instance, marijuana use has been linked to fatal traffic accidents and general driving impairment [40], even after statistically controlling for the variance accounted for by alcohol use [43]. Other work suggests that frequent or more severe marijuana use may lead to using more severe forms of other drugs (e.g., widely publicized, but sometimes controversial, "gateway theories" of the developmental nature of substance use patterns) [85]. One overarching limitation to the vast majority of work linking certain types of marijuana use to social and interpersonal functioning, and even future use of other substances, is that there is a dearth of (controlled) prospective evaluations. Thus, conclusions drawn from extant work should be viewed conservatively.

Psychological Problems

There have been a variety of psychological problems associated with marijuana use and its disorders. Perhaps the most well-known psychological problem(s) associated with marijuana use and its problems has been psychotic-spectrum disorders. There are numerous lines of empirical evidence that have provided robust evidence of an association between marijuana use and psychotic-spectrum disorders. Indeed, case reports of marijuana use have documented that such drug use can precede the onset of certain psychotic-spectrum disorders such as schizophrenia at higher rates than expected by chance of psychosis among "regular" marijuana users [11]. Although the directional nature of the marijuana-psychotic-spectrum problem association has been the subject of consistent intellectual debate (e.g., [52]), one position has been that the use of marijuana may actually increase the risk of psychotic-spectrum disorders [11]. Consistent with this marijuana-to-psychotic symptoms/disorders perspective, the acute effects of marijuana use have been found to contribute to the elicitation of psychotic episodes and exacerbations of such symptoms among previously afflicted persons (e.g., the recurrence of psychotic symptoms [80]). Other work has found that intravenous tetrahydrocannabinol administered to antipsychotic-treated patients with schizophrenia and non-psychiatric controls exacerbated positive schizophrenic symptoms in the patient sample and induced positive symptoms in controls [39]. Neuroimaging studies also have found similarities between neural networks impaired by marijuana use and those known to be implicated in the etiology of schizophrenia (see [77] for a review). Finally, in

a meta-analytic review of the existing empirical literature, Semple and colleagues [93] concluded that the early use of marijuana increased the risk of schizophrenia or a schizophrenia-like psychotic illness by approximately three-fold. Although a model indicating that marijuana may lead to psychotic-spectrum disorders provides only one possible way in which these factors may be related, it documents the importance of understanding marijuana in the context of severe mental illness.

In another area of research, scientific activity has been focused on addressing marijuana's relationship to depressive symptoms or problems [46]. The interest in this line of inquiry appears to have been historically fueled by the clinical observation that regular (e.g., on a daily or weekly basis) marijuana users often reported a "lack of motivation" for completing day-to-day activities (e.g., going to school [115]). The depression-marijuana literature has sometimes identified statistically significant relations between marijuana use and depressive symptoms and disorders [23]. However, the most recent work in this domain has indicated that the strength of such marijuana-depressive associations may be relatively weak, and markedly attenuated, or even nonexistent, after controlling for "common" variables such as gender [34]. As one illustrative example, Brook and colleagues [13] completed a study that involved a two-time (1- to 2-year interval) prospective study of Colombian adolescents (n = 2,226; 48.2% female) who were 12–17 years old. Findings indicated that marijuana use in early adolescence did not significantly predict later depressive symptoms (time 2) after controlling for distress and interpersonal functioning in earlier adolescence (time 1). This work, when considered in the context of the psychotic-spectrum research, noted earlier highlights that marijuana should not be considered to have the same types of linkages with all forms of mental illness.

Another stream of more recent work has begun to address the relations between marijuana use and anxiety symptoms and disorders. This work was initially stimulated by the observation that marijuana use may acutely promote heightened levels of anxiety symptoms and elicit panic attacks under certain conditions or among certain individuals [57, 113, 115]. For example, when a person is intoxicated from using marijuana, they may experience acute paranoia, escalating anxiety symptoms, and perhaps a panic attack. This type of experience makes intuitive sense in that marijuana can elicit a wide range of acute sensory-oriented experiences and distortions that may be perceived as out of the person's control and could be interpreted as threatening by some persons fearful of such internal stimuli and experiences. Some evidence appears consistent with this perspective. For example, Hathaway [55] found that among weekly users of marijuana (n = 104), approximately 40% reported having had at least one panic attack related to such use. These prevalence rates are noteworthy in light of lifetime rates of panic attacks among the general population of approximately 5–8% [72]. Another study found that, after covarying cigarettes per day, alcohol use, and negative affectivity, the interaction between marijuana use and anxiety sensitivity (fear of anxiety and related internal sensations) is related to increased levels of anxiety symptoms among marijuana users who also use tobacco [119]. Thus, certain individual differences such as anxiety sensitivity may be important to consider in understanding the linkages between marijuana use and anxiety states and disorders.

Another study involving a representative sample (n = 4,745) found that a lifetime history of marijuana dependence, but not use or abuse, was related to an increased risk of panic attacks after covarying the effects of polysubstance use, alcohol abuse, and demographic variables [118]. In a more recent investigation, Zvolensky and colleagues [121] prospectively evaluated marijuana use, abuse, and dependence in relation to the onset of panic attacks and panic disorder. Participants at the start of the study were adolescents (n = 1,709) with a mean age of 16.6 years (SD = 1.2; time 1) and were reassessed 1 year later (time 2) and then again as young adults (time 3; mean age = 24.2 years, SD = 0.6). Results indicated that adolescent-onset marijuana use and dependence were significantly

prospectively associated with increased odds for the development of panic attacks and panic disorder. However, marijuana use or dependence was not *incrementally* associated with the development of panic after controlling for daily cigarette smoking. These recent findings underscore the importance of considering the role of cigarette smoking in the context of marijuana use in regard to understanding panic vulnerability.

Marijuana: Motivation to Quit, Reasons for Quitting, and Success in Quitting

Though historically and presently presumed by some key segments of the general public to be "relatively harmless" [5], it is important to point out that marijuana has many cardinal features of addiction similar to more "hard drugs". Indeed, for many individuals who use marijuana, tolerance to the drug develops and, presumably, contributes to more frequent or heavier use patterns or dosing with more potent ("more pure tetrahydrocannabinol") forms of the drug [50]. For example, non-human research and, more recently, a smaller human empirical database suggest that marijuana discontinuation among regular users produces an internally consistent withdrawal pattern (see [17] for a review). Disrupted sleep, nightmares, nausea, anxiety, tension, irritability, sweating, and chills are common withdrawal symptoms [15, 18, 17, 53]. Many of these symptoms appear early after drug discontinuation [18], and some may last for weeks beyond the quit day (e.g., disrupted sleep [18, 17]). This withdrawal profile can appear relatively quickly during the course of use (e.g., relative early in the marijuana using career [14, 29, 103, 101]) and may have clinical importance in terms of predicting relapse [19], although current data are not yet developed enough to yield conclusions in this regard. With the recognition that marijuana use and its disorders are common addictive behaviors and can be related to life impairment and a variety of related negative consequences, it is natural to question how motivated users are to quit, what their reasons are for quitting, and what their relative degree of success is in doing so?

Motivation to Quit

Two bodies of empirical evidence indicate that a large number of individuals who use marijuana on a regular basis (e.g., monthly) and who meet a range of diagnostic criteria (from use through dependence) are motivated to quit. The first literature has evaluated treatment-seeking behavior. Here, the Drug Abuse Reporting Program [92] and other reports [95] first documented that a clinically significant number of individuals were seeking therapeutic services for problematic marijuana use. Other large-scale surveys independently replicated such findings [42, 59]. Dennis and colleagues [35] reported that of "the 1.5 million adult admissions to the U.S. public treatment system in 1998, 35% were admitted for treatment of marijuana problems" (p. 9). Such rates are higher than those found for cocaine (32%), opioids (18%), stimulants (9%), and other psychoactive substances (12%) [35]. Additionally, other reports involving national databases have found that the demand for treatment of marijuana use and its disorders doubled between 1992 and 1998 [108]. It also is important to note that marijuana treatment outcome studies have documented that a large number of treatment-seeking marijuana users are *not* current polysubstance abusers [100, 102]. For example, Stephens and colleagues [103] found that 80% of a large, marijuana-dependent sample ($n = 309$) did not report abuse of other substances in the past 90 days and 40% reported never abusing an illicit drug other than marijuana. These data indicate that marijuana represents a significant clinical and public health problem in its own right and commonly prompts treatment-seeking behavior even in the absence of other drug use.

The second body of evidence related to motivation to quit suggests that, despite the notable rates of documented treatment-seeking behavior,

most persons using, abusing, or dependent on marijuana actually attempt to quit on their own [30, 32, 116]. Self-quit behavior is operationally defined as attempts to quit without professional assistance (i.e., enrolling in a formal treatment program that uses pharmacological, psychosocial, or combined therapeutic approaches) [30]. Numerous studies have reported that by young adulthood, many individuals have made multiple marijuana quit attempts on their own. It also is noteworthy that rates of self-quit attempts from marijuana are generally similar to those observed for other substances (e.g., tobacco) [60]. For example, studies of weekly marijuana users have indicated that by age 30, individuals have reported a range of 3–7 quit attempts on their own (e.g., [30, 103]). Although some of these unsuccessful quitters may ultimately seek professional treatment when they continue to fail in their quit efforts, it is not presently clear what percentage will ultimately do so and under what circumstances.

These data are noteworthy for two chief reasons. First, these data suggest that a large proportion of marijuana-abusing or -dependent individuals are interested in and pursue quitting on their own. Second, there is little empirical knowledge about the phenomenology of these quit attempts (e.g., latency to lapse and relapse, withdrawal symptoms) or the mechanisms underlying success or failure in quit attempts among self-quitters not seeking professional treatment. Such knowledge is essential for understanding malleable processes underlying marijuana lapse and relapse versus sustained abstinence and, therefore, will ultimately facilitate future translational efforts to develop innovative marijuana treatment strategies targeting those at high risk for relapse.

Reasons for Quitting

Current marijuana users, ranging from monthly users to those dependent on the drug, report multiple concurrent reasons for quitting [45, 79, 103, 116]. Among adults, worry about physical and psychological effects of marijuana use is the most often cited factor for wanting to quit [79, 116]. For example, Copersinio et al. [30] reported that 60% of non-treatment-seeking adult weekly marijuana users reported worry about health problems (both real and perceived) as a motivating factor for quitting, and 63% desired to quit in order to gain more "self-control" over their lives. In another study, Reilly and colleagues [89] similarly found that anxiety or depressive symptoms were the most commonly reported "negative effects" of marijuana use and the primary reason for quitting among weekly marijuana users ($n = 268$). Others have reported similar findings among both non-treatment seekers [12] and treatment seekers [103]; such findings do not appear to vary as a function of the type of marijuana use problem [12]. Overall, these data suggest that marijuana users typically express multiple reasons for quitting, with the most common reasons pertaining to excessive negative emotional symptoms (e.g., anxiety and depression, worry about negative health effects of marijuana use) and impaired levels of personal self-control associated with regular marijuana use.

Success in Quitting

Individuals attempting to quit marijuana experience marked difficulty whether they make a quit attempt on their own or seek professional (formal) treatment. Numerous survey studies, for example, have documented that current, regular marijuana users (both those who are and are not dependent on the drug) who try to quit on their own report difficulty in remaining abstinent, as indexed by numerous unsuccessful quit attempts [30, 116].

Although self-quit attempts (without professional assistance) tend to be the most frequently employed quit strategy [12], it is striking that even among those who *do* seek professional treatment, relapse to use is a common experience. Indeed, in a critical review of the

treatment outcome literature for marijuana dependence, McRae and colleagues [82] concluded: "studies suggest that many patients do not show a positive treatment response, indicating that marijuana dependence is not easily treated" (p. 369). For example, one large-scale controlled study ($n = 291$) found that 63% of adults receiving two of the best available intervention strategies—motivational individualized intervention or cognitive-behavioral therapy—relapsed to regular use within 4 months [102]. For comparison purposes, the delayed treatment (control) condition reported that 91% of individuals were not abstinent at the 4-month assessment [102]. At 16 months, relapse rates among the active treatment conditions rose to 71 and 72% for the motivational individualized intervention and cognitive-behavioral therapy, respectively [102]. Other studies have reported similar results [29, 100, 104], and more recent clinical trials have extended such work by noting that in addition to full relapse, lapses are highly common and clinically significant. For example, Moore and Budney [84] reported that among marijuana-dependent adult outpatients receiving treatment ($n = 152$), 71% lapsed (defined as any marijuana use) within 6 months, 46% within 3 months, and 24% within 1 month. In the same study, 71% of lapsers ultimately experienced a full relapse (defined as 4 or more days of use per week) [84].

It also should be noted that there have been historically few pharmacotherapy options available for marijuana use disorders. In fact, currently there are no medications approved by the United States Food and Drug Administration for marijuana use disorders, although a number of agents are currently being investigated. See Chapter "Potential Pharmacotherapies for Cannabis Dependence" for further details.

Although marijuana relapse is now a well-documented, prevalent clinical problem, there has been relatively little scientific work focused on predictors of success or failure in attempts to quit using marijuana. The work that has been completed in this regard has been broadly guided by social learning [7], stress and coping [70], and behavioral economic [8] theories of substance use and relapse. These studies have thus far provided a number of initial and important observations: (1) early lapses are predictive of later relapses among adult and adolescent marijuana-abusing or -dependent persons, regardless of whether they receive formal treatment or not [1, 54, 73, 84]; (2) personal stressors (e.g., family conflict) are related to relapse among individuals with marijuana abuse or dependence receiving outpatient treatment [44]; (3) other substance use and peers' substance use (alcohol and other drugs) are predictive of relapse to marijuana use among adolescent marijuana-abusing or -dependent outpatients [73], and (4) the level of self-efficacy (i.e., beliefs regarding one's ability to refrain from use) for abstaining from marijuana use among adults with marijuana abuse or dependence seeking treatment is predictive, albeit modestly in terms of effect size, of later relapse [76, 105].

Marijuana: Overview of Clinical Issues Relevant to Practitioners

Given that marijuana use and its disorders are common and can be associated with a relatively wide variety of negative problems, clinicians such as primary care physicians who interact with patients in non-specialty clinical settings ought to be knowledgeable of basic issues in clinical care for this drug problem. To facilitate this process, we now turn to a discussion of some core clinical competencies by highlighting basic assessment and treatment strategies. This discussion is broadly relevant to clinical practitioners working in medical, dental, and psychological sectors of the health care industry. The topics discussed in this domain are not intended to be exhaustive or indicative of the full range of possible clinically relevant issues. They are, however, intended to offer some initial insight into the basic skills and knowledge that may be required to interact effectively with the marijuana-using population.

Basic Competencies

The most basic level of competency of clinical relevance focuses on simply being aware of the scientifically developed knowledge on the prevalence and impact of marijuana and its disorders. Here, clinicians should initially strive to attain an overall awareness of marijuana use and behavior as it relates to their patient population(s). Specifically, it is important for clinicians to recognize that marijuana use is integrally related to a wide range of negative life problems (e.g., respiratory illness). By obtaining such knowledge of marijuana use and its disorders, the clinician is better equipped to offer patients accurate information about problems related to marijuana use. This information can include psychoeducational "facts" (e.g., how marijuana may impact lung disease), but also may involve strategies designated (through scientific evaluation) as helpful to quitting, such as brief motivational interventions [103]. To gain access to this information, practicing clinicians can consider both informal and formal methods of education. More specific goal-oriented targets can include, but are not limited to, being able, efficiently and capably, to: (1) describe the prevalence of marijuana use and its disorders, (2) describe regional marijuana use patterns, (3) describe the negative physical and psychological consequences of marijuana use and dependence, (4) describe the importance and role of marijuana treatment, particularly those methods based on evidence-based resources, (5) maintain a general awareness of emerging research related to the treatment of marijuana use and its disorders, (6) understand the criteria used for defining marijuana use, abuse, and dependence, and (7) communicate an interest and willingness to consult with other resources when marijuana knowledge may be limited.

A second basic competency skill domain pertains to developing basic assessment and counseling skills for dealing effectively with marijuana use and its disorders. This domain of competence naturally builds from the foregoing description of general knowledge and awareness. This area of work necessarily begins with developing a level of "clinical comfort" with marijuana use topics and being capable of engaging a patient in a discussion focused on this topic. For this reason, the basic competency element in this domain requires counseling skills that strengthen interpersonal connection (e.g., rapport, listening to patient concerns). From the counseling perspective, a variety of core skills are necessary. These include, but are not limited to: (1) having the capacity to be an active listener and demonstrate an empathetic stance regarding clinical care involving marijuana-related issues, (2) being able to communicate the strengths and challenges to evidence-based care treatment approaches for marijuana use and its disorders in a non-threatening manner, and (3) being able to understand basic models of behavior change that pertain to marijuana use and meaningfully communicate levels of "motivational stage and readiness" to clients.

From an assessment perspective, basic competencies are needed in order to understand how to evaluate marijuana use behavior and history adequately. Without this level of proficiency, it will be challenging to document readiness to quit or success in doing so. In the assessment process, there are both historical and current factors to evaluate. The overarching goal is to learn to comprehensively document and obtain accurate information that can be used in a clinically meaningful manner. The assessment process can be usefully divided into two global phases: intake (or initial assessment) and ongoing assessment. For the intake assessment, key variables to assess include: the extent and nature of marijuana use from a lifetime and current perspective; documenting current interest and motivation in quitting; employing evidence-based technologies for documenting marijuana use, abuse, and dependence; identifying (with the client) barriers to quitting currently; identifying strengths in the client or the environment (e.g., social support) for quitting; documenting the nature of past quit history and relative degree of success in such attempts, and personal as well as cultural variables that may impact marijuana use and decisions regarding use. The

intake assessment process should also integrate information about the client's medical and psychological history (e.g., concurrent substance use) in order to understand how such factors may influence the ongoing marijuana use or attempts to quit.

Ongoing assessments require an understanding of each client and the specific variables that need to be regularly tracked in order to accurately and objectively document (and understand) the motivation to quit and marijuana use behavior. Here, there will be differences across individuals, but in most instances marijuana use behavior, ongoing life stressors, and current motivation to quit are possibly important targets. This information can be used to track and understand ongoing efforts to quit. For example, clinicians should take note of each client's specific thoughts related to marijuana use (e.g., belief that marijuana use functions as an effective method of stress management), primary reason(s) for wanting to quit smoking (e.g., health, social stigma), and situations in which marijuana use is most likely to occur (e.g., when drinking alcohol). This information, in turn, can be applied to help educate clients about their specific marijuana use patterns and, ultimately, help them formulate a plan for making a quit attempt that is individualized to their specific needs and life circumstances.

Aside from the individual level of commitment to professional development, it is a reality that most medical care occurs within a context that intersects with other health care professionals. Therefore, enlisting in an integrated manner the systems involved in such clinical work may be a powerful resource for dealing with marijuana use and its disorders. The need for such systems-oriented care is particularly evident given that educational efforts solely focused on the individual have not always been met with large degrees of success in the substance use field (e.g., [114]). Additionally, many individuals seek medical care in medical systems governed by managed care businesses or other third party payers. As a result, changes to a system of medical care can have a major impact in terms of the type and quality of care administered by practitioners working within that system.

Summary

Understanding and treating marijuana use is an important public health priority. Despite the increasing recognition that marijuana use and its disorders are not actually "harmless", the scientific literature pertaining to the etiology and maintenance, assessment, and treatment of marijuana use and its disorders is still in its beginnings. The next decade promises to be an important time to marshal resources in order to bridge major knowledge gaps and translate such developments into promising prevention and treatment approaches.

Classification

Medications derived from papaver somniferum, the opium poppy, have played a central role in medical practice for well over 3,500 years. Sumerian clay tablets, which include our oldest known medical texts, called the opium poppy "Hul Gil", the "Joy Plant". In the Greco-Roman era, poppies were cultivated for their pain-relieving, antidiarrheal, and sedative properties. Today, medications in this class are divided into two groups. Opiates are naturally occurring compounds derived from the active alkaloids of the opium poppy. This group includes morphine, codeine, and thebaine. Opioids are manufactured medications that are classified as either fully synthetic or semisynthetic. Medications in the synthetic opioid group include alfentanil (Alfenta®, Rapifen®), fentanyl, meperidine (Demerol®), methadone (Dolophine®), pentazocine (Talwin®), propoxyphene (Darvon®), and sufentanil (Sufenta®). Included in the semisynthetic opioid group are buprenophine (Buprenex®, Suboxone®, and Subutex®), hydrocodone (Hycodan®), oxycodone (Percodan®), and oxymorphone (Numorphan®), all of which are derived from thebaine. Other semisynthetic compounds derived from the opium poppy are

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_21,

hydromorphone (Dilaudid®) and heroin, which is metabolized to morphine. Both of these drugs are highly abusable. The human body also produces a number of endogenous opioids, such as endorphins, enkephalins, and dynorphins.

Etiology

There is no clearly defined etiology for opiate dependence. Risk is determined by multiple factors including genetics, psychiatric comorbidity, and social and environmental factors, including drug exposure. Twin studies suggest that genetics alone accounts for 45–50% of the risk for opioid dependence. Recent work has identified two sites on chromosome 17 that are associated with an increased risk for drug dependence; one of these sites is connected to severe symptoms of opioid dependence, but not to dependence on other drugs [44]. Further work is needed to identify the specific genes that are associated with the unique risk for opioid dependence.

Epidemiology

Patterns of Use

For most of the twenty first century, heroin was the primary opiate abused in the United States. There were major epidemics after World War I, World War II, and the Vietnam conflict. Among the general population, it is estimated that 10–30% of individuals exposed to licit and illicit opioids may develop symptoms of abuse or dependence. These numbers may be significantly higher in individuals with co-occurring psychiatric disorders, particularly those exposed to sexual abuse or combat trauma. While regular estimates of drug use in adults and adolescents have been available from the Monitoring the Future study and the National Survey on Drug Use and Health, information on drug use disorders has rarely been collected [58, 143]. There was a 16-year gap between publication of the 1990–1992 National Comorbidity Survey data and the 2000 National Survey on Drug Use and Health, which collected 12-month prevalence data on drug use disorders [143]. Depending on the survey and the criteria used, estimates for the lifetime prevalence of any drug dependence disorders have ranged from 0.4 to 7.5% [28, 47, 67, 123].

For many years, it was assumed that the lifetime risk for heroin dependence was relatively low and ranged from 0.4 to 0.7%. In 2006, the National Survey on Drug Use and Health reported that 3.79 million individuals used heroin at least once in their lifetime and 323,000 were classified with either dependence or abuse of heroin. In addition, it was estimated that there were 250,000 individuals in methadone maintenance treatment. From 1984 to 1994, new users of heroin each year ranged between 28,000 and 80,000. From 1995 to 2001, the number averaged over 100,000; in 2006, it dropped slightly to 91,000 [33]. These numbers have been relatively unchanged since 1965.

