another serotonin reuptake inhibitor, precipitated withdrawal in animals treated with a similar $\triangle^9$-tetrahydrocannabinol dosing regimen [128]. While clomipramine precipitated withdrawal symptoms in rats that received acute placebo, there were significantly fewer withdrawal symptoms observed in rats that received the acute dose of $\triangle^9$-tetrahydrocannabinol. These findings, together with data from the report showing that fluoxetine also induces behavioral signs of withdrawal in rats chronically administered $\triangle^9$-tetrahydrocannabinol [128], suggest that increased serotonergic activity following abrupt discontinuation of repeated cannabinoid agonist treatment may be an important component in the behavioral expression of cannabinoid withdrawal. More recently, however, Touriño et al [120] reported that the serotonin agonist 3,4-methylenedioxymethamphetamine dose-dependently attenuated rimonabant-precipitated $\triangle^9$-tetrahydrocannabinol withdrawal symptoms in mice. The reasons for these apparent incongruent findings are unclear, but might be related to the fact the tested medications have multiple sites of action. Some of these actions may overlap, while others may not. It is also important to note that there have been no published reports of clomipramine- or fluoxetine-precipitated cannabis withdrawal in humans, so it is not known whether precipitated withdrawal has not occurred. Thus, the impact of increased serotonin activity on cannabinoid-related withdrawal is unclear.

Lichtman and colleagues demonstrated that $\triangle^9$-tetrahydrocannabinol as well as clonidine, an α_2-receptor agonist, lessened rimonabant-precipitated withdrawal symptoms in mice [83]. In that study, mice were administered two daily subcutaneous injections of either $\triangle^9$-tetrahydrocannabinol or vehicle for two days; on the third day, animals were given one injection of their respective treatment, followed four hours later with an intraperitoneal injection of rimonabant or vehicle. Five minutes after the rimonabant challenge dose, mice were administered either an intravenous injection of $\triangle^9$-tetrahydrocannabinol (or placebo) or an intraperitoneal injection of clonidine (or placebo). Both $\triangle^9$-tetrahydrocannabinol and clonidine reversed rimonabant-precipitated paw tremors, and this effect was independent of any generalized effects on movement. While the finding that $\triangle^9$-tetrahydrocannabinol reversed precipitated cannabinoid withdrawal is consistent with previous data [127], these were the first published data to demonstrate that an α_2-receptor agonist was effective in alleviating symptoms of cannabinoid withdrawal. Clonidine has been shown to attenuate some withdrawal symptoms associated with alcohol (e.g., [7, 97]) and opioid dependence (e.g., [40, 45, 121]) in humans and laboratory animals, suggesting some features of withdrawal syndromes associated with drugs of abuse may share common underlying pathophysiological mechanisms. For instance, it is possible that withdrawal symptoms, at least in part, may be mediated by noradrenergic hyperactivity. This view is consistent with the observation that many humans experiencing withdrawal from commonly abused drugs, including alcohol, opioids, and cannabis, often report increased anxiety. One exception to this speculation, however, is the efficacy of bupropion in the treatment of nicotine dependence (see below).

Another interesting line of research aimed at understanding mechanisms underlying cannabinoid withdrawal is the examination of the role of the arachidonic acid cascade. Anggadiredja et al. [1] rendered mice $\triangle^9$-tetrahydrocannabinol-dependent by administering two daily intraperitoneal injections of $\triangle^9$-tetrahydrocannabinol for five days. On the sixth day, mice received one injection of $\triangle^9$-tetrahydrocannabinol, followed four hours later with an intraperitoneal injection of rimonabant to precipitate withdrawal. Mice in an additional treatment group were given an intra-ventricular injection of prostaglandin E_2, an end-product of the arachidonic acid cascade, immediately before the rimonabant challenge dose. Prostaglandin E_2 dose-dependently attenuated rimonabant-precipitated withdrawal symptoms including forepaw tremors, forepaw licking, and facial preening. While the exact mechanism(s) through which prostaglandin E_2

lessened withdrawal symptoms remains to be elucidated, it has been proposed that prostaglandin E_2 reduced symptoms of withdrawal via noradrenergic mechanisms [1].