Incidence of Substance Use Disorders

The most recent national survey, the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions, was designed to collect data on drug use disorders and, for the first time in a national survey, to collect separate data on both illicit drugs and prescribed medications. The National Epidemiologic Survey on Alcohol and Related Conditions surveyed 43,093 adults (18 years of age and older) in the United States, and captured data at the time when the United States' epidemic of prescription opioid abuse was at its peak. The National Comorbidity Survey and the Environmental Catchment Area Survey combined data on heroin and other opiates into a broad "drug abuse" category that also included other illicit drugs, thus making it impossible to get specific data on opiates, or to separate out information on heroin from data on prescribed opiates [28, 57]. The National Epidemiologic Survey on Alcohol and Related Conditions reported the prevalence of 12-month and lifetime drug abuse as 1.4 and 7.7%, respectively, and

the rates of drug dependence as 0.6 and 2.6%, respectively. Rates of abuse and dependence were significantly higher in men vs. women and in Native Americans vs. Whites, Blacks, and Hispanics [28]. The lifetime prevalence of nonmedical prescription opioid drug use was 4.7%. The lifetime prevalence of nonmedical opioid drug use disorders was 1.4%, indicating that approximately 30% of users were at risk for developing an opioid drug use disorder. Men were significantly more likely to progress from use to abuse to dependence than were women, as were Native Americans as compared with Whites. The mean age onset of opioid abuse or dependence was 22.8 years, and the mean age at first treatment was 26.2 years, a lag of 3.4 years. Approximately two-thirds of individuals with opioid use disorders never received treatment [57]. This prevalence of nonmedical opioid use disorders is 2–3 times higher than prior estimates of the prevalence of heroin use disorders.

Abuse of Opioid Analgesics

The abuse of opioid analgesics was traditionally thought to be a relatively small part of the United States' drug problem. While there were few data on the risk for dependence among individuals treated for chronic pain, the risk was assumed to be minimal [115, 119]. During the 1960s, the introduction of pentazocine (Talwin®) triggered a period of abuse after opiate addicts discovered that the injected combination of Talwin® and amphetamines ("T's and Blues") produced a potent euphoric effect. After this problem was identified, the Food and Drug Administration required that the medication be reformulated as a combination tablet of Talwin® and naltrexone (TalwinNX®) [91]. This formulation produced an antagonist reaction in addicted individuals if the tablets were crushed and injected, essentially eliminating significant abuse of this medication. The abuse of other opioid analgesics remained a minimal problem until the introduction of OxyContin® in 1996. From 1970 to 1995, the National Survey on Drug Use and Health reported that the annual number of new nonmedical users of pain relievers ranged from 700,000 to 1,000,000 [143]. In the 5 years following 1996, this number almost tripled to 2,500,000 [33]. These numbers reflect a new epidemic of abuse of pain relievers in the United States (see Fig. 1).

As noted above, prior to 2000, the National Survey on Drug Use and Health reported only drug use data, not data on drug use disorders [28]. In 2005, the National Survey on Drug

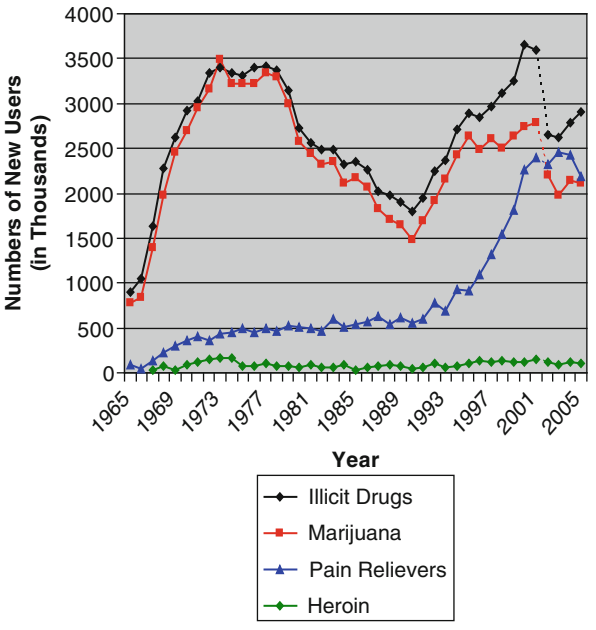

Fig. 1 New drug user patterns, 1965–2005 [33]

Use and Health reported that 4.9% of 12–17 year olds had used prescription pain relievers nonmedically in the past year. This was more than 24 times the reported use of heroin in this group (0.2% vs. 4.9%). In this cohort, past-year dependence or abuse was 1.1% (275,000 individuals) for pain relievers, vs. 0.0% (fewer than 9,000 individuals) for heroin dependence or abuse [143]. In 2006, the National Survey on Drug Use and Health reported that 33,422,000 Americans aged 12 or older admitted to the nonmedical use of pain relievers at least once in their lives and that 12,649,000 had done so in the last year. The survey classified 1,635,000 individuals aged 12 or older with dependence or abuse of pain relievers, as compared with 323,000 individuals classified with dependence or abuse of heroin. There were over 2,150,000 new illicit users of pain relievers in 2006, making the abuse of pain relievers the most common new drug of abuse, ahead of marijuana abuse (2,063,000). In comparison, there were only 91,000 new initiates to heroin use in 2006 (see Fig. 2). The 2006 National Survey on Drug Use and Health estimated that 7,800,000 adults in the United States (3.2% of the total population) were in need of treatment for some type of illicit drug problem; less than 20% of that group received any treatment in 2006. This survey made it clear that the abuse of pharmaceutical analgesics had replaced heroin as the dominant opioid abuse problem in the United States [33].

Risks Associated with the Use of Opioid Analgesics

For many years, pain management specialists had voiced concern about the undertreatment of pain. The pharmaceutical industry also identified a need for less abusable and more potent opioids for pain management. In the 1980s, the Bard Corporation developed a sustained-release technology suitable for morphine. This led to the marketing of sustained-release morphine in England under the brand name of MST Continus®; in 1984, the same medication was introduced in the United States by Purdue Pharma as MS-Contin®. This formulation proved effective in preventing significant abuse, and the medication gained wide acceptance in the American market. The expanding use of opioids for the treatment of severe pain led to an interest in a medication with greater potency, longer duration of action, and low abuse potential. Oxycodone provided the desired potency, but it could not be successfully formulated with the sustained-release technology that had been effective with morphine. This problem

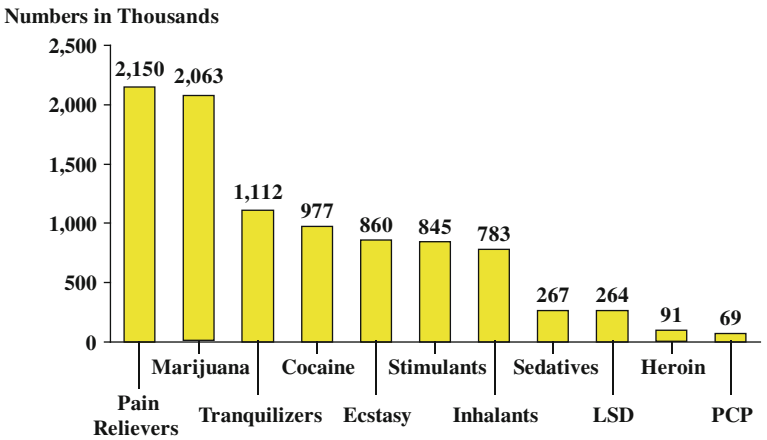

Fig. 2 Past-year initiates for specific illicit drugs among persons aged 12 or older, 2006 (National Survey on Drug Use and Health) [33]. LSD = lysergic acid diethylamide; PCP = phencyclidine

was resolved in 1996 when Purdue introduced OxyContin®, a time-release formulation of oxycodone with an acrylic coating that was designed to dissolve slowly and provide 12 h of pain control, permitting individuals with pain to sleep through the night. This formulation permitted delivery of doses ranging from 10 to 160 mg—doses far in excess of the 30-mg maximum dose previously available in oxycodone tablets. This was a major advance in the management of severe pain. Based on the experience with MS-Contin®, both Purdue and the Food and Drug Administration assumed that this formulation would have low abuse potential, and Purdue was permitted to market the medication as a potent, long-acting narcotic with a lower abuse potential than other opioid analgesics. Consequently, Purdue marketed OxyContin® as a first-line agent for the treatment of non-malignant pain. At that time, there was a general presumption that iatrogenic addiction secondary to the treatment of legitimate pain was a rare event. This assumption was based on a series of articles published between 1977 and 1982, all of which reported a minimal risk of iatrogenic addiction in the treatment of acute pain [90, 115, 119]. This view was reinforced by Portenoy and Foley [118], who found evidence of abuse problems in only 2 out of 38 individuals chronically treated with opiates for non-malignant pain. They concluded that opioid maintenance therapy was safe, except in individuals with a history of drug abuse. In 2000, Joranson et al. reviewed emergency room data from the Drug Abuse Warning Network and found no evidence of an increase in analgesic abuse, despite significant increases in the prescription of opioid analgesics [60].

In the late 1990s, clinicians in rural Virginia and northern Maine reported that young people were crushing OxyContin® tablets and snorting or injecting the drug. This method of ingestion produced a highly euphoric and reinforcing experience; abusers were exposed to very high doses of oxycodone, and many quickly became addicted. There was also a corresponding spike in overdose deaths. Despite growing evidence of addiction and overdose deaths, Purdue executives remained convinced of the efficacy and safety of their medication. By 2000, sales of OxyContin® reached over $1 billion/year and the company was marketing it as a first-line agent for a wide variety of pain syndromes, with recommendations that it be used before lower scheduled narcotics, or even before Ultram®, a non-narcotic [91]. In 2001, the Food and Drug Administration required a new label for OxyContin® that dropped claims about a reduced risk of abuse. By this time it had become apparent that overdose deaths and reports of addictive behavior did not just involve individuals who were illicitly using the drug, but that some people being treated for legitimate pain problems were becoming addicted and finding it impossible to stop their use of the drug. In retrospect, clinicians realized that the bulk of the medical literature claiming a minimal risk of iatrogenic addiction primarily reported on experience using opioids to treat acute pain and that there were few data on the risk of addiction in individuals treated for chronic pain [60]. Similarly, there were no data on the addiction risks associated with the use of long-acting high-potency agents such as OxyContin® for either acute or chronic pain. All of the published research on the abuse risk of chronic opioid treatment preceded the marketing of those medications.

As physicians became aware of the problems associated with OxyContin®, many shifted to oral methadone as a safer alternative for the management of chronic pain. From 1998 to 2006, the number methadone prescriptions for pain in the United States increased from 0.5 million to over 4 million. Unfortunately, there was a linear relationship between opioid-related overdose deaths and the increase in the prescription of pain relievers (see Fig. 3) [113].

Neurobiology

The functions of all the compounds in this class (opiates, synthetic opioids, and endogenous opioids) are mediated through a variety of receptors in the central and peripheral nervous

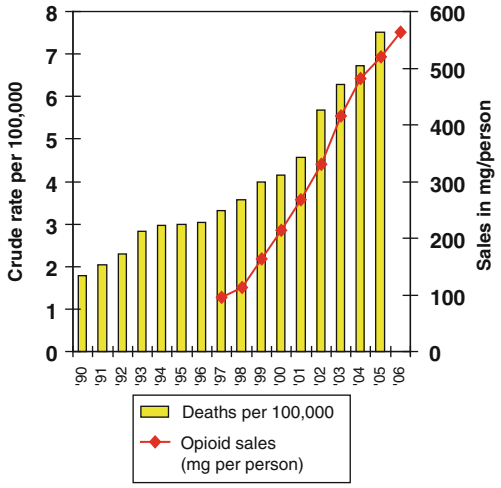

Fig. 3 Deaths per 100,000 related to unintentional overdose and annual sales of prescription opioids by year, 1990–2006 (L. J. Paulozzi, Centers for Disease Control Congressional Testimony, United States Senate Subcommittee on Crime & Drugs, Committee on the Judiciary and the Caucus on International Narcotics Control, March 12, 2008; adapted from [113])

system. The mu, delta, and kappa opioid receptors are well defined, and genes encoding for these receptors have been cloned [25, 26, 39, 64]. The mu receptor was named because of the affinity of morphine for this receptor. Full agonists at the mu receptor activate the receptor, are highly reinforcing, and include the most abused types of opioids. There are two primary subtypes of the mu receptor. Subtype 1 (mu_1) apparently mediates analgesic effects. Subtype 2 (mu_2) is likely responsible for the symptoms associated with opioid overdose (including respiratory depression) and withdrawal. Agonists at the mu receptor include morphine, methadone, and beta-endorphin. These compounds also have agonist activity at the delta receptor (named because of their presence in the vas deferens). The primary agonists at the delta receptor are met-enkephalins and leu-enkephalins.

Another group of receptors were named kappa because of their affinity for the opioid agonist ketazocine. Kappa receptors bind endogenous dynorphin and are thought to mediate spinal cord analgesia. They are also involved in the psychotomimetic and dysphoric effects seen in overdoses of pentazocine and other kappa-active synthetic opiates. Opioid antagonists (naloxone and naltrexone) are synthetic derivatives of oxymorphone and act primarily at the two mu receptor sites, though they also have some antagonist activity at the kappa receptor (see Fig. 4).

There is another group of medications that have mixed agonist-antagonist properties. For example, pentazocine acts as a kappa agonist and as a weak mu antagonist. Butorphanol has mixed kappa and mu agonist properties and

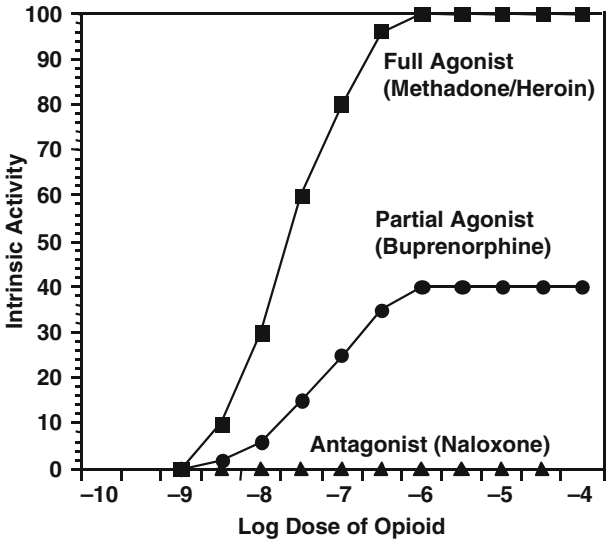

Fig. 4 Intrinsic activity: full agonist (methadone), partial agonist (buprenorphine), and antagonist (naloxone) [adapted from Fig. 2-1, Center for Substance Abuse Treatment. Clinical Guidelines for the Use of Buprenorphine in the Treatment of Opiate Addiction. Treatment Improvement Protocol (TIP) Series 40. DHHS Publication No. (SMA) 40–3939. Substance Abuse and Mental Health Services Administration, Rockville, MD, 2004]

weak antagonist properties. Buprenorphine is classified as a partial opioid agonist at the mu and kappa receptors and an antagonist at the delta receptor. While it binds tightly to the mu receptor, it only partially activates the receptor (see Fig. 4). There appears to be a plateau effect that limits activation to about 50% of receptor activity and prevents the respiratory depression seen with full mu receptor agonists; interestingly, the analgesic effect of buprenorphine does not seem to be limited by the plateau effect [31]. When a partial agonist is administered in the presence of a full agonist, the partial agonist either displaces the full agonist or prevents its binding to the receptor. As a result, the partial agonist acts as an antagonist to the full agonist [151].

More recently, a new receptor named the orphanin/nociceptin receptor or opioid receptor-like receptor has been identified [30, 95]. Orphanin/nociceptin is an endogenous opioid-like neuropeptide that acts as an agonist at the opioid receptor-like receptor. It has an inhibitory effect on synaptic transmission and appears to be involved in memory, learning, attention, and pain perception [110]. Despite the structural similarity between the opioid receptor-like receptor and the three "classical" opioid receptors, most opioids lack affinity for the nociceptin system [54], and it is not affected by opioid antagonists. The function of the nociceptin/opioid receptor-like receptor system in pain control needs further clarification, and other functions are still a matter of speculation, though investigation suggests that it has a role as a down-regulator of immune function [42]. It is also known that activation of the opioid receptor-like receptor causes motor impairment, suggesting that development of opioid receptor-like receptor agonists would be difficult.

The abuse potential of opioids can be predicted by three sets of characteristics. Drugs with a shorter half-life have a greater abuse potential (heroin > methadone). Drugs with higher lipophilicity cross the blood-brain barrier more rapidly and are more likely to be abused (heroin > morphine > methadone). Finally, those drugs with a faster route of administration have a higher abuse potential (intravenous injection > subcutaneous injection > oral ingestion). Heroin (di-acetyl-morphine) has two acetyl groups that render it very lipophilic, enabling it to cross the blood-brain barrier more rapidly than morphine, thereby making it a preferred drug for injecting opioid abusers [112, 136].

Biological Effects of Use

The primary acute effects of opioids are euphoria, analgesia, decreased consciousness and respirations, vomiting, and constricted pupils. Codeine is also effective as a cough suppressant, and morphine is used to treat cardiac-related pulmonary edema. Analgesia and euphoria are produced directly through agonist effects at the mu receptor and indirectly through activation of the dopaminergic reward system in the nucleus accumbens. In overdose situations, consciousness is depressed to levels of non-responsiveness, the pupils are pin point, and there is marked suppression of autonomic functions with decreased pulse, blood pressure, and respiration, leading to lethal respiratory depression. The skin becomes cyanotic, and skeletal muscles become flaccid. Pulmonary edema occurs in 50% of cases. Physical tolerance can develop within 1–2 weeks with repeated dosing, requiring increased doses to maintain the original opioid effect. Tolerance develops more rapidly with shorter-acting opiates and with binge patterns of use, but is very slow to develop in individuals maintained on methadone. Interestingly, there is no down-regulation of mu receptors in methadone recipients [70], supporting the observation that most neurophysiologic functions return to normal with methadone maintenance treatment [76, 77]. With chronic use, physical dependence develops and users manifest a characteristic withdrawal syndrome if the dose is reduced or stopped (see below). In some animal models, physical dependence has developed in the absence of tolerance, suggesting that these are dissociable phenomena [121]. Tolerance develops

more quickly to opiate side effects than to the analgesic effect. Chronic opiate use leads to reduced dopaminergic tone and decreased binding capacity at the D2 dopamine receptor [8, 78, 148, 149]. Once tolerance develops, opiates are required to maintain an altered homeostatic set-point within the hypothalamic-pituitary-adrenal axis and within the pathways that govern memory and hedonistic desires [75]. Abnormalities in the hypothalamic-pituitary-adrenal axis may persist for over 1 year following opioid detoxification. A relative endorphin deficiency is also present during chronic opiate abuse and during the prolonged opiate withdrawal syndrome, but endorphin levels normalize during methadone maintenance treatment [73, 77, 135]. Despite the development of tolerance, pupillary constriction, constipation and sweating may persist indefinitely. Long-term users report lethargy, decreased libido, and diminished sexual function; men have below-normal testosterone levels, and women may develop amenorrhea and have difficulty conceiving.

In physically dependent individuals, there is a characteristic withdrawal syndrome when opioids are reduced or stopped abruptly. Symptoms begin within 6–12 h following the last dose of a short-acting opiate such as heroin. Early stages are characterized by anxiety, nausea, muscle aches, and abdominal cramps. This progresses to yawning, rhinorrhea, lacrimation, sweating, piloerection (gooseflesh, "going cold turkey"), dilated pupils, diarrhea, insomnia, and elevated temperature, heart rate, blood pressure, and respirations. In the most severe stage, the syndrome includes severe craving, abdominal cramps, diarrhea, and painful cramps and muscle spasms ("kicking the habit"). Many of the acute symptoms of opiate withdrawal are driven by an overactive catecholaminergic system located in the locus coeruleus, and by dopaminergic neurons located in the ventral tegmental area. The syndrome is most severe in individuals dependent on short-acting opiates such as heroin, but it clears in 4–7 days. Withdrawal from long-acting opioids, such as methadone, is less severe but can last for 14 days or more. Withdrawal symptoms from the partial agonist buprenorphine are slightly less severe than those caused by methadone and last 5–7 days, making it the preferred opioid for use in medically supervised withdrawal (see Fig. 5 and Table 1). Following withdrawal, many addicts experience a prolonged state of dysphoria that may last for months.

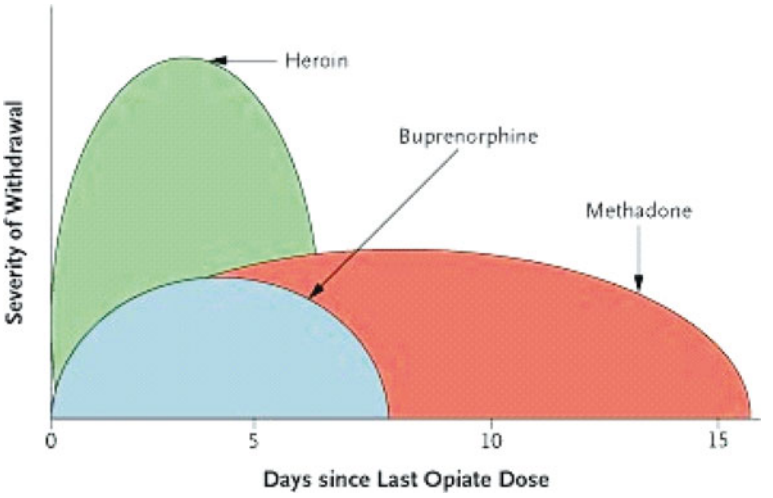

Fig. 5 Comparison of spontaneous withdrawals (Heroin > Buprenorphine > Methadone Withdrawal). The graph illustrates the severity of opioid-withdrawal symptoms after abrupt discontinuation of equivalent doses of heroin, buprenorphine, and methadone. Copyright © 2004 Massachusetts Medical Society. All rights reserved [72]

Table 1 Characteristics of spontaneous opioid withdrawal

Drug	Onset	Peak	Duration
Heroin	6–12 h	~ 3 days	4–7 days
Buprenorphine	1–3 days	~ 4 days	5–7 days
Methadone	1–2 days	~ 7 days	12–14 days

Psychological Effects of Use

In non-tolerant users, opioids produce sedation, analgesia, and, in some cases, euphoria and a profound sense of well-being. This is often described as being "high" or "on the nod." Many users also report an antidepressant effect from opioids. As use becomes more frequent, users cycle between states of euphoria and normality (see Fig. 6).

Regular use eventually leads to physical tolerance, a state where progressively higher doses are required to produce the desired experience of euphoria. Eventually the individual becomes physically dependent and starts to experience withdrawal symptoms whenever the euphoria wears off. Drug craving becomes progressively more severe, and higher doses are required to prevent the development of withdrawal. In this later stage of dependency, users rarely feel normal and typically cycle between states of low-level intoxication and withdrawal (see Fig. 6). Large doses of opiates are needed to eliminate withdrawal symptoms, and it may be difficult for the addict to achieve any state approaching normality, let alone euphoria. At this stage, addicts are chronically irritable and depressed. Individuals maintained on stable doses of long-acting opioids such as methadone, levo-alpha acetyl methadol, or buprenorphine become tolerant to any sedative effects, and they generally report the absence of craving, euphoria, or withdrawal symptoms. They often feel more alert and energized following their daily dose. However, many individuals on maintenance treatment fail to develop tolerance to the side effects of constipation and sweating.

Diagnosis

The diagnoses of opiate dependence and abuse are established using the standard *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision criteria for substance abuse or dependence [4]. Clients may present with the typical symptoms of either opiate intoxication or withdrawal described in the sections below titled "Opiate Overdose" and "Opiate Withdrawal Syndromes". A urine toxicology examination should be obtained on all clients to confirm current use and to screen for the abuse

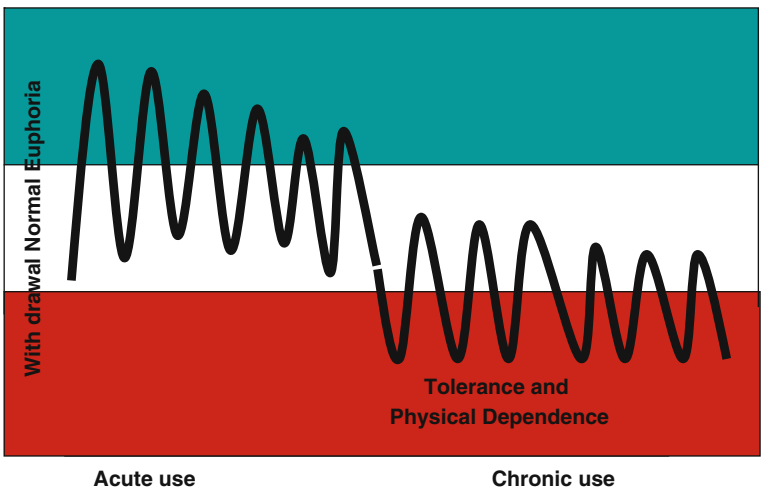

Fig. 6 Natural history of opioid dependence. Courtesy of Daniel P. Alford, MD

of other substances (see Section "Psychiatric Comorbidity"). All clients require a medical evaluation to screen for HIV/AIDS, hepatitis, and other blood-borne infections. Chronic users are likely to present with track marks and other signs of injection drug abuse, though some individuals addicted to pain relievers may have no history of intravenous drug use and may present no abnormal findings on physical examination.

Confusion exists between the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision category of opioid dependence and the common condition of physiological dependence. Physical dependence occurs whenever there is ongoing use of opiates for medical treatment. Physically dependent individuals may manifest both tolerance and withdrawal symptoms, but they show no symptoms of craving or loss of control, and the majority are able to taper off opiates with little or no difficulty. A few individuals, particularly those treated with high-potency opioids, may experience prolonged and severe withdrawal symptoms and will require a much more gradual medication taper. For some clients (between 3 and 30%), long-term treatment with opiates may trigger an iatrogenic addiction. They may experience euphoria when initially treated, and then go on to develop craving and loss of control of their medication use, eventually meeting full *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision criteria for dependence [4]. When evaluating these clients, it may be useful to look for the presence of the "4 C's" commonly associated with addiction: *C*raving, *C*ompulsive use, loss of *C*ontrol, and *C*ontinued use despite apparent harm [3]. Clinical experience suggests that individuals at highest risk for abusing pain medications are those with a prior history of alcoholism or other substance abuse, and with co-occurring psychiatric disorders, including antisocial personality disorder.

Psychiatric Comorbidity

Dependence on alcohol and other classes of drugs is common in the majority of opiate addicts and has a significant impact on the outcome of treatment. There is also a high rate of comorbidity between all of the drug use disorders and other psychiatric disorders. With few exceptions, the National Epidemiologic Survey on Alcohol and Related Conditions data showed positive and significant correlations between drug use disorders, alcohol use disorders, nicotine dependence, and antisocial personality disorder [28]. As Kessler noted in his reviews of the literature on the epidemiology of comorbidity of mental and substance use disorders, the available data have consistently shown that comorbid disorders are more chronic and have a significantly more persistent and severe course [65, 66, 68]. Unfortunately, methodologic limitations in the original National Comorbidity Survey, the Environmental Catchment Area Survey, and the National Comorbidity Survey Replication make it difficult to get specific comorbidity estimates regarding opiate use, abuse, and dependence [53, 57]. While the National Comorbidity Survey found an odds ratio of 2.4 for comorbidity between any lifetime alcohol or drug use disorder and any lifetime *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition, revised mental disorder [67], there were no drug-specific data available in that study. Responses on opiates, cocaine, cannabis, and hallucinogens were combined under a single category of drug use disorders [5]. Both the National Comorbidity Survey and the Environmental Catchment Area Survey relied on data collected prior to the recent epidemic of the abuse of pain relievers; nor did these surveys distinguish between heroin abuse and the abuse of prescribed medications.

Data specific to comorbidity in opiate addiction are relatively limited. Clinical studies have reported that a range of 55–74% of opiate addicts in treatment have an affective disorder [102]. Brooner et al. [17] evaluated 716 opiate abusers seeking methadone maintenance treatment and reported that 47% of the sample met criteria for other psychiatric disorders. The most common diagnoses were antisocial personality disorder (25.1%) and major depression (15.8%). Rosen and colleagues recently evaluated a group of 140 methadone maintenance participants over the age of 50. In this sample, 57.1% had at least one other psychiatric disorder in the previous

year. The most prevalent disorders in this cohort were major depression (32.9%), post-traumatic stress disorder (27.8%), and generalized anxiety disorder (29.7%); women had higher levels of depression than men (43.8% vs. 27.2%) and had twice the prevalence rate of panic disorder and agoraphobia [139]. As indicated above, depression and anxiety disorders are common in this population and are associated with increased severity of substance use disorders and poorer treatment outcome [17, 125]. Other substance use disorders are also common in individuals dependent on opiates. Brooner et al. [16] evaluated 68 methadone maintenance participants enrolled in an HIV education program. Among this group, lifetime rates for abuse or dependence were as follows: cocaine 55.9%, sedative/hypnotics 53%, marijuana 47.1%, and alcohol 47.1%. Forty-eight percent of the sample met criteria for a non-substance use psychiatric disorder, the most common being antisocial personality disorder (29%) and major depression (19%). Individuals with other psychiatric disorders also had a greater number of substance use disorders and a more severe clinical course.

The association between heroin abuse and antisocial personality disorder reflects an overlap of genetic and psychological factors. Individuals willing to initiate heroin use are often impulsive, and typically see themselves as non-conformists, or risk-takers, and in defiance of social convention. Their use of heroin is not surprising given the illegality of heroin and the commonly acknowledged social deviation associated with intravenous drug use. The National Epidemiologic Survey on Alcohol and Related Conditions study showed strong associations between drug use disorders, other substance use disorders, and antisocial personality disorder [28]. The authors suggested that this association is related to the unique genetic factors that underlie these groups of disorders.

As compared with earlier national epidemiologic surveys, the National Epidemiologic Survey on Alcohol and Related Conditions study provided more specific information on opiate dependence and other co-occurring psychiatric and substance use disorders. Individuals identified in the National Epidemiologic Survey on Alcohol and Related Conditions who were dependent on one type of prescription medication were highly likely to have clinically significant drug use disorders for both illicit drugs and other classes of nonmedical prescription drugs. There was a high comorbidity for mood, anxiety, personality, and other substance use disorders, including nicotine and alcohol. The specific odds ratios for comorbidity between opioid use disorders and other conditions were: other nonmedical prescription drug use disorder (80.1), other illicit drug use disorder (28.1); alcohol use disorder (11.4), nicotine dependence (6.7), any mood disorder (4.6), bipolar I disorder (4.9), any anxiety disorder (3.0), panic with agoraphobia (4.3), any personality disorder (4.9), and antisocial personality disorder (8.1), respectively. These conditions were all diagnosed according to *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria, required the criteria of "clinical significance", and ruled out conditions considered to be substance-induced [57].

Co-occurring Psychiatric Disorders and the New Opioid-Dependent Population

Recent studies suggest that some features of psychiatric comorbidity and opiate addiction have changed during the last decade. The availability of cheap, high-quality heroin has meant that most initiates begin by snorting the drug; some become addicted yet never progress to intravenous use. Members of this group minimize the risk of non-intravenous drug use. They see snorting heroin as relatively socially acceptable and do not see themselves as socially deviant (and indeed are probably less antisocial than earlier generations of heroin users). Similarly, abusers of pain relievers are even less likely to see their behavior as dangerous or antisocial (they naively assume that "legal" drugs are both safe and less likely to lead to addiction). Data from the 2006 National Survey on Drug Use and Health showed that more than 56% of the abusers of pain relievers obtain the drug free from friends or

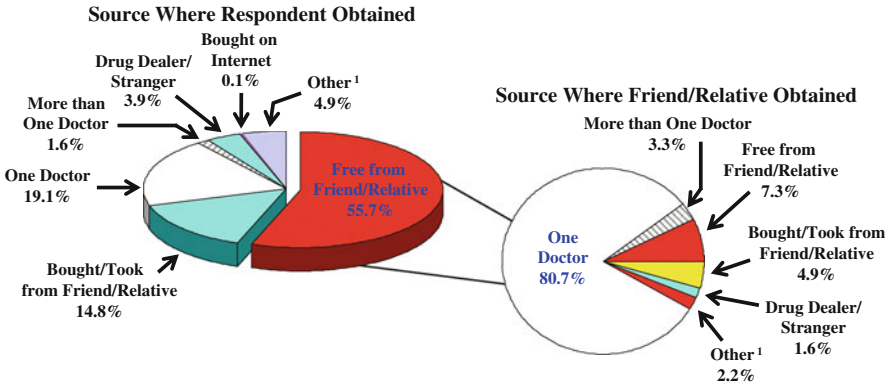

Fig. 7 Source where pain relievers were obtained for most recent nonmedical use among past-year users aged 12 or older, 2006 (National Survey on Drug Use and Health) [33]. Note: Totals may not sum to 100% because of rounding or because suppressed estimates are not shown. [1]The "Other" category includes the sources: "Wrote Fake Prescription", "Stole from Doctor's Office/Clinic/Hospital/Pharmacy", and "Some Other Way"

relatives; a few purchase or take drugs from friends, and less than 3.9% purchase from "drug dealers" [33] (see Fig. 7).

This type of distribution system reinforces the perception that the illicit use of these drugs is normative. It is only after these individuals become physically dependent and have escalating habits that they are forced to seek out illicit suppliers. At some point they may recognize that heroin is cheaper than opioid pharmaceuticals and they may then switch to snorting and/or intravenous heroin use. As the severity of their opioid dependence progresses, they are also likely to manifest symptoms of a substance-induced personality disorder, with both dependent and antisocial features. Such substance-induced antisocial traits typically resolve when these individuals become engaged in addiction treatment, but they may reappear during periods of relapse.

Iatrogenic Addiction

There is a growing and less well-defined group of individuals who are iatrogenic opioid addicts. Since the mid 1990s, careless and over-enthusiastic prescribing of highly potent opioid analgesics has placed many individuals at increased risk for addiction. Of particular concern are veterans returning from combat in Iraq and Afghanistan who may be suffering from both combat stress and physical injuries requiring treatment with potent opioids. Comparison of prescription opioid abusers and heroin abusers shows higher levels of chronic pain, depression, and benzodiazepine use among the abusers of prescription opioids [13, 96]. They are also less likely to use illicit non-opioid drugs or to inject drugs [137]. As compared with heroin addicts, this group is more likely to have had psychiatric treatment, yet have fewer family problems, be more socially stable, and have fewer illegal sources of income [13, 29]. They also tend to resist referrals for methadone maintenance and are likely better candidates for naltrexone treatment or office-based buprenorphine treatment [40].

The abuse of other substances is also less common in this population as compared with heroin addicts [137]. Alcohol abuse or dependence has been a long-standing problem among individuals on methadone maintenance. Marijuana use is also very common, though clinicians have disagreed over the clinical significance of this behavior. During the 1980s, cocaine abuse became rampant among opiate abusers. While this problem has declined among the general population, it remains epidemic among

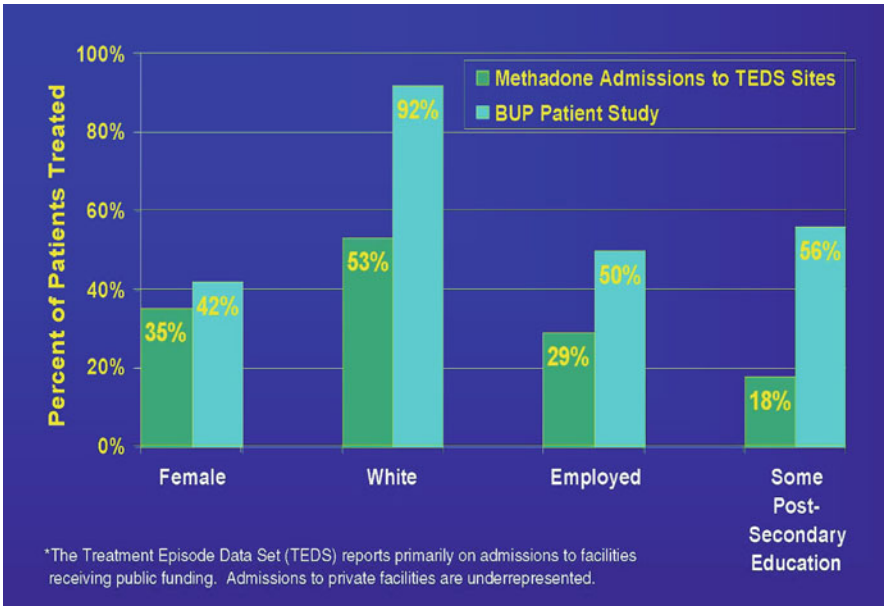

Fig. 8 Methadone recipients* and buprenorphine (BUP) recipients study sample: demographic differences [144]

heroin addicts. The concurrent abuse of all of these substances continues to be a problem among those on methadone maintenance; however, clinicians report less frequent problems of this type in clients treated with buprenophine in the office-based setting. Dobler-Mikola et al. reported on the first 6 months of methadone maintenance treatment for 103 participants and noted that 51% continued to use cocaine and 61% continued to use heroin [36]. In contrast, Mintzer et al. reported that 54% of Suboxone® recipients at 6 months were clean from all drugs [93]. In a separate study, Fiellin et al. reported that the self-reported frequency of opiate use dropped from 5.3 days/week to 0.4 days/week during a 6-month buprenorphine maintenance trial; 50–57% of the participants had at least one cocaine-positive urine test during the 6-month trial [41].

The demographics of this new opioid-dependent population are more apparent in individuals being treated with buprenorphine. The Substance Abuse and Mental Health Services Administration was required by the legislation (Drug Addiction Treatment Act of 2000) that authorized the office-based use of buprenorphine to complete a national survey reviewing demographic data on buprenorphine recipients who were being treated in that setting. As compared with individuals on methadone, this study indicated that buprenorphine recipients were younger, included higher percentages of Whites and women, and were far more likely to be employed and have higher levels of education (see Fig. 8) [144].

Clinicians have generally reported that these clients are less deteriorated, appear much less socially deviant, and are more typical of the general population. On average, addicted individuals enter buprenorphine maintenance treatment 5 years earlier than methadone maintenance clients enter treatment. They are significantly less likely to have used needles and consequently have a much lower incidence of hepatitis C and HIV disease.

Clinical Management

Opiate Overdose

Opiate overdose is a life-threatening emergency. Patients typically present with depressed

consciousness, depressed respirations, and miotic pupils. With meperidine (Demerol®) overdoses, the pupils may not be miotic. Similarly, with severe hypoxia, or in overdoses with multiple classes of drugs, the pupils may be dilated. It is also common to see hypotension and diminished heart rate and occasionally pulmonary edema. The patient should be checked for venous sclerosis (track marks), but these may be missing in younger addicts who may be taking prescription medications orally or may be inhaling or smoking heroin. A drug overdose should be suspected in any comatose individual, and serum toxicology and blood glucose should be obtained immediately.

The primary goal of treatment is to sustain or restore vital functions and to immediately reverse the overdose with an opioid antagonist.

1. Immediately assess the adequacy of airway, breathing, and circulation (A, B, & C). Initiate intubation and resuscitation, and support vital functions as needed.
2. Establish an intravenous line and administer 50% dextrose/water solution.
3. In cases of suspected recent oral drug ingestion, gastric lavage should be initiated. Care must be taken to avoid aspiration; patients should be intubated if there is evidence of respiratory depression.
4. Naloxone (Narcan®) 0.2–0.4 mg intravenously will begin to reverse the effects of an opiate overdose within 1 min. If there is no response to the initial dose, repeat doses may be administered every 2–3 min. If there is no response after a total dose of 10 mg naloxone, it can be assumed that the coma is not solely caused by an opiate. The patient should then be evaluated for other causes of coma, including the ingestion of other drugs, trauma, and diabetic coma.
5. All overdose patients should be hospitalized and monitored for a minimum of 24 h, particularly if an ingestion of multiple drugs is suspected.
6. Patients who have overdosed on long-acting opioids such as methadone or propoxyphene need to be monitored for 24–48 h. Since the antagonist effects of naloxone will last for only 30–90 min, such patients should be monitored in an intensive care unit and placed on an intravenous naloxone drip.
7. Patients who present with symptoms of interstitial pneumonia, pulmonary congestion, or edema should be treated with oxygen, and with intubation and assisted ventilation if required. In these circumstances, cardiac function is normal and there is no change in heart size. Treatment with diuretics and digitalis will be ineffective and should be avoided.
8. Any overdose patient should have a psychiatric evaluation and should be referred for substance abuse treatment. Physicians need to stress the importance of further treatment and strongly encourage attempts to curb or eliminate further drug use. Whenever possible, opiate overdose kits containing intranasal naloxone and instructions for managing overdoses should be provided to all drug-abusing individuals and their friends and families.

Opiate Withdrawal Syndromes

The withdrawal syndrome for short-acting opiates (heroin or morphine) begins 6–12 h after last use. Early symptoms include opiate craving, anorexia, anxiety, and irritability. These are coupled with clinical signs of increased respirations and blood pressure, sweating and yawning, lacrimation, rhinorrhea, piloerection (gooseflesh), tremor, and dilated pupils. After 48–72 h, the symptoms progress to include nausea, vomiting, diarrhea, insomnia, tachycardia, abdominal cramps, and involuntary muscle spasms and limb movements. Observable signs subside over 5–7 days, but a prolonged state of craving, depression, irritability, and dysphoria may persist for months.

The signs and symptoms associated with withdrawal from long-acting opioids such as methadone or propoxyphene are similar to those described above, but they may not begin until 24–48 h after the last dose and may last for

3 weeks or more. Individuals detoxifying from methadone also complain of deep bone pain that may last for weeks. As with individuals withdrawing from short-acting opiates, there is a similar protracted withdrawal state. Buprenorphine has a withdrawal syndrome similar to other long-acting opioids, but it is usually less intense and of shorter duration (see Fig. 5) [72].

Opiate Detoxification

Similar to the treatment of other withdrawal syndromes, the primary objective is to substitute the short-acting drug of abuse with a longer-acting drug in the same class and gradually taper at a rate that prevents severe withdrawal and avoids intoxication or excessive sedation. The preferred medications for opiate detoxification are oral methadone and sublingual buprenorphine [71, 117]. Clinical experience suggests that methadone is preferred for less motivated individuals with larger opiate habits, or for individuals with histories of polydrug abuse or significant psychiatric comorbidity. Buprenorphine is preferred for highly motivated individuals with smaller habits. In circumstances where opioids are not available, the alpha-adrenergic agonist clonidine may be substituted. Clonidine moderates autonomic withdrawal symptoms but does not control insomnia, restlessness, craving, or dysphoria. In combination with methadone, it may permit more rapid detoxification with lower doses of opioids. However, clonidine alone is not an adequate treatment for the withdrawal syndrome. Addicts rarely prefer clonidine, and relapse rates are higher than those seen with other medications [45, 82].

Before starting withdrawal medication, the client should have a thorough physical with urine toxicology and a complete drug and medical history. Except in those who are currently on medication-assisted treatment with either methadone or buprenorphine, it is almost impossible to estimate accurately the person's level of dependence. Clients' reports are often misleading, and it is highly dangerous to estimate the quality and quantity of street drugs. Even when clients are transferred from maintenance programs, the clinician must always contact program staff to verify the dose before starting treatment. The only safe way to avoid an inadvertent overdose is to document the presence of mild opiate withdrawal before initiating treatment. This is best done using a standard opiate withdrawal scale such as the Clinical Opiate Withdrawal Scale or the Objective Opiate Withdrawal Scale [52, 152]. Once clients score in the mild to moderate withdrawal range on the Clinical Opiate Withdrawal Scale, they can be given an initial dose of 20 mg methadone orally or 4 mg buprenorphine sublingually.

For younger individuals with minimal habits, it is prudent to start with 10 mg methadone or 2 mg buprenophine. Clients should be periodically monitored with a withdrawal scale and can be redosed in 2–4 h if withdrawal symptoms do not subside. If 10–20 mg methadone was effective as an initial dose, it may be repeated in 12 h if necessary. In no circumstance should the total 24-h dose exceed 40 mg methadone or 12 mg buprenorphine. If symptoms progress on the second treatment day, the total daily dose may be increased to 60 mg methadone or 16 mg buprenorphine, but doses in this range are rarely necessary in inpatient settings. Once symptoms are adequately controlled, the dose should be tapered at a rate that prevents further withdrawal and minimizes distress. Methadone can be decreased 5 mg/day or a maximum of a 20% dose reduction per day. Inpatient methadone detoxification can usually be completed in 5–7 days [117]. Buprenorphine can be decreased at the rate of a 50% dose reduction per day, though a more gradual reduction spread over 13 days has a better outcome and was significantly more effective than clonidine [82]. A recent review compared buprenorphine detoxification treatment with clonidine and methadone [45]. Compared with clonidine, buprenorphine-treated clients stayed in treatment longer (particular in outpatient detoxification), had fewer withdrawal symptoms, and were more likely to complete treatment. There was no significant difference in outcome comparing methadone to

buprenorphine in severity of withdrawal or completion of treatment, but withdrawal symptoms resolved more quickly in buprenorphine-treated individuals.

While detoxification can be accomplished on either an inpatient or an outpatient basis, the best results are seen with very prolonged outpatient tapers, or with a 1- to 2-week inpatient detoxification followed by long-term residential care. Brief (3- to 4-day) inpatient detoxification treatment has a very high relapse rate, averaging 90–95% within 1 year. Better outcomes are seen with multiyear maintenance treatment followed by gradual outpatient detoxification. Yet, in the best of circumstances, there is an 80% relapse rate within 1 year [7]. Since the fatality rate for active opiate dependence ranges from 8 to 20% per year, addicts need to understand the risks when detoxification is not followed by long-term residential treatment.

Other protocols for detoxification have involved a rapid inpatient clonidine taper combined with a transition to narcotic antagonist treatment utilizing naltrexone or naloxone. Naltrexone is used to precipitate withdrawal, and then increasing doses of clonidine are used to suppress withdrawal symptoms as naltrexone is quickly increased to antagonist maintenance levels [107, 127]. While this approach provides a quick and cost-effective model for detoxification, there is no evidence that it produces higher levels of long-term abstinence as compared with other detoxification approaches [46]. "Ultra-rapid" detoxification protocols have been proposed utilizing escalating doses of naltrexone given under general anesthesia or heavy sedation [14]. O'Connor and Kosten reviewed the existing literature on rapid and ultra-rapid detoxification and concluded that the studies were inadequate because of the small numbers of subjects included, variations in protocols utilized, lack of randomized design and/or control groups, and lack of long-term follow-up [106]. Well-designed, long-term studies are necessary to demonstrate that these procedures have greater efficacy over standard detoxification protocols beyond the short-term detoxification period [138]. In addition, deaths have been reported during the 16–40 h following ultra-rapid detoxification [63]; for this reason alone, ultra-rapid detoxification procedures cannot be recommended.

Other medications have been proposed for opiate detoxification, but none have been studied adequately. Proposed agents include *N*-methyl-*D*-aspartate receptor antagonists, such as dextromethorphan and memantine, and the serotonin type 1A receptor agonist buspirone. Buydens-Branchey et al. compared placebo with a methadone taper vs. two dose levels of buspirone. There was no significant difference noted between the subjects treated with a methadone taper and those treated with either buspirone dose [19].