Convergent evidence supports this hypothesis. In an in vitro study of the effects of prostaglandin E_2 on electrically-evoked tritiated norepinephrine overflow, Exner and Schlicker [37] found that prostaglandin E_2 inhibited the electrically-evoked norepinephrine tritium overflow from mouse and rat brain cortex slices. Data from an earlier, similarly designed study [66] were consistent with those obtained by Exner and Schlicker [37]. In addition, as mentioned above, clonidine, administered 5 min after rimonabant in $\triangle^9$-tetrahydrocannabinol-dependent mice, reversed the precipitated withdrawal [83], providing further evidence for the role of noradrenergic processes in cannabinoid withdrawal.

The effects of lithium, a commonly used mood-stabilizing medication for the treatment of bipolar disorder, have also been assessed on cannabinoid withdrawal symptoms. Examination of lithium was based on the clinical observation that increased irritability, anxiety and depression often accompanies cannabis withdrawal; lithium effectively decreases these symptoms. Cui et al. [31] administered two daily injections of HU210, a synthetic cannabinoid agonist, to rats on five days; on the sixth day, animals were given one injection of their respective treatment, followed four hours later with an injection of AM281, a cannabinoid antagonist. The effects of lithium were examined by administering varying doses 15 min before the AM281 challenge dose. Lithium dose-dependently prevented symptoms of cannabinoid withdrawal. The investigators speculated that their findings were mediated via lithium-enhancing effects on central nervous system oxytocin activity and were not related to lithium-associated mood stabilizing effects. This hypothesis was based on the following observations: (1) oxytocin administration mimicked the effects of lithium on cannabinoid withdrawal; (2) pretreatment with an oxytocin receptor antagonist blocked lithium-related effects on cannabinoid withdrawal; (3) pretreatment with an oxytocin receptor antagonist alone enhanced AM281-precipitated cannabinoid withdrawal [31]; and (4) divalproex, another mood stabilizer used in the treatment of mania, failed to attenuate AM281-precipitated cannabinoid withdrawal (unpublished observations from the same group of researchers). The fact that animals exhibit a stress-like response (e.g., increased grooming behaviors and increased release of corticotropin-releasing hormone) during cannabinoid withdrawal, however, suggests that the mechanisms involved in the stress response may also play a role in the cannabinoid withdrawal syndrome. Given that increased oxytocinergic transmission markedly diminishes the stress response (e.g., [23, 95, 96]), it seems plausible that oxytocin plays an integral role in lithium-related effects on cannabinoid withdrawal symptoms. Nevertheless, the exact mechanism responsible for lithium-associated ameliorating effects on cannabinoid withdrawal is an issue that can only be resolved with further research.

One important factor that might limit the generality of the above results is that cannabinoid drugs were administered to animals non-contingently; that is, they were not self-administered but were administered by the experimenter. Data from studies comparing non-contingent and contingent drug administration indicate that substantial differences (e.g., mortality rate and neurochemical) exist that are related to context of drug presentation [36, 63]. Future studies should assess the utility of medications to alleviate cannabinoid withdrawal symptoms in animals undergoing abrupt discontinuation of self-administered cannabinoids.

Despite this potential limitation, the above results suggest that the administration of oral $\triangle^9$-tetrahydrocannabinol might be a useful strategy to treat cannabis withdrawal. Additionally, the data showing that clonidine mitigates cannabinoid withdrawal are encouraging and suggest that pharmacological agents that decrease noradrenergic output are excellent candidate medications to test in humans undergoing cannabis withdrawal. Although side effects, such as