Opiate Pharmacotherapy

Naltrexone

Naltrexone is an orally effective mu-opioid antagonist that was approved for the treatment of opiate dependence in 1984. It has a high receptor affinity that prevents the binding of most other opioids [105] (see Fig. 4); its long half-life permits thrice-weekly dosing. Unfortunately, client compliance has been very poor, and side effects of anxiety and dysphoria may be problematic. It is rarely effective with most addicts but has worked well in highly motivated individuals under external monitoring [131]. The recent development of a 30-day depot formulation holds promise for improved efficacy and has renewed interest in the use of this medication [27].

Methadone

Methadone was developed as an analgesic during World War II. It is a full agonist at the mu and delta receptors (see Fig. 4) and acts as an *N*-methyl-*D*-aspartate antagonist [50]. In 1965, Dole and Nyswander reported its successful use as a maintenance medication for

chronic opiate addiction. It is a highly lipophilic, long-acting, and orally effective medication that controls craving and opiate withdrawal with a single daily dose. In company with counseling and other supportive services, up to 70% of addicts are able to eliminate their opiate use [7, 37]. Clients demonstrate no euphoria, mental dulling, or motor impairment. Long-term methadone dosing normalizes brain endocrine physiology and re-establishes normal activity along the hypothalamic-pituitary-adrenal axis [75]. Federal regulations limit maintenance treatment to highly regulated methadone clinics, and individuals must document a 1-year history of addiction and a current state of physiologic dependence to qualify for maintenance treatment. Successful treatment requires adequate dosing (60–120 mg daily), strong ancillary services delivered by professionally trained therapists, and long-term, if not indefinite, treatment [7, 20, 88, 142]. Methadone has typical opiate side effects and does not appear to have significant hepatotoxicity.

Methadone should not be started in maintenance clients until opiate withdrawal has been documented, and the starting dose should not exceed 30 mg orally, with a maximum of 40 mg as the total first-day dose. In individuals with significant persistent withdrawal symptoms, the dose may be increased to 50 mg on the second day, but from that point forward, dose increases should be held to a maximum of 10 mg/week. Recent reports of prolonged QTc waves and torsade de pointes have raised concerns about the safety of methadone, particularly in doses over 100 mg. Deaths have been reported among individuals being treated for pain when doses were increased rapidly. Because of its long half-life, methadone may quickly accumulate to toxic levels if individuals are not given adequate time to develop tolerance to previous doses. Electrocardiograms should be obtained before starting treatment and should be repeated regularly in those receiving doses over 100 mg. Methadone is metabolized by the CYP4503A4 system. Drugs that induce that system, such as phenytoin, rifampin, or efavirenz, may reduce methadone levels and precipitate withdrawal. Similarly, drugs that inhibit the CYP4503A4 system, such as cimetidine or the macrolide antibiotics, will increase methadone levels.

Levo-Alpha Acetyl Methadol

Levo-alpha acetyl methadol is an orally effective, long-acting derivative of methadone that has been approved for maintenance treatment. Because of its long half-life, it can be dosed thrice-weekly [100]. Despite clinical efficacy [59], levo-alpha acetyl methadol was never widely accepted by methadone clinics or opiate addicts. It has particular utility in individuals who are rapid metabolizers of methadone and have traditionally been difficult to stabilize on methadone. After the Food and Drug Administration required a black-box warning because of the risk of death associated with prolonged QTc intervals and torsade de pointes, the manufacturer voluntarily withdrew levo-alpha acetyl methadol from the market.

Buprenorphine

Buprenorphine, a partial agonist at the mu-opiate receptor, was approved by the Food and Drug Administration in 2002 for the treatment of opiate dependence. Its effectiveness has been demonstrated in a number of double-blind, placebo-controlled trials [59, 61, 81, 141]. Buprenorphine is available in a sublingual formulation, either alone (Subutex®) or in a combination tablet with naloxone (Suboxone®). As a partial opiate agonist, it binds tightly to opiate receptors but does not fully activate the receptor. Because of this "ceiling effect", there is no significant respiratory depression regardless of the dose of buprenophine ingested (see Fig. 4). For this reason, it has been recognized as an unusually safe opioid. This property, coupled with a slow onset of action and the combination formulation with naloxone (to reduce the illicit intravenous use of the medication), was thought to limit the abuse potential of the medication. Both the Food and Drug Administration and the

Drug Enforcement Administration approved its use in office-based settings, without the regulatory limitations placed on methadone maintenance treatment. The introduction of office-based buprenorphine treatment has been a major public health success [144]. As anticipated, the availability of maintenance treatment in private office settings has attracted a large population of addicted but higher-functioning individuals. There are currently over 300,000 individuals on buprenorphine maintenance in the United States, compared with 275,000 individuals on methadone maintenance. Individuals are attracted to the greater flexibility of office-based treatment and to the lesser intensity and shorter duration of withdrawal symptoms with buprenorphine as compared with methadone. It should be noted, however, that there is no evidence that buprenorphine detoxification is associated with any less of a long-term relapse rate than is seen with methadone. It is critical that all maintenance clients be engaged in individual or group counseling and/or 12-step programs. Pharmacotherapy without ancillary services is rarely effective [49, 88, 97].

Federal regulations limit practitioners of office-based buprenorphine treatment to 30 active clients and require a waiver for a second Drug Enforcement Administration number based on American Board of Psychiatry and Neurology certification in addiction psychiatry, certification in addiction medicine by the American Society of Addiction Medicine or the American Osteopathic Association, or completion of an 8-hour training course. To qualify for treatment, clients must be at least 16 years old and must meet *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria for opiate dependence. In comparison with methadone, this permits the treatment of younger people with short addiction histories. These individuals are more likely to primarily abuse pain relievers, not heroin, and many have never used intravenous drugs. As a group, they are less likely to be HIV positive, to have hepatitis C, or to have criminal records, and are more likely to be employed and to have had some college education. Clinicians have reported that most of their buprenorphine recipients are highly motivated and respond very positively to treatment [97, 144].

Treatment initiation with buprenorphine requires careful attention to its antagonist-like properties. Because of its high affinity for the opiate receptor, buprenorphine will displace most other agonists. However, as a partial agonist, it does not fully activate the receptor. The net result is that the addict experiences this action as an antagonist effect. Severe but relatively brief withdrawal may be precipitated whenever buprenorphine is taken in the presence of a full agonist. To initiate buprenorphine treatment successfully, the clinician must, therefore, determine that the client is currently opiate free. This is best done by counseling the client to abstain from opiates for at least 24 h and by documenting the presence of opiate withdrawal using withdrawal scales such as the Clinical Opiate Withdrawal Scale. Once the individual demonstrates mild to moderate withdrawal on the Clinical Opiate Withdrawal Scale, he or she may safely take the first buprenorphine dose. It is recommended that an initial dose of 4 mg sublingually be given under observation in the clinician's office and that the client be observed for an additional 2 h to ensure that there is no precipitated withdrawal. Supplemental doses can be given if withdrawal symptoms persist, with a maximum recommended first-day dose of 8 mg. The dose can be raised in 2- to 4-mg increments over the next 2–3 days to a dose that eliminates any further withdrawal symptoms and craving. The usual maintenance dose ranges between 12 and 16 mg sublingually daily. Urines should be monitored regularly. Higher doses should be considered if craving and opiate use do not cease within 1–3 weeks. Because of the ceiling effect, there is no pharmacological justification for daily doses over 32 mg.

Novel Anticraving Medications

While agonist replacement and antagonist treatments have demonstrated efficacy in reducing craving for opiates, other pharmacologic agents

have also been investigated. Only a small number of studies have been conducted with these medications, and further studies are needed to determine their efficacy. A 12-week randomized, placebo-controlled trial showed that baclofen recipients remained in treatment longer, but baclofen did not reduce the rate of positive urines [6]. In a small trial, pentazocine-dependent individuals were given either naltrexone alone or gabapentin and naltrexone. Participants given gabapentin and naltrexone reported less craving during and shortly after detoxification than those given naltrexone alone [79]. In another small, 12-week trial, methadone maintenance participants who were given magnesium had fewer positive urines for opiates than those given placebo [86]. Although topiramate has been investigated for its use in detoxification [157, 158], there are no trials to date that have tested its efficacy in reducing craving for opiates.

Psychosocial Treatment

A variety of psychosocial treatments have been used to treat substance use disorders. While pharmacotherapy is an important component of treatment, non-pharmacologic strategies remain crucial for the overall success of treatment. Although most of these treatments are not specific to opiate dependence, this section will review the psychosocial treatments in common use.

Outpatient Drug-Free Programs (Post-Detoxification Treatment)

A variety of individual and group psychotherapies may be very helpful in modifying clients' behaviors and lifestyles. Commonly used individual psychotherapies include cognitive behavioral therapy, contingency management, motivational enhancement therapy, and 12-step facilitation. In addition, various group therapies are also frequently utilized, including family therapy and intensive outpatient group treatment.

Relatively few randomized trials have been conducted to examine the effects of psychosocial treatments for opiate dependence in the outpatient drug-free post-detoxification setting. Nevertheless, a recent meta-analysis of controlled trials for psychosocial treatments concluded that contingency management and cognitive behavioral therapy for opiate dependence produced effect sizes that are low-moderate to high-moderate, comparable to the effect size of pharmacologic treatment for anxiety disorders [38].

Cognitive behavioral treatments are among the most frequently employed interventions that are empirically tested across a broad range of substances, including opiates [22]. Cognitive behavioral therapy attempts to help clients learn the various feelings, thoughts, behaviors, and situations that raise the likelihood of drug use, and to help them cope more effectively with negative emotional states. Individuals are also taught to avoid triggers and situations that promote drug use. Typically, cognitive behavioral therapy approaches place an emphasis on functional analysis of drug use as well as skills training [22]. There have been several studies that have reported positive results utilizing cognitive behavioral therapy, but not in a drug-free context [9, 80, 122]. A recent study also showed positive results with exposure therapy in a drug-free setting, a behavioral technique aimed at reducing cue reactivity by exposing abstinent individuals to drug-related cues while preventing their conditioned responses [87]. Community reinforcement approaches, also based on operant conditioning theory, have been shown to be helpful for clients on methadone maintenance treatment, who have been shown to reduce their use of illicit opiates if given alternate reinforcers—i.e., take-home methadone [1, 140].

Contingency management is a generic behavioral intervention based on the principle of operant conditioning, using primarily positive reinforcements to promote abstinence [55]. A common strategy involves the use of a voucher that can be used to purchase retail items in the community if therapeutic goals are met—i.e., negative urines [129]. There are two randomized

trials to date that have shown positive results when contingency management is used in conjunction with naltrexone [23, 24]. One study examined voucher reinforcement for heroin and cocaine users in an outpatient drug-free program but did not show any significant difference with the no-voucher group [62]. This finding is consistent with other studies that have found an increased likelihood of negative results when treating individuals with polysubstance dependence [38]. A meta-analysis examining all the studies that utilized voucher-based reinforcement therapy or related monetary-based incentives to treat substance use disorders concluded that overall voucher-based treatments were superior to control treatments [83].

Motivational enhancement interventions include the various strategies that attempt to increase clients' motivation to change their drug use, reduce ambivalence, and increase commitment to abstinence [35]. This approach uses the "stages of change" model to help identify where clients are in the recovery process and to help them progress more rapidly. Motivational interviewing is the most frequently utilized interviewing style that attempts to increase motivation for change [92]. No studies have been conducted for opiate-dependent individuals in a drug-free setting. One study has been conducted with participants in a methadone program, but it did not contain all the components necessary to qualify as motivational enhancement therapy and did not show any reduction in opiate use as compared with controls [133].

Twelve-step facilitation is a manualized, evidence-based treatment with a large research base that can be integrated with other therapies that the client is receiving [126]. It is a technique used to help clients engage in and maximize their response to 12-step meetings. Twelve-step facilitation was initially created for Project MATCH and was shown to be as effective in reducing alcohol use as was motivational enhancement therapy and cognitive behavioral therapy [101]. However, there are no studies that have examined the efficacy of 12-step facilitation specifically for opiate-dependent individuals in a drug-free setting.

Group therapy is the most widely used psychosocial treatment for substance use disorders [15]. Since users may be less likely to trust clinicians and others in a position of authority, group treatments utilizing family members, peers, and other users can dilute the negative countertransferences that users experience. Groups can be offered in a wide variety of settings (inpatient, outpatient, and residential), target specific populations (such as gay men and lesbians, women with post-traumatic stress disorder, combat veterans, or individuals with bipolar disorder), and can have a variety of theoretical approaches (12-step, cognitive behavioral therapy, and interpersonal). Groups can provide relief from the tremendous shame and isolation that clients experience, as well as provide a safe environment for obtaining support, confirmation, and advice [15]. Furthermore, groups can correct disturbed interpersonal interactions by establishing a healthy and mutually supportive attachment to others [43]. Several studies have examined group therapy for opiate users in the setting of agonist maintenance treatment (see the section below titled "Outpatient treatment in the setting of methadone and buprenorphine maintenance").

Family therapy includes treatments that involve family members of the substance user. It is designed to help the family manage and cope with the distress caused by the negative consequences of drug use [109]. A particularly well studied family therapy is behavioral couples therapy, which is designed for married or cohabiting couples [108]. This treatment works to promote a cohesive relationship and better communication with family members, which in turn can lower the risk of relapse.

McLellan et al. have defined "intensive outpatient programs" as programs that offer at least 9 h/week of structured programming and "partial hospital programs" as programs that offer at least 20 h of services per week [88]. In one study, compared with individuals in "traditional" outpatient treatment, which offers no more than 4 h of programming per week, clients in intensive programs received more addiction-focused treatment but fewer medical and employment-focused services. At the 6-month follow-up,

both groups had notable improvements in substance use, health, and social functioning [88]. In another study, graduates from an intensive program were more likely to be abstinent from drugs at the 6-month follow-up and less likely to be incarcerated than those who did not complete the program [150].

Drug Courts

Drug courts are being increasingly utilized to offer treatment in place of incarceration [128]. Standard features of drug courts include regular and close monitoring of progress by the judicial officer, urine drug testing, coordinated aftercare plans, and dismissal or reduction of charges upon successful completion of treatment [128]. While not specific to opiate users, an extensive meta-analysis revealed that drug court participants had lower re-arrest and conviction rates than those who did not participate [146].

Outpatient Treatment in the Setting of Methadone and Buprenorphine Maintenance

Individuals maintained on methadone or buprenorphine clearly benefit from additional psychosocial interventions. In a study by Woody and colleagues, methadone maintenance clients who received professional treatment (cognitive or supportive-expressive therapy) showed greater improvements than those individuals who received only drug counseling [154]. The greater benefit was found to be sustained at the 12-month follow-up, and similar results were replicated in a community sample [155]. A recent meta-analysis of psychosocial treatments combined with agonist maintenance treatment concluded that the addition of psychosocial support to standard methadone maintenance treatment significantly reduces the use of heroin during treatment [2].

There has been one study published to date that specifically tested the benefit of cognitive behavioral therapy combined with buprenorphine maintenance treatment [97]. Although the participants were dually dependent on cocaine and opiates, those who attended more therapy sessions had significantly more negative urines for opiates and cocaine. Although the study duration was only 70 days, the results appeared to support previous data that showed beneficial effects of buprenorphine and cognitive behavioral therapy for maintenance clients [61]. Kakko et al. [61] compared buprenorphine maintenance with placebo; all subjects received weekly group cognitive behavioral therapy and weekly individual counseling. One-year retention in treatment was 75% in the buprenorphine group and 0% in the placebo group. While not the primary hypothesis of the study, these results suggest that 6 days of medication treatment followed by placebo coupled with cognitive behavioral therapy and individual counseling was a very ineffective treatment for chronic opioid dependence [61]. In another study, standard methadone maintenance treatment was compared with methadone maintenance plus weekly group therapy. At 6 months, the group therapy clients had significantly less drug use than the control group [134].

Therapeutic Communities

Therapeutic communities for substance use disorders are based both in the community and in prisons, and include a variety of short- and long-term residential and ambulatory programs that provide medical, mental health, vocational, educational, family counseling, legal, and administrative services [32]. The general goal of therapeutic communities is to promote abstinence, change antisocial behaviors, and develop prosocial attitudes and skills by living together with others in a structured environment [156]. Features that differentiate therapeutic communities from other residential treatments are their coordination of a comprehensive range of treatment services in one setting, use of the community itself as the therapist and teacher, and a view that holds that the individual, not the drug, is the

essence of the disorder [32]. Another element of therapeutic communities is the "encounter", a variety of peer-led supportive/confrontational sessions, aimed at giving members feedback from others on whether they are meeting community expectations of recovery [32].

A recent meta-analysis examining the efficacy of therapeutic communities showed that there is little evidence that therapeutic communities offer significant benefits compared with other residential treatments, or that one type of therapeutic community is better than another [139]. However, the authors also acknowledged that the analysis may be biased and that firm conclusions cannot be drawn.

Therapeutic communities have been frequently utilized in correctional facilities [153]. One meta-analysis demonstrated that substance-dependent prisoners treated in therapeutic community programs have lower recidivism rates compared with those without treatment [114]. Another study examined prison-based psychosocial treatments and reached a similar conclusion [94]. Optimal results were seen when inmates participated in prison-based therapeutic communities that were followed by community-based aftercare [56, 84].

Conclusions Regarding Psychosocial Treatment

Although relatively few studies have been conducted exclusively with opioid-dependent individuals, the psychosocial therapies described above have been shown to be effective in this population and are critical in the overall treatment of addiction. A wide variety of these treatments can be offered to suit the needs of individual clients. While no one psychosocial intervention has been shown to be superior to another, the evidence taken as a whole clearly favors incorporating psychosocial therapies, with or without pharmacologic treatments. In addition, the efficacy of pharmacologic therapies is clearly improved when combined with psychosocial treatments.

Managing Co-occurring Psychiatric Disorders

The Incidence of Co-occurring Psychiatric Disorders

The incidence of co-occurring psychiatric disorders in individuals with opiate dependence ranges from 13 to 85% (see Table 2). The lifetime prevalence for any drug use disorder is 37.5% in individuals with bipolar I disorder [47]. There is also a high lifetime prevalence of post-traumatic stress disorder in those with substance use disorder although clients may initially deny a post-traumatic stress disorder history. Individuals with post-traumatic stress disorder may only be willing to discuss this problem after they have developed a more trusting relationship with their clinician. Villagomez et al. reported a lifetime post-traumatic stress disorder prevalence of 20% in women and 11% in men [147]. The prevalence is even higher in adolescents with substance use disorders, with a 24.3% incidence in boys and a 45.3% incidence in girls [34]. Similarly high rates of co-occuring disorders are reported in older methadone clients [130]. These findings indicate that all opioid-dependent individuals should be screened for other psychiatric disorders on admission. Severe problems such as suicidal or homicidal ideation, or psychosis, require immediate assessment and consideration for hospitalization. Less severe symptoms of anxiety and depression are very common in individuals entering treatment; many of these symptoms are substance-induced and will clear once the client's substance use is under control. Appropriate diagnosis is difficult when clients are either intoxicated or in withdrawal. The first goal of treatment is, therefore, to stabilize the addiction.

Table 2 Lifetime prevalance in opioid-dependent individuals [132]

	Men (%)	Women (%)
Affective disorders	70.7	85.4
Anxiety disorders	13.2	25.4
Phobic disorder	8.2	13.9

Substance-Induced Disorders vs. Independent Disorders

Once the individual has achieved abstinence or has been stabilized on methadone or buprenorphine, a more comprehensive psychiatric evaluation should be done to determine whether there are any persistent psychiatric symptoms. The first step in this evaluation is to separate substance-induced psychiatric disorders from independent psychiatric disorders. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision criteria for a substance-induced disorder require that symptoms occur during, or within 30 days of, intoxication or withdrawal, and that the symptoms can be presumed to be related to substance use. If symptoms persist 30 days beyond substance use, they are presumed to reflect an independent psychiatric disorder [4]. Independent psychiatric disorders are more likely if there is a family history of psychiatric disorders. These symptoms do not diminish with sobriety, and they typically continue with little change during prolonged periods of abstinence. The age of onset for most psychiatric disorders is in the early teens and typically precedes the development of any substance use disorder by 5–10 years. A careful longitudinal history will clarify the sequence of symptoms and will help to separate an independent psychiatric disorder from any substance-induced psychopathology. It is difficult to make this assessment in the presence of active substance use. Unless there is a clear history that confirms the presence of other psychiatric disorders, treatment should focus primarily on the addiction.

Managing Co-occurring Psychiatric Disorders

In the case of co-occurring psychiatric disorders, a more comprehensive treatment plan is required to address both conditions. Treatment is most effective if the psychiatric treatment is integrated into the substance abuse treatment program. All involved clinicians should work in close collaboration to ensure coordinated care. Treatment elements need to be integrated throughout the entire course of treatment, from assessment, to initial detoxification or stabilization, and through aftercare [18]. Substance abuse clients will respond to most standard evidence-based forms of psychiatric treatment, including psychotherapy and pharmacotherapy [145]. However, standard treatments for psychiatric disorders cannot be expected to treat the substance use problem. Sobriety from all substances of abuse must remain a primary treatment goal and will require active participation in addiction treatment. Structured psychotherapy approaches are most effective, particularly cognitive behavioral therapy. The "seeking safety" treatment model developed by Najavits for treating co-occurring post-traumatic stress disorder and substance use disorders is particularly useful for managing addicted individuals with a range of psychopathology [98].

There are few published data on the treatment of co-occurring depressive disorders in opioid-dependent individuals; most of the available data come from studies on methadone maintenance clients. In a placebo-controlled trial, Nunes et al. demonstrated efficacy for imipramine in the treatment of depressed methadone maintenance clients [103]. Results with selective serotonin reuptake inhibitors in this population have generally been negative [116], though two studies reported improvement in depression in methadone recipients using sertraline [21, 51]. Kosten et al. failed to demonstrate efficacy for desipramine in the treatment of depressed buprenorphine-maintained subjects, and warned against using this combination of medications [74].

While it is common practice to prescribe selective serotonin reuptake inhibitors and other antidepressants to treat anxiety disorders in individuals with substance use disorders [111], including those maintained on methadone and buprenorphine, there are few data to demonstrate efficacy in this specific population. McRae et al. have demonstrated efficacy for buspirone in

the treatment of anxiety disorders in methadone recipients [89]. Short-acting benzodiazepines are typically avoided in this population because of concerns about abuse and toxicity [11]. However, Bleich et al. demonstrated efficacy for the long-acting benzodiazepine, clonazepam, in the treatment of anxiety disorders in methadone recipients with a prior history of benzodiazepine abuse [10]. There has been particular concern about prescribing benzodiazepine for individuals maintained on buprenorphine, related to reports of overdose deaths in France secondary to the intravenous injection of combinations of buprenorphine and high-potency benzodiazepines [12, 69, 104]. Despite these concerns about the risks of benzodiazepine use in opioid addicts, a comprehensive review of the literature has shown efficacy for the treatment of generalized anxiety disorder, panic disorder, and agoraphobia and probable efficacy for social phobia, with little evidence of added risk for medication abuse or increased relapse [120]; also see [111].

There are relatively few data on the treatment of schizophrenia and co-occurring opioid dependence. The incidence of schizophrenia is thought to be relatively low in this population, though the Environmental Catchment Area Survey reported a 47% lifetime prevalence for any substance use disorder in this population [123]. Alcohol use disorders are the most common substance use disorders seen. Methadone clinics report a very low incidence of psychosis. In general, individuals with schizophrenia and co-occurring opioid dependence are poorly compliant with medication, do not respond well to typical antipsychotics, and show high rates of relapse and hospitalization. However, this population has responded positively to treatment with the atypical antipsychotics, particularly clozapine. It has been speculated that clozapine (a weak D_2 blocker, but a potent noradrenergic A_2 blocker) may normalize mesolimbic dopamine circuits and thus reduce craving for opiates and other drugs of abuse [48].

When considering pharmacotherapy for any psychiatric disorders, caution is required to avoid the use of abusable medications, especially short-acting benzodiazepines. Treatment should always begin with non-abusable medications with proven efficacy for the specific condition. Clients need to be monitored closely to ensure sobriety and compliance with treatment. Depressed clients can be treated with most of the standard antidepressants. When treating anxiety disorders, attention should be given to psychological therapies and coordinated pharmacotherapy. Benzodiazepines should be used with caution and should not be prescribed unless the individual has failed to respond to adequate trials of antidepressants or buspirone. If required, long-acting benzodiazepines are preferred to the more abusable shorter-acting drugs such as alprazolam. Atypical antipsychotic medications may be particularly effective in this population, though quetiapine should be used with caution because of its abuse potential. Any client who fails to respond to treatment should be monitored closely to ensure medication compliance and to rule out any relapse to substance use.

Primary Prevention

In the last two decades, prevention activities in the United States have focused on interdiction and on public education with a primary abstinence message, “Just say no.” The gradual decline in the use/abuse of marijuana, cocaine, and heroin [33, 58] suggests that this approach may have had a positive impact on the use of some illicit substances. However, the recent epidemic of the abuse of prescription pain relievers and a corresponding increase in opioid-related overdose deaths indicate the need to reassess prevention techniques. Young adults, in particular, seem to have interpreted the messages against illicit drugs to imply that licit drugs are safe and non-addictive. The medical community has also underestimated the addictive risks involved in the use of opioids to treat acute and chronic pain. There is clearly a need for a national education campaign to inform the public and physicians about the risks associated with prescription pain relievers and the availability of effective treatment [28]. Physicians have not

been well trained in the management of pain or in the safe prescription of potent opioids with long half-lives. In 2008, the Center for Substance Abuse Treatment of the Substance Abuse and Mental Health Services Administration launched a major campaign to improve physician education in these areas. Other efforts are under way to improve medical school curricula and residency training to achieve a better understanding of the addictive disorders and to improve substance use disorder screening and the management of individuals at risk for substance use disorders [85, 99, 124]. Food and Drug Administration approval of a variety of alcohol anticraving medications and the availability of buprenorphine for the office-based treatment of opioid dependence have opened a new era for the medical treatment of substance use disorders. Corresponding changes in physician education are necessary if these new treatment options are to achieve their full potential. Physicians and the public need education to destigmatize substance use disorders, and to improve general awareness of the effectiveness of addiction pharmacotherapy and manually guided therapies such as cognitive behavioral therapy, motivational enhancement therapy, and 12-step facilitation.

Epidemiologic evidence has consistently shown that primary psychiatric disorders strongly predict the later development of substance use disorders, with a range of 5–10 years between the onsets of the two conditions. This presents a clear opportunity for primary prevention. Kessler has estimated that the effective early treatment of psychiatric disorders would prevent as much as 50% of all substance dependence disorders [66]. Needle exchange programs provide another opportunity for prevention of disease and outreach to opiate abusers. A large percentage of new cases of hepatitis C are a direct result of injection drug users sharing hypodermic needles. In order to prevent the spread of hepatitis C and HIV, needle exchange programs were developed to provide sterile needles and associated injection supplies at no cost. Sometimes the dirty needles must be exchanged for clean needles. These programs also typically offer a variety of other services, such as “bleach kits”, HIV testing, condoms, and referrals to treatment.

Conclusion

As with other chronic relapsing medical disorders, physicians and other clinicians have important roles to play in long-term treatment approaches that integrate appropriate pharmacotherapy with psychotherapy and self-help interventions. Routine screening, particularly for adolescents and young adults, client education about the risks and benefits of potent pain relievers, conservative management of less severe pain syndromes, and early and aggressive treatment of depression and anxiety disorders all will play a role in reducing the incidence of opiate use disorders. Once patterns of opiate misuse or abuse are identified, referrals for treatment, including appropriate pharmacotherapy, and long-term management approaches hold the most promise for successful control and amelioration of the problems associated with opiate dependence.

Introduction

Methamphetamine, which was developed in 1893, is a synthetic stimulant that affects regions of the central nervous system and other major organ systems. Until 1951, no prescription was necessary to obtain methamphetamine or other amphetamine-containing products. Prescriptions for variants of these drugs were freely dispensed in the 1960s, and methamphetamine abuse and dependence increased during this period. "Crank" or "crystal", different versions of methamphetamine, became popular in the 1960s, and "ice", a smokable derivative of methamphetamine, emerged in the late 1980s in Hawaii. The evolution of methamphetamine use between 1988 and 2008 has varied. The early to mid 1990s witnessed escalating problems with methamphetamine throughout many parts of the United States; however, the highest rates of use were in the Western region of the country, particularly in suburban and rural communities. The primary reason for the growth of methamphetamine use was the wide availability of pseudoephedrine, the primary precursor of methamphetamine, which is contained in many over-the-counter cold medications including Sudafed®, Nyquil®, and Claritin-D®. Methamphetamine was manufactured and distributed by small mom-and-pop type "kitchen

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_22,

chemists," as well as larger syndicates and drug cartels. Extended use of methamphetamine has severe physical and mental effects on the user. Those exposed to methamphetamine production sites, including children, can suffer serious health consequences from explosions, fires, and toxic gases and wastes. Consequently, methamphetamine abuse and dependence has had a substantial impact on the treatment, health care, criminal justice, and social welfare systems. From 2003 to 2006, the federal government and many states imposed strict pre-cursor control laws that restrict the retail sales of medications that contain pseudoephedrine. These efforts have substantially reduced the availability of methamphetamine and increased its price in many areas of the United States.

From the early 1990s through 2005, numerous indicators indicated steady increases in the use of methamphetamine. However, in 2007, 529,000 persons aged 12 or older were current users of methamphetamine, a reduction from 731,000 in 2006 [96]. Similarly, the Community Epidemiology Work Group of the National Institute on Drug Abuse recently reported that methamphetamine indicators from law enforcement (arrests and seizures) and emergency room data from 20 of 22 metropolitan areas, showed either a stable or downward trend of methamphetamine use during 2006 and 2007 [53]. Similarly, treatment admissions for methamphetamine, which increased dramatically from the 1990s to 2005, showed a decline in 2006.

While methamphetamine use peaked and has seemed to stabilize in many parts of the United States, global trends remain highly problematic. Epidemiological data from several countries, including regions of Southeast and East Asia (i.e., Thailand, Cambodia, Indonesia, Malaysia, and the Philippines), Canada, Australia, South Africa (i.e., Cape Town), and parts of Europe (e.g., Czech and Slovak republics) indicate that methamphetamine production, trafficking, and use are steadily increasing [18, 30, 54].

Neurobiological Impact of Methamphetamine

Although individuals initiate use of methamphetamine for a variety of psychological and socio-cultural reasons, once methamphetamine has been ingested, profound changes occur in the structure and chemistry of the brain. Methamphetamine blocks the reuptake of released dopamine in the synaptic clefts, resulting in increased levels of dopamine in the synapse of neurons in the nucleus accumbens and other areas of the mesolimbic region of the brain [104]. The chronic and long-term use of methamphetamine results in lower levels of dopamine receptors that are associated with increased dependency, i.e., loss of control and compulsive drug use [83]. Methamphetamine use also results in a significant loss of dopamine transporters (used as markers of the dopamine terminal), which is associated with slower motor function and decreased memory, attention, and cognitive functioning, such as inhibitory control [55, 63, 88]. Furthermore, methamphetamine increases cytoplasmic concentration of dopamine, which promotes oxidation products that are toxic to the nerve terminals [31, 72, 83]. The neurotoxicity of methamphetamine is further accentuated by its prolonged half-life and, therefore, long duration of action.

Recent investigations into the neurobiological phenomena associated with methamphetamine dependence have employed magnetic resonance imaging and functional magnetic resonance imaging, as well as positron emission tomography and single photon emission computerized tomography. Brain imaging studies have provided delineated depictions of brain activity during methamphetamine intoxication and in early phases of abstinence following methamphetamine withdrawal, yielding potential therapeutic targets for prospective medications and even for behavioral therapies. In brief, the research has documented abnormalities in cortical and limbic systems, deficits in dopaminergic and serotonergic neurotransmitter systems,

deficits in gray matter, and variations in glucose metabolism compared with nonusers of methamphetamine [1]. Changes in glucose metabolism have been shown to be associated with severity of psychiatric symptoms [14]. Imaging studies of methamphetamine-abusing individuals have also revealed greater activity in the amygdala and less activity in the infralimbic cortex among methamphetamine abusers than in non-using individuals, as well as changes in glial cell proliferation or metabolism and in neural integrity [1].

Other findings include reduced concentrations of the neuronal marker N-acetylasparate and total creatine in the basal ganglia, and the striatum has been shown to be considerably affected by methamphetamine use, with lower levels of dopamine transporters and lessened dopamine receptor availability [85], indicating compromises that manifest in cortical regions that control executive function [1]. In chronic methamphetamine abusers, there are structural changes including greater cortical volume and changes in the hippocampus that relate to cognitive deficit [98]. Increased striatal volume and decreased striatal metabolism have been found and postulated to be a function of increased water content or as result of inflammation [13].

A number of investigations have explored longer-term abstinence and neurobiological changes after cessation of methamphetamine abuse, showing some recovery but not full reversion to a normal state over a period of several months of abstinence. After protracted abstinence, methamphetamine abusers showed increased metabolism in the thalamus, similar to controls, whereas recently abstinent methamphetamine abusers had lower metabolism in both the striatum and thalamus [104]. Furthermore, after methamphetamine cessation and recovery over time, there appears to be some improvement in dopamine transport function [103]. Sekine and colleagues [86], for example, found that serotonin transporter density generally decreased as the years of methamphetamine use increased and serotonin transporter density was correlated inversely with aggression scale scores.

Implications of neurobiological findings for treatment approaches, both pharmacotherapies and behavioral therapies, include the need to improve cognition in order to facilitate learning among methamphetamine-experienced subjects, whose weakened ability to concentrate may be attributable, at least in part, to errors and differential activity in the anterior and middle cingulate gyrus and insula [49]. Recent research has confirmed that methamphetamine-abusing individuals can be compromised in terms of responses to external stimuli, lessening their ability to meaningfully participate in or benefit from behavioral therapies. New knowledge from such studies will lead to potential therapeutic targets for interventions designed to facilitate cessation of methamphetamine use and reduce relapse.

Acute and Chronic Health Effects of Methamphetamine Abuse and Dependence

Euphoria, increased blood pressure, elevated body temperature, and rapid heart and breathing rates are commonly experienced acute effects of methamphetamine use. Other immediate clinical symptoms include reduced fatigue, reduced hunger, increased energy, increased sexual drive, and increased self-confidence. Depending on the nature and extent of abuse, negative acute physiological effects can include intense stomach cramps, shaking, bruxism, disrupted menstrual cycles, “formication,” or the sensation of insects creeping on the skin, and insomnia [73]. Heavy and long-term chronic methamphetamine use can result in many life-threatening medical illnesses and disabilities [65].

Cardiopulmonary consequences are common among methamphetamine abusers. Chest pain, hypertension, shortness of breath, and tachycardia are common in emergency room cases involving methamphetamine toxicity

[80]. Also seen in emergency rooms among methamphetamine abusers is acute coronary syndrome. Turnipseed and colleagues [101] documented acute coronary syndrome in 25% of methamphetamine abusers admitted for chest pain, possibly resulting from myocardial ischemia and its attendant risk of arrhythmias and cardiogenic shock [105]. Cardiovascular symptoms, including irregular heartbeats have developed in more than half of the methamphetamine abusers studied by Beebe and Walley [3]. Cardiomyopathy related to methamphetamine use may be reversible; however, this is dependent on cessation of drug use [41]. Pulmonary edema was found in over 70% of methamphetamine-related deaths [44]. Damage to small blood vessels in the brain can result in stroke, paralysis, and brain damage [68, 104].

"Meth mouth" and other oral complications are common among chronic methamphetamine abusers, even though the contribution of level of methamphetamine abuse to their etiology is questionable. Oral health problems most often seen among methamphetamine abusers include rampant caries, tooth fracture, and periodontal disease (e.g., gingivitis, periodontitis) [89, 90]. In addition to caries and gingivitis, methamphetamine abusers often present with tooth wear and temporomandibular joint syndrome related to bruxism, which may be a reaction to anxiety and restlessness, especially during early abstinence [17].

Skin excoriations or cutaneous ulcers are common among methamphetamine abusers, notably occurring in response to reported sensations of bugs crawling below the skin and subsequent scratching [5]. Self-inflicted wounds have been documented among methamphetamine abusers, postulated to occur in presence of dopaminergic agonism that manifests in a similar manner to motor stereotypies and hyperkinetic movements [42]. In addition to consequences such as those above and cellulitis and abscesses resulting from injection of methamphetamine, users and associates are prone to severe burns and chemical injuries that occur during manufacture of the drug [81].

Many users suffer from neurocognitive impairments [50, 93] and psychiatric comorbidity, particularly severe psychosis, depression, and suicidal ideation [56, 109]. A recent examination of methamphetamine-related emergency department admissions indicates that among the 15,038 emergency room-related visits from February 2006 to June 2006, 353 were methamphetamine related, with the top four medical reasons reported related to mental health (18.7%), trauma (18.4%), skin infections (11.1%), and dental diagnoses (9.6%) [34].

Methamphetamine Use, Sexual Behavior, and Communicable Diseases

Methamphetamine use is highly prevalent among men who have sex with men [91]. Several surveys show consistently high rates of methamphetamine use among men who have sex with men [45]. In the Young Men's Survey of men who have sex with men (ages 15–22) in seven U.S. cities, 32% (Los Angeles), 28.5% (San Francisco), and 28.2% (Seattle) of young men who have sex with men reported methamphetamine use in the previous 6 months [97]. A number of studies among methamphetamine-dependent populations of men who have sex with men indicate strong associations between methamphetamine use and the sexual transmission of infectious diseases, including HIV/AIDS and other sexually transmitted infections (such as syphilis) compared with men who have sex with men who do not use methamphetamine [46].

Studies of methamphetamine users in general also show strong associations between methamphetamine use and HIV risk [62, 79, 87]. A recent study by Rawson and colleagues [76] found that male and female methamphetamine users tend to engage in frequent sexual activity, to have multiple, anonymous sexual partners, and to report low rates of condom use

and high rates of unprotected anal and vaginal sex. Men tend to report that their sexual thoughts, feelings, and behaviors became associated with methamphetamine use and that methamphetamine use made them obsessed with having sex and led to their engagement in riskier sexual acts (i.e., anal sex) [79]. Although both men and women methamphetamine users report increased sexual desire while under the influence of methamphetamine, men tend to experience greater sexual enhancements and desires that have been linked to more unusual and riskier sexual acts [9].

Studies of methamphetamine users in general also show strong associations between methamphetamine use and communicable disease risk, including HIV, hepatitis A, B, C, and other sexually transmitted infections, due to risky sexual and drug use practices [67]. Risky drug use practices among methamphetamine users, including injection and drug-sharing behaviors (e.g., sharing water for needle or pipe preparations and/or to rinse syringes/pipes and cotton) have also significantly increased the risk of infectious diseases [26, 27, 32, 40, 47, 62, 75, 76, 79, 87, 102].

Affected Populations

Youth

While national trends concerning methamphetamine use by youth under the age of 24 have been equivocal, in some geographic regions there is an indication of significant problems associated with methamphetamine use by this population. State and local data from treatment programs reveal that methamphetamine use among youth is a major problem [10]. The Phoenix House, a large treatment center in Southern California, revealed that admissions for methamphetamine accounted for approximately half of the center's youth admissions in 2005–2006, doubling since 2002. When examining methamphetamine youth admissions by age, data indicate that youth represent the highest proportion; however, methamphetamine use among younger youth (12–17 years old) is also problematic [75]. Treatment admission data from Los Angeles County indicate increased admission rates for female methamphetamine-abusing youth, particularly Latinas [25, 75]. The literature on clinical risk factors associated with methamphetamine use among youth suggests that methamphetamine-abusing youth tend to have past histories of physical and sexual abuse/trauma, family history of substance abuse, and current psychological problems, including affective emotional and conduct disorders [61, 66, 75, 108]. Risky sexual behaviors, including violence and aggression, as well as multiple sex partners and unprotected sexual intercourse, have also been implicated among methamphetamine-abusing youth [2, 107].

Women

Research indicates that women are using methamphetamine at rates relatively equal to men [37]. Almost half (46%) of national admissions to publicly funded treatment are adult female methamphetamine users, compared with 31% of admissions for other drugs (i.e., heroin, alcohol, marijuana) [96]. Studies show that women tend to progress faster to drug dependence, suffer more adverse consequences [29], and present for treatment with greater psychological distress [4], compared with their male counterparts. A large body of literature comparing drug-dependent women with drug-dependent men indicates that women are more likely than men to report extensive histories of trauma, neglect, and abuse [57]. In fact, between 70% and 85% of women who develop methamphetamine dependence have reported a history of sexual and physical abuse [8, 60, 73]. Such histories have been linked to an increased likelihood of domestic violence in adult relationships, chronic addiction, criminal activity, homelessness, and psychiatric co-occurring illness [58].

In a recent study, Messina et al. [59] reported that methamphetamine-dependent women offenders tend to have had significantly greater exposure to childhood abuse and household dysfunction than have methamphetamine-dependent men and more often reported sexual abuse in adolescence and as an adult.

Methamphetamine-Using Pregnant Women and Their Children

Methamphetamine use among pregnant women, in particular, is a major public health problem in the United States. Compared with non-methamphetamine-using pregnant women, pregnant methamphetamine-using women had a 3.5 times greater likelihood of having a lower birth weight child and pre-term births [94]. Winslow and colleagues [106] indicated that the use of methamphetamine by pregnant women has been linked to placental abruption, intrauterine growth retardation, and preterm birth. To date, there is limited research on the impact of prenatal methamphetamine exposure on the developing fetus. Smith and colleagues [95] recently examined the neurobehavioral effects of prenatal methamphetamine exposure (as measured by meconium assay and self-report) in a longitudinal follow-up study and found that exposure to methamphetamine was associated with increased physiological central nervous system stress. First-trimester methamphetamine use was related to elevated stress abstinence, and third trimester methamphetamine use was associated with poor quality of movement. When parents use or produce methamphetamine, the potential consequences for their children include asthma or other respiratory ailments. Children in the vicinity of small-scale methamphetamine manufacture in residential settings can suffer burns. The explosive, corrosive, and toxic chemicals involved in methamphetamine production and their by-products can affect children and others even after clandestine labs have been dismantled.

Criminal Offenders

The number of incarcerations and other problems within the criminal justice system among methamphetamine-dependent individuals have increased, which supports the strong association between methamphetamine dependence and participation in illegal behaviors [22]. Since 2002, the criminal justice system has been the top referral source for methamphetamine treatment [12]. The latest national statistics indicate that a large proportion of admissions for primary methamphetamine/amphetamine abuse across the country was from the criminal justice system (49%), compared with 34% for other categories of drugs [96]. In California, more than half of drug-abusing offenders diverted from the judicial system to treatment in lieu of incarceration were primary methamphetamine users [21].

Methamphetamine-dependent offenders seeking treatment may require different treatment options and plans tailored to their special characteristics [12]. It has been suggested that drug courts may be an effective tool for promoting successful treatment outcomes for methamphetamine-dependent offenders [39]. Drug courts are governed by a number of key components, including the integration of treatment with criminal case processing; early identification and prompt placement of eligible drug offenders into the program; provision of a continuum-of-services treatment plan; alcohol and drug testing; and ongoing judicial interaction [100]. A recent study examined the treatment response of methamphetamine-dependent individuals within a drug court setting and found that drug court participation was associated with better rates of engagement, retention, completion, and abstinence compared with methamphetamine users who did not participate in a drug court treatment setting [52]. Follow-up analyses revealed that participants who were enrolled in the drug court intervention used methamphetamine significantly less frequently compared with methamphetamine users without drug court supervision.

Clinical Management of Methamphetamine Users

Managing Methamphetamine Intoxication

Acute agitation from methamphetamine intoxication is most often the condition that leads users to seek medical attention, and "talking down" the patient in a calm environment is a first course of action. Addressing possible methamphetamine toxicity may involve emetics or lavage to remove methamphetamine pills, but toxicity from intravenous or smoked routes of administration may necessitate the use of charcoal and medications such as ammonium chloride or quelidrine to hasten clearance of methamphetamine from the gastrointestinal tract and the circulatory system. No medications are available to reverse methamphetamine overdose. Either a benzodiazepine or an antipsychotic may be used in extremely agitated individuals who pose a threat to others. A standard approach is provision of haloperidol in 5 mg by mouth or parenteral repeated doses, frequently in combination with 1–2 mg of lorazepam and 1 mg of the anticholinergic cogentin. Also useful are intramuscular injections of 2 mg lorazepam, 5 mg haloperidol, or both, administered in several doses over a 12-h period and with patient evaluation for 12 h.

Managing Acute Methamphetamine Psychosis

Symptoms of methamphetamine-induced psychosis can be difficult to differentiate from those of other disorders that may pre-date drug abuse, and so a definitive diagnosis is required before commencing treatment. Methamphetamine abusers frequently report auditory hallucinations, which is more typical of schizophrenia, in addition to visual (flashing lights, peripheral artifacts), olfactory, and tactile sensations. Symptoms of methamphetamine psychosis include: persecutory delusions, ideas of reference, hallucinations (visual and auditory, olfactory, tactile), relative clear sensorium, stereotypy and compulsive acts, anhedonia and depression, blunt affect, poverty of speech, and being prone to excited delirium and violence.

Methamphetamine-induced acute psychosis, which generally is transient, can require use of either a benzodiazepine or an antipsychotic, both of which should be halted when acute symptoms have resolved. Low-dose antipsychotics between psychotic episodes may be useful, but there is no empirical guidance on the efficacy or appropriateness of such treatment. Such agents are contraindicated for adolescents and young adults, in whom methamphetamine-induced psychosis has increased more than five-fold from 1993 to 2002 [15]. Treatment of this population should follow the treatment described above for intoxication.

Managing Chronic Methamphetamine Psychosis

Symptoms of persistent or chronic methamphetamine psychosis are often so similar to those of schizophrenia that some clinicians may regard them as clinically equivalent conditions, although a good case is made for methamphetamine *producing* a persistent psychosis that resembles schizophrenia [70]. Regardless of the causal direction or association, the symptoms of schizophrenia and of persistent methamphetamine psychosis are not readily distinguishable, and the treatment for this condition remains basically the same as in recent practice (see Table 1).

Managing Methamphetamine Withdrawal

Methamphetamine withdrawal symptoms consist of severe fatigue, cognitive impairment,

Table 1 Managing chronic methamphetamine psychosis

Preventing relapse of psychosis symptoms:
- Clients with chronic methamphetamine psychosis that were given small doses of Haldol® did not have further recurrences of psychosis symptoms, whereas those not medicated did [84].