hypotension and sedation, associated with clonidine may limit its clinical use for cannabis dependence, other α_2-receptor agonists such as lofexidine, which has a more favorable side effect profile, may hold promise in treating cannabis withdrawal. Indeed, this strategy was investigated in a recent study employing human marijuana abusers (see below). Data indicating that lithium, as well as oxytocin, prevented cannabinoid withdrawal provide potentially novel treatment strategies, although the clinical use of systemic oxytocin for anti-cannabinoid withdrawal effects might be limited because high doses may be required, which increase the likelihood of unpleasant peripheral side effects. Because oxytocin has been shown to produce similar effects as benzodiazepines [123], an alternative approach might be to evaluate the effects of a benzodiazepine on cannabinoid withdrawal symptoms. Clinicians however, may be wary about the potential for abuse associated with the use of some benzodiazepines, e.g., alprazolam, particularly in sedative abusing populations [131, 132], thus others such as clonazepam or oxazepam may be more likely candidates. Finally, the data regarding the role of serotonergic activity in cannabinoid withdrawal are less clear: findings from two studies indicate that medications that augment serotonin activity may precipitate or worsen withdrawal, while results from another suggest that increased serotonin activity dampens withdrawal.

Studies of Human Research Participants

Although the majority of cannabis users may not experience symptoms of withdrawal, data from a variety of human laboratory and clinical studies demonstrate that an abstinence syndrome can be observed following abrupt cessation of heavy, near-daily use of smoked cannabis [17, 18, 50, 59, 81, 90] or oral $\triangle^9$-tetrahydrocannabinol [49, 71, 72]. Cannabinoid withdrawal syndrome in humans may include a variety of symptoms including increased negative mood states (e.g., increased anxiety, restlessness, depression, and irritability), disrupted sleep, decreased food intake, and in some cases, aggressive behavior [52, 80]. These symptoms have been reported to begin 1 day after cannabinoid cessation, peak effects are observed on days 2–6, and most effects persist from 4 to 14 days, depending on an individual's level of cannabis dependence [18]. Because cannabis withdrawal may be one factor maintaining continued cannabis use (i.e., frequent marijuana smokers may continue their use not only for marijuana-related intoxicating effects, but also to avoid undergoing withdrawal symptoms), medications that would alleviate cannabis withdrawal symptoms could be useful.

Table 2 summarizes the studies that have employed human research participants to evaluate the potential of medications to alleviate marijuana withdrawal symptoms. As can be seen, the majority of the published research in this area has been conducted in our laboratory. Our group at Columbia University/New York State Psychiatric Institute has conducted a series of carefully-controlled, within-participant design, residential laboratory studies. During these studies non-treatment seekers, frequent marijuana smokers smoked active marijuana cigarettes on several consecutive days, five times per day, followed by several days of marijuana abstinence. During abstinence, placebo marijuana cigarettes were smoked and the effectiveness of potential treatment medications to attenuate marijuana withdrawal symptoms was examined. The first medication tested in these studies was bupropion (0, 300 mg/d), a Food and Drug Administration-approved tobacco smoking cessation aid and antidepressant [51]. The rationale for the use of this medication was related to the observation that bupropion had been shown to maintain tobacco smoking abstinence, in part, because of its ability to decrease negative mood symptoms (e.g., increased anxiety, depression, and irritability) associated with nicotine withdrawal. Given that similar negative mood symptoms are also associated with marijuana withdrawal, bupropion was expected to improve symptoms of

Table 2 Published studies that have employed human research participants to evaluate medication effects on marijuana withdrawal symptoms

Investigators	Medication (dose, p.o.)	Outcome
Haney et al. [51]	Bupropion (0, 300 mg/d)	Bupropion worsened symptoms during withdrawal.
Haney et al. [52]	Nefazodone (0, 50 mg/d)	Nefazodone decreased some withdrawal symptoms, but it had no effect on most symptoms.
Haney et al. [54]	Divalproex (0, 1500 mg/d)	Divalproex worsened mood and psychomotor performance during marijuana consumption and during marijuana withdrawal.
Haney et al. [54]	Δ^9-THC (0, 50 mg/d)	Δ^9-THC reduced marijuana withdrawal symptoms and reversed the withdrawal-associated psychomotor performance decrements and weight loss associated with marijuana withdrawal.
Budney et al. [21]	Δ^9-THC (0, 30, 90 mg/d)	Δ^9-THC dose-dependently attenuated marijuana withdrawal symptoms.