Benzodiazepines versus antipsychotics for methamphetamine psychosis:
- Relapse of psychosis symptoms has been inhibited by use of antipsychotic medication, but relapse has not been prevented by use of benzodiazepines.
- Beneficial effects of early antipsychotic treatment must be weighed in the context of possible adverse effects from such medications.

Long-term use of antipsychotics for persistent psychosis:
- Possibly deleterious long-term effects of antipsychotics indicate a need for caution in adults; likely negative effects on brain development in youths argue against use of antipsychotics.
- Adverse effects in adults may outweigh possible benefits.

feelings of depression and anxiety, anergia, confusion, and paranoia. For the majority of individuals experiencing acute withdrawal/early-phase abstinence, most symptoms resolve within 2–10 days. Rest, exercise, and a healthy diet may be the best management approach for most people in withdrawal. Those with heightened agitation and sleep disturbance may respond to benzodiazepines, but acute depression and anhedonia associated with early abstinence generally resolve without intervention. Clinicians should be aware of possible dehydration and hyperthermia. Drug craving may be addressed via behavioral treatments or periods of residential care.

In the process of dealing with near-term abstinence, clients who exhibit severe paranoia, episodes of psychosis, powerful craving for methamphetamine, and protracted dysphoria and anhedonia will present challenges for the clinician. Furthermore, certain groups of individuals present for treatment with special concerns, as detailed below:

- *Female methamphetamine users*—higher rates of depression, often with histories of sexual and physical abuse; responsibilities for children.
- *Injection methamphetamine users*—very high rates of psychiatric symptoms; severe withdrawal syndromes; high rates of hepatitis.
- *Homeless, chronically mentally ill individuals*—high levels of psychiatric symptoms at admission and during treatment.
- *Individuals under the age of 21*—antipsychotic medications and other mediations should be avoided or used with caution.
- *Men who have sex with men*—at very high risk for HIV, hepatitis, and other sexually transmitted diseases.

Methamphetamine Use and Co-occurring Disorders

Many methamphetamine-dependent individuals present for treatment with symptoms of psychiatric problems [109], although distinguishing the degree to which these symptoms can be attributed to methamphetamine use versus underlying mood disorders is often difficult. In a recent examination of predictive factors associated with diagnosing methamphetamine-dependent individuals with major depression, Glasner-Edwards and colleagues [23] identified having a lifetime history of suicide attempts and current depressive symptoms (as measured by the presence of a Beck Depression Inventory score of 20 or above) as two robust predictors.

Clinically, suicidal behavior has been a major concern regarding methamphetamine-dependent individuals [109]. Some research has implicated methamphetamine-related intoxication, withdrawal, and psychiatric symptoms in elevating users' risk of depression and suicide [48]. A recent study documents injection drug use, current depressive symptomatology, and a clinical history of psychiatric problems as significant risk factors for suicidal behaviors in methamphetamine-dependent users [24].

Treatment Outcomes with Methamphetamine Users

A body of literature has been developed on treatment outcome evaluations for methamphetamine abuse. Engagement in treatment, retention in treatment for at least 90 days, abstinence during treatment, and treatment completion have been consistently shown to successfully predict positive treatment outcomes with methamphetamine-dependent populations [33, 35]. Risk factors for poor treatment outcomes have been identified as daily methamphetamine use, injection methamphetamine use, having less than a high school education, young age at treatment admission, having a disability [6], polydrug use [7], childhood trauma and abuse [60], and having an underlying psychotic disorder [24] or major depression [23]. Treatment participation and active recovery efforts, including frequent 12-step program participation, have been associated with successful treatment outcomes [36]. Research has also shown that women and men respond to treatment similarly in terms of retention and completion, although women tend to have slightly better treatment outcomes, including more improved relationships with family and fewer medical problems as compared with men [8, 37].

Few studies to date have examined the longitudinal impact of treatment, including patterns of use and psychosocial outcomes. In a recent longitudinal examination of outcomes over a 10-year period, Hser and colleagues [36] found that quitting was predicted by current treatment and self-help participation among stimulant users (including methamphetamine and cocaine users), and that cessation of drug use was less likely among methamphetamine users with an early drug-use onset, relative to cocaine or heroin users.

Treatment Approaches for Methamphetamine Abuse and Dependence

The majority of studies investigating the effectiveness of treatment for stimulant addiction have focused on cocaine abuse and dependence, with fewer studies on methamphetamine. Despite differences between the two stimulants in individual health, psychological, and cognitive effects, both groups tend to show comparable responses to psychosocial behavioral treatments [16, 38, 51].

Evidence-based behavioral treatment for methamphetamine-dependent individuals *does* work as documented by the authors and colleagues [77, 92]. Treatment has profound effects, including reductions in methamphetamine use during treatment, increased treatment retention, decreased use of other drugs, decreased criminal involvement, and reduced high-risk sexual practices among gay and heterosexual users [71, 74].

Behavioral Therapies for Methamphetamine Abuse and Dependence

Cognitive Behavioral Therapy

Cognitive behavioral therapy is a short-term, focused approach to help substance users become abstinent and avoid relapse. The underlying assumption is that learning processes play

an important role in the development and continuation of substance abuse. Key elements of cognitive behavioral therapy are:

- Functional analyses of substance abuse
- Individualized training in recognizing emotional states
- Exercises, such as thought stopping and managing thoughts about drug use
- Coping skills, problem-solving, planning for emergencies, and refusal skills
- Examination of the client′s cognitive processes related to substance use
- Identification and debriefing of past and future high-risk situations
- Encouragement and review of extra-session implementation of skills
- Practice of skills within sessions.

Cognitive behavioral therapy promotes abstinence via skill training, including learning and practicing strategies for: (1) reducing availability and exposure to drugs and related cues, (2) fostering resolution to stop drug use by exploring positive and negative consequences of continued use, (3) self-monitoring to identify high-risk situations and to conduct functional analyses of substance use, (4) recognition of conditioned craving and development of strategies to cope with craving, (5) identification of seemingly irrelevant decisions that can culminate in high-risk situations, (6) preparing for emergencies and coping with relapse to substance use, (7) drug refusal skills, and (8) identifying and confronting thoughts about drugs. Several versions or packages of cognitive behavioral therapy-based interventions are available in manual form, including the National Institute on Drug Abuse cognitive behavioral therapy, a 12-session approach [11]. The Matrix Model is a blended treatment approach that incorporates principles of cognitive behavioral therapy in individual and group settings, family education, motivational interviewing, and behavioral therapy; while not a "pure" cognitive behavioral therapy intervention, the Matrix Model employs cognitive behavioral therapy principles. This manualized therapy has been proven effective in reducing methamphetamine use during the 16-week application of the intervention, in comparison with a "treatment as usual" condition in a large Center for Substance Abuse Treatment-funded multisite trial [77, 78]. The Matrix Model also has been evaluated as a stand-alone treatment for subgroups of methamphetamine abusers (e.g., gay and bisexual men and heterosexuals) and as the behavioral treatment platform in pharmacotherapy trials for methamphetamine dependence [20].

Contingency Management

Also known as motivational incentives, contingency management is an intervention for drug abuse that employs immediate reinforcement for demonstration of desired behaviors (e.g., a drug-free urine test). Roll and colleagues [82] recently conducted a multisite clinical trial in which a contingency management protocol was evaluated as an addition to an outpatient methamphetamine treatment program. Participants in the contingency management condition demonstrated a superior clinical performance on multiple outcome measures (number of methamphetamine-negative urine samples, number of consecutive weeks of abstinence, percent that completed the trial with continual abstinence). At present, contingency management appears to produce the most robust reductions in methamphetamine use of any single technique.

Medications for Treatment of Methamphetamine Abuse and Dependence

Recent discoveries about the effects of methamphetamine abuse on the brain and the mechanisms of methamphetamine dependence have offered many opportunities for the discovery and development of novel medications to treat methamphetamine dependence [64].

Although multiple medications have been investigated for treating methamphetamine dependence, only a handful have shown promise, including bupropion [19, 69]; however, the research literature still lacks substantiation of the efficacy or clinical utility of any medication as a treatment for methamphetamine dependence. Under consideration or in current trials are several compounds, including disulfiram, modafinil, vigabatrin, baclofen, lobeline, varenicline, mirtazapine, topirimate, and aripiprazole. Past work has failed to demonstrate the efficacy of compounds such as selegilene and assorted other medications such as sertraline, gabapentin, rivastigmine, risperidol, and ondansetron [48] as potential treatments for methamphetamine dependence. In a small European study, methylphenidate has shown preliminary efficacy in reducing relapse among newly abstinent individuals who had been amphetamine dependent [99]. Most recently, a Swedish study found naltrexone (the opiate antagonist used as an alcoholism treatment medication) given orally was effective in suppressing relapse to stimulant use among individuals meeting *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria for amphetamine dependence [43].

Given that medications for treating stimulant dependence have yet to be proven broadly effective, future pharmacotherapy will probably be integrated with behavioral therapy. Medications in development generally are intended to address some form of deficit caused by methamphetamine use or withdrawal, either neurobiological or syndromal. Medications that may be useful in helping attain abstinence or sustain recovery from methamphetamine dependence are still in development. Briefly, bupropion (Wellbutrin®), modafinil (Provigil®), and, to a lesser extent, baclofen (Lioresal®) have exhibited some utility as adjuncts to behavioral therapy in treating methamphetamine dependence. Other medications (e.g., gabapentin, lobeline, vigabatrin, ondansetron, and varenicline as Chantix®) are under consideration. Also under consideration is agonist therapy (i.e., "replacement/substitution" medication) [28], which is similar to methadone for opioid dependence, although this approach is not designed to produce abstinence from stimulants.

Future Directions in Research and Practice

Research topics on methamphetamine that are garnering increased attention include: (1) cellular mechanisms of action of methamphetamine and their relationship to neurotoxicity; (2) the interplay between the limbic brain circuitry underlying reward and the frontal brain that exercises control over the limbic brain, and (3) the disinhibition of the limbic brain resulting from functional or structural disconnection from the executive brain. As knowledge emerges about these complex interactions, researchers and clinicians face new challenges as well as new opportunities for the development and implementation of pharmacological and behavioral treatment strategies to address methamphetamine dependence.

Regardless of the advances in scientific understanding of the neurobiological phenomena associated with methamphetamine abuse, utilization of such knowledge often occurs with much delay and sometimes never happens. The "real world" in which clinical researchers conduct investigations of new treatments and in which clinicians treat clients is not always receptive to findings from human laboratory studies or even Phase III trials, and implementation of research-proven practices never occur in an optimally timely manner without first overcoming various obstacles.

The first part of any solution to the problem of methamphetamine abuse involves greater awareness by all those involved in pertinent disciplines, from basic scientists to primary care physicians. Clearly, clients must also be educated about what happens to them when they use methamphetamine and when they cease using. To accomplish at least part of that

awareness raising, new curricula need to be developed and refined at all levels, in academic institutions at the undergraduate and postgraduate levels and in community practice settings, where clinicians may seek and find definitive training in the science and practice of addiction medicine.

Sedative-Hypnotics and Anxiolytics

Bachaar Arnaout and Ismene L. Petrakis

Contents

Introduction

The sedative-hypnotics and anxiolytics are central nervous system depressants that also have muscle relaxant and anticonvulsant effects and are widely used in psychiatry, neurology, anesthesiology, and general medicine. The most common of these are the benzodiazepines and the new-generation non-benzodiazepine hypnotics (i.e., zaleplon, zolpidem, and eszopiclone), which due to their better safety profiles have largely replaced the barbiturates and other older agents, particularly in the treatment of insomnia and anxiety. This group of medications also includes chloral hydrate, meprobamate, carisoprodol, glutethimide, and methaqualone. Gamma-hydroxybutyrate, which has some properties associated with the sedative-hypnotics, is usually classified as a "club drug".

Beyond their use in the treatment of anxiety disorders and insomnia, the benzodiazepines also are often used for the management of agitation, the treatment of seizures, as muscle relaxants, for premedication in anesthesiology, and as the mainstay of treatment for the management of medication detoxification from alcohol. The new-generation non-benzodiazepine hypnotics are used primarily for the treatment of insomnia. The barbiturates nowadays are most commonly prescribed for the treatment of epilepsy and for anesthesia, and can also be used for detoxification from alcohol. The older sedative-hypnotic and anxiolytic agents such as chloral hydrate, meprobamate, carisoprodol, glutethimide, and methaqualone are less commonly used nowadays.

These groups of medications have a similar mechanism of action in that they all enhance the activity of the brain's main inhibitory neurotransmitter, gamma-aminobutyric acid (GABA), leading to the opening of chloride channels and cell membrane hyperpolarization. In a simplified but clinically useful model, the central nervous system maintains a balance between inhibitory signals mediated by gamma-aminobutyric acid and excitatory signals mediated by the brain's primary excitatory neurotransmitter, glutamate

[24]. When the balance sways toward glutamate-mediated excitatory transmission, the individual experiences arousal and anxiety; conversely, gamma-aminobutyric acid-mediated inhibitory transmission results in tranquility and sedation. The benzodiazepines bind to gamma-aminobutyric acid-A receptors, where they enhance gamma-aminobutyric acid activity [55]. The new-generation non-benzodiazepine hypnotics have a similar mode of action but appear to have relative selectivity to certain subunits of the gamma-aminobutyric acid-A receptor, resulting in a prominent sedative-hypnotic effect and a relatively weaker anxiolytic effect [18]. The barbiturates also potentiate gamma-aminobutyric acid activity at the gamma-aminobutyric acid-A receptor but may additionally exert a direct effect on opening the chloride channel [42]. Chloral hydrate, meprobamate, carisoprodol, glutethimide, and methaqualone also appear to exert their effects through GABAergic transmission. All of these medications can be used to reduce anxiety at lower doses and to induce sleep at higher doses. Commonly used sedative-hypnotic and anxiolytic drugs along with their approximate dose equivalencies are included in Table 1. Since all of these drugs have wide therapeutic applications and are among the most commonly used, the conceptualization of what constitutes inappropriate use of the sedative-hypnotics and anxiolytics is often difficult to determine. The use of these drugs in a fashion other than as prescribed (i.e., non-medical use) has been defined as "misuse", and the terms "abuse" and "dependence" are based on their *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision definitions [1].

Table 1 List of sedative-hypnotics and anxiolytics with approximate dose equivalencies

Generic name	Trade name	Dose equivalency (mg)
Benzodiazepines		
Alpazolam	Xanax	1
Chlordiazepoxide	Librium	25
Clonazepam	Klonopin	1
Clorazepate	Tranxene	15
Diazepam	Valium	10
Estazolam	ProSom	1
Flurazepam	Dalmane	20
Lorazepam	Ativan	2
Oxazepam	Serax	20
Quazepam	Doral	20
Temazepam	Restoril	20
Triazolam	Halcion	0.25
Non-benzodiazepine hypnotics		
Eszopiclone	Lunesta	3
Zaleplon	Sonata	10
Zolpidem	Ambien	10
Barbiturates		
Amobarbital	Amytal	100
Butabarbital	Butisol	100
Butalbital	Fiorinal	100
Pentobarbital	Nembutal	100
Phenobarbital	Luminal	30
Secobarbital	Seconal	100
Other agents		
Chloral hydrate	Noctec	500
Glutethimide	Doriden	250
Meprobamate	Miltown	800
methaqualone	Quaalude	300

Despite their most common appropriate therapeutic use, non-medical use of the sedative-hypnotics and anxiolytics can be problematic and often occurs in individuals with other substance use disorders as well as those with general psychiatric disorders. In the National Epidemiologic Survey on Alcohol and Related Conditions, conducted in 2001–2002 with a sample of 43,093 respondents representative of the United States, the lifetime prevalence of non-medical use of sedatives and tranquilizers was 4.1 and 3.4%, respectively, and the lifetime prevalence of sedative and tranquilizer abuse and/or dependence was 1.1 and 1.0%, respectively [39]. In the same survey, the 12-month prevalence rates were: 0.09% for sedative abuse, 0.07% for sedative dependence, 0.08% for tranquilizer abuse, and 0.05% for tranquilizer dependence [85]. The survey reported high rates of lifetime comorbidity between sedative and tranquilizer use disorders and alcohol use disorders (odds ratios of 13.4 and 14.2, respectively), mood disorders (odds ratios of 4.9 and 4.8, respectively), anxiety disorders (odds

ratios of 3.7 and 4.2, respectively), and personality disorders (odds ratios of 5.6 and 6.6, respectively) [39]. Comorbidity is likely to be even higher in clinical populations. For example, in a sample of 427 treatment-seeking individuals with alcohol use disorders, the lifetime prevalence of anxiolytic abuse or dependence was 20% [71]. Conversely, in a sample of 30 consecutive patients undergoing inpatient detoxification from benzodiazepines because of severe benzodiazepine dependence, 100% had another lifetime substance use disorder, 33% had lifetime major depression, and 30% had lifetime panic disorder [7].

Intoxication and Overdose

As noted earlier, the benzodiazepines are most commonly used as anxiolytics and sedative-hypnotics. However, there are reports of their consumption for the purpose of intoxication, which is described as similar to alcohol intoxication [73], leading to the saying, "benzodiazepines are the driest of martinis". There are some differences between intoxication from benzodiazepines and alcohol intoxication. For example, benzodiazepine users less commonly report the social disinhibition associated with alcohol use. Disinhibition and aggression related to benzodiazepine use is relatively rare, and is more likely to occur in those with high baseline levels of hostility as well as those with pre-existing brain damage [36]. With dose escalation, pleasurable intoxication may progress to manifestations of more profound toxicity, such as impairment in attention or memory, slurred speech, incoordination, unsteady gait, nystagmus, stupor or coma, and eventually respiratory depression. The benzodiazepines have a fairly wide therapeutic index, and overdose rarely results in death in healthy individuals. However, though safer than the barbiturates [77], the benzodiazepines have been associated with lethal overdoses when used alone [19], and especially when combined with other central nervous system depressants, such as alcohol [43, 77] and opioids including buprenorphine [41, 87, 95].

The mechanism by which benzodiazepines manifest their rewarding potential is not fully understood. While activation of dopamine in the nucleus accumbens of the mesolimbic reward pathway is thought to underlie the rewarding properties of most drugs of abuse, the benzodiazepines appear to decrease rather than increase dopamine activity in the nucleus accumbens [21]. It has been hypothesized that the rewarding effect for the benzodiazepines may be mediated though their actions on the gamma-aminobutyric acid system [17].

Laboratory studies that have tried to evaluate the rewarding properties of the benzodiazepines have found that healthy individuals have no preference for the benzodiazepines over placebo; in fact, healthy subjects have demonstrated a preference for placebo over higher doses of the benzodiazepines [97]. However, individuals with a substance use disorder history, especially to sedatives, may be more likely to experience benzodiazepines as rewarding [97]. There is also evidence that individuals with a history of moderate alcohol consumption, anxiety, and insomnia [31], as well as children of alcoholics [10, 11], may be more likely to experience the reinforcing effects of the benzodiazepines. Interestingly though, research on the use of the benzodiazepines for the treatment of anxiety disorders in former substance abusers has not found evidence of induction of relapse to substance use [56, 61]. There is some evidence that benzodiazepines with a rapid onset of action such as diazepam [30, 32] and those with a short half-life such as alprazolam [3] may have a relatively more reinforcing effect, although these results are controversial [72]. Taking the drug intravenously also has been associated with increased reinforcing effects [78].

When misused, the central nervous system depressants are often taken in combination with other drugs [14, 15], often leading to complex and dangerous interactions. For examples, individuals may use the benzodiazepines to enhance intoxication with opioids or alcohol, or to self-medicate the anxiety associated with stimulant use as well as the discomfort associated with stimulant or opioid withdrawal.

The non-benzodiazepine hypnotics are even less likely to be taken for intoxication; however, they carry a risk of misuse, especially among individuals with other substance use disorders and psychiatric comorbidity [9, 33]. Though they are likely safer than the benzodiazepines, there have been reports of coma, respiratory depression, and fatal overdoses on high doses of zolpidem, especially when combined with other drugs [13]. The barbiturates have a narrower therapeutic window in comparison with the benzodiazepines and carry more risk of dangerous central nervous system depression and death on overdose. Fatal overdose also may occur with other older agents; however, both their medical and recreational use has declined since the introduction of the benzodiazepines.

Benzodiazepine intoxication is managed according to the level of severity. Mild intoxication can be managed with supportive care and medical monitoring, while overdose is managed in an intensive care setting. Flumazenil, a benzodiazepine receptor antagonist, is used intravenously to reverse benzodiazepine overdose [92]. Flumazenil should be used with caution as its use may induce benzodiazepine withdrawal and increase the risk of grand mal seizures [92]. Flumazenil also has been used in overdose related to the new-generation non-benzodiazepine hypnotics [8, 26, 37]. Since the barbiturates exert their activity independently of the benzodiazepine binding site, flumazenil does not block their effects and is not useful in barbiturate overdose.

Tolerance and Withdrawal

Physiological dependence requires the presence of tolerance or withdrawal [1]. Tolerance is marked by the gradual need to use increased doses of the substance to achieve the same effect, or is a diminished effect with the same dose. Tolerance to the sedative-hypnotics and anxiolytics occurs through central nervous system adaptation to the drug at the receptor level [6]. Depending on the agent used, its dose, and the duration of use, tolerance can develop in days to months. Tolerance to the benzodiazepines is more likely to develop to the sedative-hypnotic and motor impairment effects than to the anxiolytic and short-term memory impairment effects [29, 47]. Tolerance can be minimized by using the medication for a short period, taking "drug holidays", and using the lowest effective dose. Cross-tolerance can occur between the benzodiazepines and other depressant drugs, including alcohol [40].

Withdrawal is marked by the presence of a characteristic syndrome on cessation or reduction in the use of the substance, and can be avoided or relieved by taking the same or a closely related substance. Symptoms of withdrawal from the benzodiazepines resemble those of alcohol withdrawal, and are generally the result of central nervous system excitation, which is the opposite of the primary action of the drug. Withdrawal progresses from a syndrome of anxiety, insomnia, and tremor to nausea, vomiting, diaphoresis, tachycardia, hypertension, and rarely to grand mal seizures [51] and delirium in rare, severe cases [46, 99]. Withdrawal usually develops after taking the benzodiazepines for months; however, milder withdrawal may emerge after days to weeks of use. Withdrawal severity correlates with the duration of use [66] and the potency and dose of the drug taken [51], as well as individual susceptibility and general health status.

Syndromes that occur commonly after cessation of use of the benzodiazepines can be divided into:

- Acute withdrawal, characterized by relatively severe symptoms emerging several hours to days following dose reduction or cessation of use. Use of short-acting agents is associated with relatively more intense but shorter duration of acute withdrawal symptoms, peaking 2 days after discontinuation, whereas longer-acting agents result in milder but longer withdrawal, peaking in 4–7 days [58, 67].
- Protracted withdrawal, characterized by ongoing anxiety and depression, as well as mild sensory and motor disturbances

that can linger for months [4]. More severe presentations such as psychotic depression also have been reported [54].

- Symptom recurrence, which is the reemergence of pre-existing symptoms, such as anxiety, that were previously masked by the benzodiazepine [58]. Although often difficult to distinguish, re-emerging symptoms tend to be stable over time, unlike withdrawal symptoms, which tend to subside gradually.
- Symptom rebound, which is the exacerbation of pre-existing symptoms after cessation of use, and is, therefore, a combination of genuine withdrawal and symptom re-emergence [22, 58].

Of note, physiological dependence (i.e., tolerance or withdrawal) may occur even when the medications are adequately used at therapeutic doses, and does not necessarily indicate that substance dependence has developed, as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision. Nonetheless, the presence of physiological dependence should alert the clinician that the individual may have *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision–diagnosed substance dependence, in which case the presence of tolerance and withdrawal is associated with greater severity of the disorder [74]. The less ambiguous term "addiction" is not present in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision but is considered to be the equivalent of "substance dependence".

Benzodiazepine withdrawal can be managed by supportive measures in less severe cases. In more severe cases, pharmacologic detoxification is often achieved by substituting the substance with a long-acting benzodiazepine such as clonazepam or chlordiazepoxide and gradually reducing the dose over several days in inpatient detoxification programs. Intermediate-acting benzodiazepines, such as lorazepam, also are effective; however, a simple taper of the original medication also has been used. While inpatient detoxification may be needed when concurrently detoxifying from several drugs such as alcohol and opiates, a more gradual taper also can be achieved over several weeks to months in the outpatient setting [76]. Evidence suggests that gradual detoxification is more effective than abrupt discontinuation, which is associated with a higher dropout rate [16]. It also is recommended that the taper be slower after reaching about 50% of the original dose [69, 76]. An older method, using phenobarbital substitution [81], is less commonly used, but is used when detoxifying individuals from the barbiturates [80]. Since benzodiazepine or barbiturate withdrawal is associated with serious morbidity and the possibility of mortality, the clinician should evaluate individuals carefully and consider pharmacologic management of benzodiazepine withdrawal. Of other, non-sedative-hypnotic/anxiolytic medications studied for benzodiazepine detoxification, the anticonvulsant carbamazepine has the most promising data, suggesting its possible utility when used as an adjunct to the benzodiazepines, and its use also may improve drug-free outcome [16].

The literature on physiological dependence to the new-generation non-benzodiazepine hypnotics has been scarce. Tolerance and withdrawal from these drugs have been reported but appear to be relatively rare, as compared with the benzodiazepines [33], possibly due to their relative selectivity at the gamma-aminobutyric acid-A receptor. Caution, however, is advised, as there have been reported cases of withdrawal seizures [12], as well as withdrawal delirium and psychosis, after discontinuation of the use of the new-generation non-benzodiazepine hypnotics [86, 88, 96]. A detoxification regimen similar to that used with the benzodiazepines and barbiturates has been suggested in managing withdrawal from the new-generation non-benzodiazepine hypnotics [63].

Withdrawal from the barbiturates and other older agents is associated with a clinical picture comparable to that of the benzodiazepines, and may lead to withdrawal seizures as well as delirium. Treatment includes detoxification with phenobarbital, a benzodiazepine, or by a gradual taper of the original substance.

Abuse and Dependence

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision [1] offers clear definitions of substance abuse and dependence that apply to all substances of abuse including the sedative-hypnotics and anxiolytics. Tables 2 and 3 summarize the criteria for substance abuse and dependence, respectively, as adapted from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision [1].

Evaluating for sedative-hypnotic and anxiolytic abuse or dependence when a patient has been prescribed the medication by a physician is potentially difficult. For example, if an individual manifests psychosocial deterioration, it is often difficult to determine whether it is the effect related to benzodiazepine dependence or whether it is the result of an undertreated anxiety disorder. Some potential ways to disentangle this may be to evaluate psychosocial functioning. The trajectory of the patient's level of functioning may be a good clinical barometer; if his or her level of functioning improves with the use of a benzodiazepine, then it is likely that the prescribed substance is beneficial. Conversely, the patient's demand for increasing doses of the medications despite deteriorating psychosocial functioning is one indication that a substance use disorder may have developed. The patient's level of functioning can be evaluated by accessing previous records, as well as collateral information and involvement of significant others, after obtaining the patient's consent.

Other indicators of the presence of a substance use disorder are reports of loss of prescriptions, running out of the medication, obtaining the medication from several prescribers, and other signs of loss of control over use of the substance. Even when these signs are present, the physician should retain an "open mind" to the possibility of what is sometimes called "pseudoaddiction" [48], namely when a behavioral pattern typical of substance dependence occurs but is related to the patient's efforts of obtaining a medication that he or she needs for a genuine disorder. While this term is usually used in pain medicine to refer to patients who seek opioids for undertreated pain, a similar pattern also may occur with benzodiazepine use for anxiety or other disorders. In such instances, with adequate treatment of the underlying psychiatric disorder, this behavioral pattern should resolve. Naturally, there is no simple strategy to managing these complex clinical situations, and in all cases the clinician should clarify the reasons for the patient's use of these agents, evaluate the risk/benefit ratio of prescribing these medications, and subsequently use clinical judgment to develop a reasonable treatment plan in collaboration with the patient.

Table 2 Criteria for substance abuse, adapted from the *Diagnostic and statistical manual of mental disorders*, 4th edition, text revision [1]

Substance abuse is a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by at least one of the following four criteria within a 12-month period:
1. Failure to fulfill major role obligations
2. Recurrent use in physically hazardous situations
3. Recurrent substance-related legal problems
4. Continued use despite persistent or recurrent substance-related social or interpersonal problems

Table 3 Criteria for substance dependence, adapted from the *Diagnostic and statistical manual of mental disorders*, 4th edition, text revision [1]

Substance dependence is a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by at least three of the following seven criteria within the same 12-month period:
1. Tolerance
2. Withdrawal
3. Use in larger amounts or over a longer period than intended
4. A persistent desire or unsuccessful efforts to cut down or control use
5. A great deal of time spent in activities necessary to obtain the substance, use it, or recover from its effects
6. Giving up or reducing important social, occupational, or recreational activities because of use
7. Continued use despite persistent or recurrent substance-related physical or psychological problems

A common clinical dilemma revolves around whether a physician should prescribe benzodiazepines to individuals with a history of other (non-benzodiazepine) substance use disorders. While their use is unquestionably of great value in detoxification from alcohol and other substances, their value as anxiolytics and sedative-hypnotics in this patient population is difficult to determine. The prudent course seems to be that while the benzodiazepines should not be absolutely contraindicated in patients with a history of substance use disorders, since some individuals may in fact benefit from treatment with benzodiazepines without misusing them, special care should be exercised and, if possible, the benzodiazepines should not be the first line of treatment. When absolutely indicated, their use should be monitored and the clinical course followed over time for signs of abuse or dependence.

Treatment of sedative-hypnotic and anxiolytic abuse and dependence usually involves successful detoxification, followed by psychosocial interventions aimed at achieving long-term abstinence. People with sedative-hypnotic and anxiolytic abuse and dependence often have other co-occurring substance use disorders and psychiatric disorders [39], which should be screened, adequately diagnosed, and concurrently treated. There are no agents approved by the Food and Drug Administration for the long-term treatment of benzodiazepine dependence. However, pharmacologic strategies are being investigated to target achieving abstinence from the benzodiazepines; agents that have shown promising potential include the benzodiazepine antagonist flumazenil [27] and the anticonvulsants carbamazepine [16] and valproate [34]. Although controversial, maintenance substitution treatment with a long-acting agent, such as clonazepam, also has been suggested [93]. Long-acting benzodiazepines may provide adequate relief from low-grade anxiety, which may be a trigger to relapse to other benzodiazepine and alcohol use. These strategies, while interesting and promising, are still in their experimental stages, and data supporting their safety and efficacy are limited.

Data on the new-generation non-benzodiazepine hypnotics have been scarce; however, there is emerging evidence that they do carry a risk of abuse and dependence, especially among individuals with other substance use disorders and psychiatric comorbidity [9, 33]. Although abuse and dependence related to these medications seem to be less likely than with the benzodiazepines, caution should nonetheless be exercised with their prolonged use. Since the introduction of the benzodiazepines, use of the barbiturates and other older agents has been declining, and abuse of and dependence on these agents are relatively rare.

Mood and Anxiety Disorders

The benzodiazepines, unlike many other medications used in psychiatry, offer patients substantial and quick relief from anxiety and insomnia, which, whether primary or related to other disorders such as depression or psychosis, are among the most common symptoms in the practice of psychiatry. The benzodiazepines can be taken continuously or as needed and often lack many of the side effects common to psychiatric medications such as weight gain, liver toxicity, and sexual dysfunction. However, while often successfully prescribed for the initial phases of anxiety disorders and depression, the controversy lies in their continued use beyond the acute phase. Some research suggests their continued efficacy for the long-term treatment of panic disorder, without the need for progressive dose escalation [65, 98]. Many long-term benzodiazepine users actually decrease their dose and make attempts to stop use [70]. Other research, however, questions the long-term efficacy of the benzodiazepines for the treatment of anxiety and depression [60], and suggests that their chronic use may be associated with depressive symptomatology [79], although direct causation has not been clearly established. There is also concern that continued use may result in interdose rebound symptoms or simply mask withdrawal rather than treat an underlying anxiety disorder.

Moreover, some research has demonstrated that anxiety levels may actually decrease after successful discontinuation of benzodiazepine use [31]. There also is evidence suggesting that both short-term and long-term use of the benzodiazepines may interfere with other effective treatments such as cognitive behavioral therapy for panic disorder [59, 90]. As noted earlier, depression and psychotic depression have been described in protracted withdrawal from the benzodiazepines [4, 54]. Additional precautions in prescribing these medications should be taken due to the frequent use of the benzodiazepines in suicide attempts [53] and accidental overdose.

It is recommended to use non-benzodiazepine medications such as the selective serotonin reuptake inhibitors, as well as other antidepressants and buspirone, as first-line agents for mood and anxiety disorders, especially in individuals with a history of substance abuse. Other strategies to manage acute anxiety include the use of antihistamines, anticonvulsants, and antipsychotics. Effective psychotherapies, such as cognitive behavioral therapy, also have been developed for specific disorders. The benzodiazepines are safest when reserved either as short-term adjuvants to other medications in the initial stages of treatment or as long-term treatment only in refractory cases. Moreover, they should be avoided generally in individuals with an active substance use disorder and cautiously in those with a remitted substance use disorder.

Many long-term benzodiazepine users can be gradually detoxified from these drugs on an outpatient basis. The difficulty often lies in patients' perceptions that the benzodiazepines are the only effective medications. With a good therapeutic alliance, a detoxification regimen often can be successfully negotiated and achieved. Patients should be reassured that there are numerous non-benzodiazepine medications that are effective in managing insomnia and anxiety disorders. In treating these individuals, clinicians need to distinguish protracted withdrawal from the re-emergence of symptoms of a mood or an anxiety disorder (i.e., symptom relapse).

Cognitive Disorders

Acute use of the benzodiazepines is known to cause cognitive impairment, especially among the elderly and those with pre-existing brain damage, and is likely to resolve after tapering or discontinuing the medication. In more severe cases, this may progress to developing delirium [25]. As noted earlier, delirium also can be a sign of withdrawal from the benzodiazepines.

The extent of the effects of prolonged use of the benzodiazepines on cognition is difficult to determine. Research has demonstrated lack of tolerance to benzodiazepine-associated short-term memory impairment even after years of use [29, 47]. After cessation of use, cognition is likely to gradually improve within weeks [68]; however, some cognitive deficit after prolonged use may linger even months after stopping the medication, and it is unclear whether this reflects permanent residual cognitive deficit [5, 84, 91]. In light of this evidence, caution should be taken with prolonged use of the benzodiazepines, especially in those prone to cognitive impairment.

Use of other GABAergic drugs, including the new-generation non-benzodiazepine hypnotics, can cause cognitive impairment [52]. Delirium also may be associated with the use and withdrawal from the new-generation non-benzodiazepine hypnotics [86, 96], as well as other GABAergic agents.

Psychotic Manifestations

Psychosis related to the use of the benzodiazepines is relatively rare. However, psychosis may be associated with benzodiazepine withdrawal delirium [35] and is an indication for medically supervised detoxification. When part of delirium, psychotic symptoms should be considered as part of the withdrawal picture and treated with appropriate, often very high doses of the benzodiazepines with close medical monitoring. Antipsychotic medications should be used with caution and only as adjuncts to the

benzodiazepines; it is especially unclear to what extent they are beneficial in treating withdrawal delirium beyond their sedative effect. In fact, they may be useful for managing agitation but may also inappropriately cover underlying withdrawal symptoms. Antipsychotic medications also may lower the seizure threshold and potentiate the delirium due to anticholinergic activity. If antipsychotics need to be used in combination with the benzodiazepines to manage agitation in the context of benzodiazepine withdrawal, high-potency antipsychotics such as haloperidol should be considered. As noted earlier, psychotic depression also has been reported as a presentation of protracted benzodiazepine withdrawal [54].

Psychosis, marked by hallucinations and delusions after weeks of benzodiazepine use at a therapeutic level, also has been reported and may be related to underlying brain damage [94]. In this case, psychosis is likely to resolve with dose reduction or cessation of use of the benzodiazepine. Psychosis also may be associated with intoxication or withdrawal from the new-generation non-benzodiazepine hypnotics [50, 86, 88] as well as other GABAergic sedative-hypnotics and anxiolytics.

Sleep Disorders

Short-term use of the benzodiazepines results in a decrease in sleep latency and number of awakenings, an increase in total sleep time, and improvement in sleep quality [38, 57]. Other effects of short-term use include daytime drowsiness [38], as well as disruption of sleep architecture: stage 2 increases, slow-wave sleep decreases, and rapid-eye-movement sleep latency decreases [62]. Continued use of the benzodiazepines can result in tolerance to their sedative action, which may occur after several days [82], and can eventually lead to rebound insomnia when their use is stopped [83]. There also is concern that chronic use may be simply masking rebound insomnia rather than treating an underlying sleep problem [31]. Individuals who demand escalating doses of the benzodiazepines may be misinterpreting tolerance and rebound insomnia as a need for a dose increase.

As noted earlier, the new-generation non-benzodiazepine hypnotics may be less likely to result in tolerance, especially when used at therapeutic doses. Eszopiclone and the extended-release form of zolpidem (Ambien CR®) have been shown to be effective and safe in the long-term management of insomnia in a double-blind, placebo-controlled design [44, 45], and zolpidem and zaleplon have been shown to have long-term efficacy in open-label studies [2, 49]. These data may encourage physicians to prescribe these medications more freely than the benzodiazepines. However, an assessment group from the National Institute for Health and Clinical Excellence, an independent organization providing guidance on health-related issues in the United Kingdom, concluded that randomized controlled trials have not been able to demonstrate substantial consistent differences between zolpidem, zaleplon, zopiclone (of which eszopiclone is an (S)-isomer), and the benzodiazepines in terms of their efficacy or in treatment emergent adverse events [20]. Overall, caution should be exercised with prolonged use of all GABAergic sedative-hypnotics, and other strategies such as sleep hygiene should be incorporated into treatment. Other pharmacologic strategies are also available, such as ramelteon (Rozerem®), a melatonin receptor agonist with no known abuse potential [64].

The barbiturates and other older agents share many characteristics of the benzodiazepines and the new-generation non-benzodiazepine hypnotics but are less likely to be prescribed for the treatment of insomnia.

Sexual Dysfunction

Data on the effect of the benzodiazepines on sexual dysfunction are scarce, at times conflicting, and mostly based on prospective data with certain design limitations as well as on retrospective data and case reports. Benzodiazepine use has been associated with sexual dysfunction in both

men and women, manifested as decreased sexual desire, erectile dysfunction, inhibited orgasm, and inhibited ejaculation [23, 28, 89]. These side effects seem to emerge after weeks of use and are likely to subside after dose reduction or cessation of use. There are few available data on sexual dysfunction related to the new-generation non-benzodiazepine hypnotics, the barbiturates, chloral hydrate, meprobamate, carisoprodol, glutethimide, and methaqualone.

While not a specific side effect of the medication, the dangers of sedative-hypnotic and anxiolytic misuse also include drug-facilitated sexual assaults ("date rape"), especially when potent fast-acting agents are added to alcoholic beverages, inducing passivity and amnesia. Flunitrazepam (Rohypnol), which is not approved by the Food and Drug Administration but is available on the "black market", has been associated with drug-facilitated sexual assaults. Other drugs that have been associated with drug-facilitated sexual assaults include other benzodiazepines, zolpidem, chloral hydrate, meprobamate, and other agents [75].

Summary

The benzodiazepines, the new-generation non-benzodiazepine hypnotics, and the barbiturates, as well as other older agents, share a similar mode of action by enhancing GABAergic transmission in the central nervous system. While all these medications have legitimate medical uses, they also are associated with the risk of misuse, abuse, and dependence, particularly in those with other substance use disorders. They also are associated with psychiatric and medical complications. These medications are safest when they are prescribed for short periods and at the lowest effective dose, their use is monitored, and special precautions are taken when prescribing them for individuals with a substance use disorder history.

Clinical Aspects of Inhalant Addiction

Yu-Chih Shen and Shih-Fen Chen

Contents

Types of Inhalants Being Abused

Inhalants encompass a wide range of pharmacologically diverse substances that readily vaporize. Unlike most other substances of abuse, which are classified into groups that share a specific central nervous system action or perceived psychoactive effect, inhalants are grouped by their common route of administration. Inhalants are classified into three groups on the basis of their currently known pharmacologic actions (Table 1) [27]. Group I includes volatile solvents, fuels, and anesthetics that contain aliphatic, aromatic, or halogenated hydrocarbons. All of these ingredients are found in thousands of commonly used and readily available consumer products. Group II includes nitrous oxide. Group III includes volatile alkyl nitrites. The most commonly abused inhalants are found in Group I. Virtually any hydrocarbon can have mind-altering effects when inhaled in large enough doses. Nitrous oxide, or "laughing gas", is diverted from medical or dental anesthesia use and sold in balloons for inhalation or is simply inhaled from whipped cream aerosol cans. Alkyl nitrites, or "poppers", are also abused; typically, amyl nitrite ampoules intended to treat angina are "popped" open and inhaled.

Epidemiology

The type, frequency, and method of inhalant abuse vary widely in relation to the age of the abuser, the geographic region, and availability. Overall, the onset of inhalant abuse may occur in children as young as 5 or 6 years of age, and the peak age of abuse is 14–15 years. Inhalant abuse usually declines by 17–19 years of age but can continue into adulthood. Abuse by adults may be related to certain occupations where abusable solvents, propellants, or anesthetics are readily available. Inhaled nitrites have a long history of being abused in combination with male homosexual behaviors [27]. Inhalants are sometimes referred to as "gateway" drugs, which means

Table 1 Pharmacologic classification of inhalants and common street names

Group	Common street names
I. Volatile solvents, fuels, and anesthetics	Air blast, discorama, hippie crack, medusa, moon gas, oz, poor man's pot
II. Nitrous oxide	Laughing gas, buzz bomb, shoot the breeze
III. Volatile alkyl nitrites	Poppers, snappers, boppers, pearls, amys, quicksilver

they are among the first drugs people try before moving on to other substances, such as alcohol, marijuana, and cocaine [28].

According to a 2006 survey by the National Institute on Drug Abuse [14], the prevalence of lifetime inhalant use among adolescents in the U.S. has ranged between a low of 10.3% in 1976 (when inhalants were first included in the survey) and a peak of 18.0% in 1990. The 2006 rate was 11.1%; this rate has remained stable since 2002. According to the 2008 National Survey on Drug Use and Health [26], inhalants were the most frequently reported class of illicit drugs among adolescents aged 12 or 13 (3.4 and 4.8%, respectively). Among first-time users of inhalants aged 12–15 years of age, the three most commonly used types of inhalants were glue, spray paints, and gasoline. In comparison, nitrous oxide or nitrites were the most common type of inhalants used among past-year inhalant initiates aged 16 or 17. This survey showed no significant male-female differences in lifetime prevalence of inhalant abuse in the 12- to 17-year-old group but confirmed a greater prevalence of inhalant abuse by men than by women in the 18- to 25-year-old group, suggesting that sustained use of inhalants is more common among males.

In India and South Asia, three of the most widely abused inhalants are the contact adhesives, toluenes in paint thinners, and Iodex®, an anti-infective, muscle-stress-relieving balm. Another very common inhalant in India and Asia is Erase-X™, a correction fluid that contains toluene. It has become very common for grade school, high school, and college students to use it because it is easily available in stationery shops in India. Dung sniffing has also been noted as a problem among poor and homeless people in countries such as Thailand and Malaysia. Animal or human dung is placed into a plastic bag or tin and left out in the sun, where it starts to decompose, releasing methane gas, which has narcotic properties. Local police were unsure of what action could be taken, given that dung is not an illegal substance and it would be nearly impossible to restrict supplies of it [16]. Despite these epidemiologic data, inhalants remain among the least-studied groups of abused substances.

Mechanisms of Action

The immediate effects of groups I and II inhalants are similar to the early classic stages of anesthesia [3]. The abuser is initially stimulated and then disinhibited and prone to impulsive behaviors. Speech becomes slurred and gait is uneven. Euphoria, frequently with hallucinations, is followed by drowsiness and sleep, particularly after repeated inhalations. Coma is unusual because as the user becomes drowsy, exposure to the inhalant is terminated before large enough doses are absorbed. The mechanisms of action of these inhalants have not been well defined. It is likely that inhalants act as a mix of *N*-methyl-*D*-aspartic acid antagonist and gamma-aminobutyric acid agonist to produce central nervous system depressant effects [4].

Nitrites have pharmacologic effects that are significantly different from those of other inhalants. Instead of direct central nervous system effects, they primarily cause vasodilation and smooth muscle relaxation [22]. The sensations of floating and increased skin tactility as well as warmth and throbbing occur within 10 s of inhalation and then diminish within 5 min. Abuse of nitrites may result in tachycardia, flushing, blurred vision, headache, lightheadedness, significant hypotension, syncope,

and high enough levels of methemoglobinemia to cause cyanosis and lethargy. Other inhalants are used to alter mood, but nitrites are inhaled to enhance sexual feelings, penile engorgement, and anal sphincter relaxation to intensify sexual experience.

Morbidity and Mortality

Inhalant abuse causes psychosocial as well as organic morbidity. Ongoing inhalant abuse is associated with failure in school, delinquency, and an inability to adjust to societal norms [7]. The chief organic morbidity is central nervous system damage resulting in dementia and cerebellar dysfunction [9, 11, 23]. Typically, there is a loss of cognitive and other higher functions, gait disturbances, and loss of coordination. Imaging studies demonstrate a loss of brain mass [11] and white matter degeneration [9, 23]. Other organic effects are related to specific chemicals found in some but not all products. The strength of the association ranges from definite to likely to speculative. Definite associations include peripheral neuropathy, deafness, and metabolic acidosis. Likely morbidities include embryopathy, neonatal withdrawal, and lung damage. Speculative morbidities include cardiomyopathy, toxic hepatitis, decreased visual acuity, aplastic anemia, and leukemia [27].

Death due to inhalant abuse can occur by several mechanisms, including asphyxia, suffocation, risky behaviors, aspiration, and sudden sniffing death syndrome [21]. Asphyxia is probably of only theoretical concern because it requires the partial pressure of the inhalant to be so high that oxygen is displaced. Suffocation occurs when the mode of use involves inhalation through the nose and mouth from a plastic bag, which may occlude the airway if the user loses consciousness. Disinhibition while under the influence of inhalants may cause dangerous behaviors such as drowning, jumps or falls from heights, hypothermia, and fire-associated deaths (due to the flammability of most inhalants). The risk of death from aspiration is similar to that for alcohol or other depressants and is related to the combination of decreased level of consciousness and loss of protective airway reflexes.

Chronic nitrous oxide abuse causes short-term memory loss and peripheral neuropathy [5]. The peripheral neuropathy results when nitrous oxide inactivates vitamin B12 and mediates a pernicious-anemia-type syndrome, which includes anemia, leukopenia, sensorimotor neuropathy, and posterior/lateral column spinal cord disease. Nitrites are abused mainly for their sensory and sexual effects, and use may promote higher-risk sexual practices, facilitate transmission of sexually transmitted infections, and result in pharmacologic interactions, such as with sildenafil (Viagra®) [22]. Chronic abuse of volatile alkyl nitrites has documented hematologic and immune system effects without associated cognitive deficits [22].

Psychiatric Disorders in Inhalant Users

The Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text Revision, provides two categories of inhalant-related disorders (Table 2) [1]. The first category is inhalant use disorders (inhalant abuse and dependence), which are characterized by a maladaptive pattern of inhalant use. The second category,

Table 2 *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision, inhalant-related disorders

Inhalant use disorders
Inhalant abuse
Inhalant dependence
Inhalant-induced disorders

Inhalant-related disorder not otherwise specified

Modified from American Psychiatric Association [1]
[a]Specify if: with onset during intoxication

inhalant-induced disorders (intoxication delirium, persisting dementia, psychotic disorder, anxiety disorder, and mood disorder), results from the toxic effects of inhalants. Conditions related to abuse of either anesthetic gases or nitrites are not listed under the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision, categories for inhalant use disorders. Instead, these are classified as other (or unknown) substance-related disorders. Some effects and disorders associated with those compounds are briefly discussed elsewhere in this chapter.

Inhalant Abuse and Dependence

The cardinal feature of inhalant abuse is repeated use of inhalants that produces adverse social consequences or physical hazards. Inhalant dependence is characterized by repeated use of inhalants, resulting in combinations of social or physical consequences, loss of control, or development of tolerance or withdrawal symptoms. Despite the absence of an inhalant withdrawal diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision, some people still complain about withdrawal symptoms, including sleep disturbances, irritability, sweating, tachycardia, nausea, shakiness, illusions, delusions, and hallucinations [15].

Two differential diagnoses should be considered [24]. First, polysubstance dependence is common in adolescents. Abuse of or dependence upon other drugs can be traced through an individual's history, physical findings, and drug screens. Second, impulsive behaviors during chronic inhalant use might mimic or be comorbid with conduct disorder or antisocial personality disorder. Conduct or antisocial behaviors that appear before the onset of inhalant abuse or in periods of abstinence suggest the presence of these disorders.

No controlled studies guide the treatment of inhalant use disorder. Treatment usually takes a long time and involves enlisting the support of the person's family; changing the friendship network if the individual "uses" with others; teaching coping skills, and helping the individual increase his or her self-esteem.

In research with animal models of inhalant abuse, *N*-methyl-*D*-aspartic acid, gamma-aminobutyric acid, glycine, nicotine, and serotonin-3 receptors appear to be important targets of action for several abused solvents. Emerging evidence suggests that other receptor subtypes and nerve membrane ion channels are also involved [4]. Evidence postulates that lamotrigine (Lamictal®), a phenyltriazine anticonvulsant, might be effective for inhalant dependence because it modulates release of the excitatory amino acid, glutamic acid, blocks serotonin-3 receptors, and inhibits dopamine uptake [25]. Buspirone (BuSpar®) and risperidone (Risperdal®) also have been reported to be effective for treating inhalant use disorder [19, 20]. The efficacy of these agents in inhalant use disorder requires more investigation.

In addition to inhalant use disorder, most inhalant users have comorbid conduct disorder, attention-deficit hyperactivity disorder, major depressive disorder, dysthymic disorder, alcohol dependence, and psychosis [17, 24]. Psychiatrists often prescribe bupropion (Wellbutrin®) or atomoxetine (Strattera®) for attention-deficit hyperactivity disorder, antidepressants for depression, naltrexone or acamprosate (Campral®) for comorbid alcohol dependence, and antipsychotics for psychotic symptoms [24]. In addition to psychiatric management, appropriate medical care is also required for the disorder's medical sequelae [18].

Inhalant Intoxication and Inhalant Intoxication Delirium

When too much of an inhalant is taken, the user becomes intoxicated. According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision, the signs

of inhalant intoxication include: dizziness, nystagmus, incoordination, slurred speech, unsteady gait, lethargy, depressed reflexes, psychomotor retardation, tremor, generalized muscle weakness, blurred vision, diplopia, euphoria, stupor, or coma. Inhalant intoxication delirium is a state in which a person gets extremely intoxicated, with a disturbance of consciousness and a change in cognition.

Differentiation of the diagnosis of inhalant intoxication from that of other types of substance intoxication depends on an individual's history and the evidence of inhalant use such as perioral rash and the presence of inhalant odor and residue. Polysubstance dependence is common among inhalant users. Concomitant intoxication with other substances may be assessed by history and toxicologic examinations [24]. Intravenous injection of dextrose and naloxone (Narcan®) will help rule out coma due to diabetes and coma of narcotic origin, respectively [18]. If the mood disturbance, anxiety, or psychosis appears prominently during inhalant intoxication and is severe enough to warrant clinical attention, the diagnosis should be inhalant-induced mood, anxiety, or psychotic disorder, respectively. If delirium develops in the course of inhalant intoxication, the diagnosis is inhalant intoxication delirium rather than inhalant intoxication [8].

Inhalants are rapidly metabolized and excreted. Inhalant intoxication usually lasts a few hours or less unless there are medical complications. Inhalant intoxication usually resolves spontaneously and requires no medical attention [10]. However, medical complications such as cardiac arrhythmias, trauma, bronchospasm, or laryngospasm need treatment, and clinicians should note the client's vital signs and level of consciousness [18]. The treatment of inhalant intoxication delirium is similar to that used for inhalant intoxication, but the variations of levels of consciousness require special attention to the individual's safety. If the delirium results in severe behavioral disturbances or cognition changes, short-term treatment with a dopamine receptor antagonist may be helpful [13]. Sedative medications, including benzodiazepines, are contraindicated because they may enhance the inhalant's depression of the central nervous system [4].

Inhalant-Induced Persisting Dementia

Inhalants are commonly used both in industry and by consumers as fat solvents. Thus, because the brain is a lipid-rich organ, chronic solvent abuse is neurotoxic and can cause dementia [9, 11, 23]. Inhalant-induced dementia is typically associated with memory impairment and at least one of the following: aphasia, apraxia, agnosia, and executive function disturbance. These symptoms can be associated with delirium, which can persist beyond the usual duration of inhalant intoxication or withdrawal [1].

There are, typically, two other differential diagnoses that should be considered among individuals suspected of having inhalant-induced persisting dementia. First, many inhalant-dependent individuals are concomitantly dependent on alcohol or other sedatives that can also produce dementia. Second, histories of head injury are common among those who are dependent on inhalants [18, 24]. Thus, even among individuals with a documented course of inhalant-induced persisting dementia, other causes of dementia also need to be considered in the differential diagnosis.

Few inhalant-dependent individuals have been studied prospectively. Despite some reports of improvement after abstention from inhalants, most neurocognitive deficits persist and worsen [29]. Additionally, as neurocognitive deficits progress to dementia, inhalant-dependent individuals gradually lose the cognitive capacity to avoid relapses, and each relapse may accelerate brain degeneration.

No controlled studies have been performed to guide the treatment of individuals with inhalant-induced persisting dementia. Correcting the reversible—and slowing the progression of irreversible—factors of inhalant-induced dementia are the primary approach to treatment. Individuals may require extensive support within their families or in foster or domiciliary care.

Inhalant-Induced Psychotic Disorder

Clinical evidence suggests that tetraethyl lead can provoke psychotic symptoms [6]. The cardinal features of inhalant-induced psychotic disorder are prominent delusions or hallucinations (mostly visual) developing during or within 1 month of inhalant intoxication or withdrawal. These psychotic symptoms can occur during intoxication, delirium, and even some time after the inhalant has been withdrawn, and can complicate a pre-existing psychotic disorder [1].

The course of inhalant-induced psychotic disorder is typically brief, lasting a few hours to days beyond the intoxication. Treatment of medical complications, together with conservative management of inhalant intoxication, is appropriate [18]. Agitation, confusion, and psychosis may respond to the administration of antipsychotics such as haloperidol (Haldol®) [13].

A thorough search of the literature revealed only one controlled study that investigated therapy among people with inhalant-induced psychotic disorder [13]. In this study, 40 males admitted to an acute psychiatric unit for treatment of inhalant-induced psychotic disorder were assigned to receive 5 weeks of treatment with carbamazepine (Tegretol®) or haloperidol, supplied in identical-appearing capsules. Individuals in both treatment groups improved significantly over time, but adverse effects were significantly more common and more severe in the haloperidol group. Carbamazepine appears to have comparable efficacy but fewer adverse effects than haloperidol for the treatment of inhalant-induced psychotic disorder. Nevertheless, because there was no placebo group in this study, these data cannot establish that medication was better than no medication.

Inhalant-Induced Anxiety Disorder

The essential features of inhalant-induced anxiety disorder are prominent anxiety, panic attacks, obsession, or compulsion developing during or within 1 month of inhalant intoxication or withdrawal. Inhalant use that is etiologically related to the disturbance causes clinically significant distress or impairment in social or occupational life, or disruptions in other important areas of functioning. The anxiety symptoms are not better accounted for by an anxiety disorder that is not inhalant induced, and the anxiety does not occur exclusively during the course of a delirium [1].

The course and treatment of inhalant-induced anxiety disorders are like those of inhalant intoxication. Sedative medications, including benzodiazepines, are contraindicated because they may enhance the inhalant's depressant effects on the central nervous system, thereby precipitating inhalant-induced anxiety disorder [4].

Inhalant-Induced Mood Disorder

The essential features of inhalant-induced mood disorder include prominent and persistent disturbance in mood with: (1) depressed mood or markedly diminished interest or pleasure in daily life and activities, and (2) elevated, expansive, or irritable mood developing during or within 1 month of substance intoxication or withdrawal. The depressed mood is not better accounted for by a mood disorder that is not inhalant induced, and the mood disturbance does not occur exclusively during the course of an episode of delirium [1].

The course and treatment of inhalant-induced mood disorders are like those of inhalant intoxication. The course is brief, lasting a few hours to days beyond the intoxication. Although antidepressants or antimanic medications are seldom appropriate for these relatively brief disorders, the risk of suicide requires a carefully monitored psychosocial intervention. Suicidality has a very strong relationship with inhalant use disorder [12]. Inhalant use disorders in incarcerated youth, as well as inhalant use without abuse or dependence (particularly in girls), may signal elevated suicide risk. Suicide risk assessments, therefore, should include questions about inhalant use.

Prevention and Management Considerations

As with other types of substance abuse, the most effective way to curtail use is through prevention [2]. There are many potentially preventive strategies; however, most of these have proved to be impractical. Restricting the availability of some of these products merely results in a shift to the use of other products. Limiting the availability of inhalants is impractical because they comprise a large group of products that are universally available and have legitimate uses. Reformulating a product by replacing the hydrocarbons with other chemicals is not practical because this usually results in a less effective product. Adding a noxious chemical to the product to prevent misuse also is ineffective because there are multiple products that would require such adulterants. Warning labels on packages may be counterproductive because they allow children to identify sniffable substances more easily. Criminalization of the user is not a meaningful deterrent for the prevention of inhalant abuse, either for the experienced user or for the person who is experimenting for the first time. Criminalization of the vendor is ineffective, again because of the issue of dealing with multiple products that have legitimate uses.

Education is considered to be the most effective preventive strategy [2]. Progressive, school-based inhalant abuse prevention courses, taught beginning in kindergarten, with developmentally appropriate modules taught throughout elementary school, are seen as the most efficient strategy and should be implemented—particularly in areas where inhalant abuse is prevalent. Offering alternative activities in recreational facilities, for example, and promoting traditional cultural values encourage positive lifestyles, thereby reducing the risk for inhalant abuse and other destructive behaviors. Prevention workers are especially effective when they are from the local community. However, they must be appropriately trained and have access to ongoing support.

Psychiatrists are encouraged to be aware that inhalant abuse can occur in all client populations, including their own. They need to be knowledgeable about the epidemiology of inhalant abuse, particularly regarding local and regional trends, and about the serious health consequences of inhalant abuse. In particular, they need to know about unique clinical features such as central nervous system damage and sudden sniffing death syndrome. Finally, they need to help educate children, adolescents, parents, teachers, media representatives, and vendors of volatile substances about inhalant abuse prevention and the health risks of inhalant use. Psychiatrists can serve as a valuable community resource regarding inhalant use awareness, prevention, detection, and management [27].

Treating inhalant users is difficult because of the many pharmacologic, clinical, and demographic factors that make this type of substance abuse unique. Treatment strategies are still being developed, and additional research is needed to identify effective strategies to help these individuals.

Introduction

Anabolic-androgenic steroids refer to the male hormone, testosterone, and many of its natural and synthetic derivatives. All anabolic-androgenic steroids have androgenic (masculizing) and body-building (anabolic) effects, despite efforts to develop compounds with only anabolic effects; but some are relatively more anabolic or androgenic than others. Oxandrolone, for example, has greater anabolic activity and less androgenic activity than testosterone [67]. All anabolic-androgenic steroids also share a cholesterol-like and -derived chemical structure in common with other classes of steroid compounds, such as corticosteroids, mineralocorticoids, and estrogens. The current development of synthetic non-steroidal selective androgen receptor modulators has recently produced anabolic-androgenic drugs that are not steroids [30, 84], but little is known about the abuse potential of these pre-marketed substances.

United States Food and Drug Administration-approved medical uses of anabolic-androgenic steroids include male hypogonadism (androgen deficiency [6]) hereditary angioedema (a dermatological disorder), treatment of weight loss associated with AIDS, burns, and other catabolic states [67], and relatively rare types of anemias including Fanconi's and those related to bone marrow suppression (aplastic anemia) or kidney failure. Other uses of anabolic-androgenic steroids, including experimental ones, have included male contraception

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_25,

[60], post-menopausal hormonal therapy and treatment of depression [43], sexual disorders [87], osteoporosis [96], and metastatic breast cancer. For many of these indications, except male hypogonadism and hereditary angioedema, anabolic-androgenic steroids are second or third-line choices. For example, erythropoietin has largely replaced anabolic-androgenic steroids to treat specific types of anemia.

Anabolic-androgenic steroids are used illicitly to facilitate muscle growth and strength, which many consider to improve athletic performance or aesthetic appearance. Thus, anabolic-androgenic steroids are sometimes referred to as performance-enhancing drugs (also known as ergogenic drugs), which include human growth hormone, erythropoietin, stimulants, clenbuterol, and various nutritional supplements, the latter of which are popular in adolescents [15, 37]. Within the international sports community, ergogenic aids are commonly referred to as "doping agents" and subject to detection by the World Anti-Doping Agency [5, 86]. It is now accepted that anabolic-androgenic steroids can increase muscle size and strength when combined with proper exercise and nutrition [50], but that does not necessarily translate into enhanced performance for any given sport.

Anabolic-androgenic steroids have both similarities to and differences from so-called "classical" addictive drugs, such as alcohol, cocaine, nicotine, and opioids. A major difference is that anabolic-androgenic steroids are not initially taken for their psychoactive or euphorigenic effects. Anabolic-androgenic steroids users are much more generally focused on their bodies than their minds. Subgroups of anabolic-androgenic steroids users may even avoid "classical" addictive drugs [90], because of their damaging effects to the body (e.g., cigarettes). Unfortunately, an emphasis on the myoactive (muscle-active) effects of anabolic-androgenic steroids has in part contributed to an underestimation of their psychoactive effects. Nevertheless, from the time that testosterone was first synthesized in 1935, the medical world quickly became interested in its potential to improve mood [101], and the interest continues to the present day [43]. Recent advances in the neurobiology of anabolic-androgenic steroids and the discovery of neurosteroids have further increased overall attention to the psychoactive properties of anabolic-androgenic steroids. There is now general consensus that anabolic-androgenic steroids have important psychiatric effects [50, 86], including the potential for addiction [103]. As Wood [102] wrote, "it is time to cease pretending that the effects of anabolic-androgenic steroids stop at the neck".

Epidemiology

The use of anabolic-androgenic steroids to enhance athletic performance dates back at least to the early 1950s. At the 1956 World Games, Americans discovered that Soviet athletes were using testosterone, and soon began adopting the practice for their own athletes. Up until the late 1970s, use of these drugs was largely confined to, and endemic in, elite athletes, including competitive college-level and professional athletes. By the early 1980s, the drugs had clearly filtered down to high school athletes. As the decade progressed, use had spread to all classes of athletes as well as to non-athletes who simply wanted to enhance their physical appearance. A now classic epidemiological study published in 1988, revealed that 6.6% of male high school seniors in the United States reported using anabolic-androgenic steroids, and over two-thirds had started prior to age 16 years [13]. By 1991, over 1 million Americans had tried anabolic-androgenic steroids [105].

The annual University of Michigan Monitoring the Future study has tracked anabolic-androgenic steroid use in 8th, 10th, and 12th graders since 1989 [42]. In 2006, lifetime use among 8th and 12th graders, respectively, was 1.6 and 2.7% (2.2 and 4.3% for males and 1.1 and 1.2% for females, respectively). Among college students, lifetime non-medical use of anabolic-androgenic steroids was generally stable from 1993 to 2001 at <1%, although past-year use by men increased from 0.4 to 0.9%

[62]. Thus, use appears to decline from high school to college, perhaps due to a selection effect.

Overall, young men who train extensively by lifting weights for athletic or aesthetic purposes are at highest risk to use anabolic-androgenic steroids [3]. Most studies also support a correlation with alcohol and other drug abuse, with some exceptions (e.g., Striegel et al. [90]). Other studies have found that dissatisfaction with body image is associated with anabolic-androgenic steroid use [11, 47]. When severe, dissatisfaction with one's physique may meet diagnostic criteria for body dysmorphic disorder [76]. Among anabolic-androgenic steroid users, a subtype of body dysmorphic disorder has been labeled muscle dysmorphia [14]. Men who view their size and muscularity as inadequate no matter how big or muscular will usually fit *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition criteria. This syndrome has been compared to eating disorders—especially among women who believe they are too fat no matter how much weight they lose—thus acquiring the name *reverse anorexia nervosa* or *bigorexia* [19, 44, 65]. Muscle dysmorphia also has features of obsessive-compulsive disorder [17].

Pharmacology

Chemical Structure

Derived from cholesterol, anabolic-androgenic steroids have a four-ring structure with 19 carbon atoms. Modifications at the C-17 and other carbon atoms are responsible for much of the variety among synthetic anabolic-androgenic steroids [50]. Alkylation at the C-17 atom in its alpha position results in most of the oral forms of anabolic-androgenic steroids, because this structural modification confers resistance to first-pass liver metabolism. The C-17-alkyl-anabolic-androgenic steroids may also be more likely to cause liver toxicity and cholesterol abnormalities. Esterification at the C-17 atom in its beta position results in the commonly injected testosterone esters (testosterone cypionate, testosterone enanthate, and testosterone propionate). Because testosterone is rapidly metabolized by the liver, the testosterone esters were designed as depot medications, and are released slowly from the muscles into which they are injected.

Pharmacokinetics

Most oral forms of anabolic-androgenic steroids are relatively short-acting with half-lives of approximately 24 h, whereas injected anabolic-androgenic steroids are relatively long-acting with half-lives of several days to weeks. Thus, testosterone esters when injected for medically-indicated replacement therapy are usually administered every 2–4 weeks; whereas oral forms are typically administered daily. Gel forms and transdermal forms of testosterone are applied topically to, and absorbed by, the skin for replacement therapy. Their pharmacokinetics also requires daily administration. A buccal form of testosterone is available that is applied to the upper gingiva and requires dosing every 12 h. The topical forms of testosterone are not typically used illicitly, however, because they are difficult to administer in the supraphysiological doses preferred by illicit users.

Testosterone can be viewed as a "prohormone" for both dihydrotestosterone [23] and estradiol. When testosterone is aromatized by the enzyme, aromatase, estradiol is formed and acts on estrogen receptors. When reduced by the enzyme 5α-reductase, dihydrotestosterone is formed and acts on androgen receptors. Testosterone also acts directly on androgen receptors, but dihydrotestosterone is about 10 times more potent. Different organs are genetically programmed to express one enzyme or the other preferentially depending on its function. Thus, 5α-reductase predominates in the testes where spermatogenesis occurs, and aromatase predominates in the female breast causing enlargement. Similarly, preferential gene expression may drive the synthesis of either

estrogen or androgen receptors depending on the tissue site and function of the organ.

Urine Testing

Testing for anabolic-androgenic steroids in the urine, although critical for athletic competitions at the elite level, is rarely performed in routine clinical practice, including addiction treatment settings. One reason is that anabolic-androgenic steroid users are not frequently seen in addiction treatment settings. Another reason is that testing is expensive and requires specialized laboratories that can perform mass spectrometry/gas chromatography across a large number of different anabolic-androgenic steroids (Table 1). The detection of anabolic-androgenic steroids in urine has recently been reviewed [81].

Patterns of Illicit Use

Illicit use of anabolic-androgenic steroids is typically characterized by: (1) combining several anabolic-androgenic steroids, including injection and oral preparations together ("stacking"); (2) increasing doses of anabolic-androgenic steroids to a peak regimen and then tapering doses over time ("stacking the pyramid"); (3) alternating periods of use with periods of non-use ("cycling"); (4) using a combination of human and veterinary preparations, and (5) adhering to a regulated training schedule and dietary regimen. Other drugs are commonly taken together with anabolic-androgenic steroids to enhance physical performance [5], to treat or prevent unwanted side effects of anabolic-androgenic steroids (e.g., estrogen blockers), and to mask detection of anabolic-androgenic steroids in the urine (e.g., probenicid). Many surveys suggest that anabolic-androgenic steroid users are more likely than non-users to abuse other addictive drugs. In this regard, it is of interest that anabolic-androgenic steroids can increase sensitivity to alcohol [40], amphetamine [7, 88], and opioids [16]. Arvary and Pope [1] reported that anabolic-androgenic steroids may serve as gateway drugs to opioid dependence. On the other hand, abuse of illicit drugs may be less likely among by elite athletes and some bodybuilders, because they do not want to harm their bodies with drugs that could degrade their performance or appearance [90].

Anabolic-androgenic steroids are readily available through social networks associated with weightlifting gyms [61]. While classified as Schedule III controlled substances in the Unites States, anabolic-androgenic steroids have recently been available without a prescription in some other countries. Among such countries has been Mexico, which has resulted in smuggling anabolic-androgenic steroids across the border.

Table 1 Representative anabolic-androgenic steroids used by weightlifters and bodybuilders

Injected testosterone esters
Testosterone cypionate
Testosterone propionate (Testoviron)
Testosterone enanthate (Delatestryl)
Testoseterone ester mixture (Sustanon)
Injected veterinary forms
Boldenone undecylenate (Equipoise)
Stanozolol (Winstrol-V)
Trenbolone acetate (Finajet, Finaplex)
Other injected forms
Nandrolone decanoate (Deca-Durabolin)
Nandrolone phenpropionate (Durabolin)
Oral forms
Methandostenolone (Dianabol), also known as methandienone
Methyltestosterone (Android, Testred)
Oxandrolone (Anavar)
Oxymethalone (Anadrol)
Stanozolol (Winstrol)

Adverse Medical Effects