Δ^9-*THC* Δ^9-tetrahydrocannabinol, *p.o.* by mouth

marijuana withdrawal. The data, however, indicated otherwise: bupropion worsened several ratings of mood, including irritability, restlessness and depression, and self-reported sleep quality. The mechanism(s) mediating bupropion-worsening effects on marijuana withdrawal is unclear, but the mechanism of action most commonly attributed to bupropion is inhibition of dopamine reuptake and, to a lesser extent, norepinephrine reuptake inhibition ([6]; see also [106]). Thus, bupropion-associated effects on marijuana withdrawal symptoms could be related to enhanced norepinephrine activity. This suggestion is consistent with the above-cited data showing that clonidine, a medication that decreases noradrenergic activity, lessened precipitated Δ^9-tetrahydrocannabinol withdrawal symptoms [83] as well as the withdrawal symptoms associated with alcohol and opioid dependence (for review, see [58]).

Another study conducted by our team investigated the effects of nefazodone (0, 450 mg/d) on symptoms of marijuana withdrawal [52]. Nefazodone, an atypical antidepressant, is thought to exert its major therapeutic effects via antagonistic actions at the serotonin-2a receptor [32, 118], although it has also been shown to produce relatively weak inhibition of norepinephrine and serotonin uptake sites in vitro. A major reason for investigating nefazodone-related effects on marijuana withdrawal symptoms was that it had been demonstrated to treat effectively depression, agitation, and anxiety (symptoms also associated with marijuana withdrawal) in clinical populations [39, 133]. Data from the study by Haney et al. [52] revealed that nefazodone decreased a few symptoms associated with marijuana withdrawal (i.e., ratings of "Anxious" and "Muscle Pain"), but it had no effect on most symptoms (e.g., ratings of "Irritable" and "Trouble Sleeping"). Because nefazodone did relieve some discomfort associated with marijuana withdrawal without worsening other symptoms and because only one active dose was tested, further study of this agent, using a broader dosing range, in the treatment of marijuana withdrawal could be warranted but may not occur because of the "Black box" warning (i.e., the highlighted portion of the package insert) about hepatoxicity.

Divalproex (0, 1500 mg/d), approved for the treatment of epilepsy, mood disorders, and migraine headaches, was evaluated for effectiveness in decreasing marijuana withdrawal symptoms [54]. Divalproex's precise neurochemical mechanism of action remains unknown, although some divalproex-related therapeutic effects have been attributed to its ability to dampen sustained repetitive neuronal firing via modulation of Na^+ channel activity [84]. Other therapeutic effects might be related to its ability to increase central nervous system gamma-aminobutyric acid activity [24, 99]. The rationale for testing the effects of divalproex on marijuana

withdrawal symptoms was not based on a proposed neurochemical mechanism of action, but instead was based on clinical evidence indicating that the medication had been used successfully to treat some symptoms commonly associated with marijuana withdrawal (e.g., irritability and mood lability [35, 44]). Unfortunately, divalproex did not reduce marijuana withdrawal symptoms. In fact, many withdrawal symptoms, including anxiety and irritability, were significantly increased when participants were maintained on divalproex compared to when they were maintained on placebo [54]. Divalproex not only worsened marijuana withdrawal-associated mood, but it also produced psychomotor performance disruptions during marijuana consumption and during marijuana abstinence. The results are in agreement with data from the aforementioned unpublished study using rodents, which showed that divalproex had no effect on AM281-precipitated withdrawal. In short, these data do not support the use of divalproex as a marijuana treatment medication.

Two other groups of researchers have examined lithium carbonate, another mood stabilizer, for effectiveness in decreasing cannabis withdrawal symptoms. The rationale for testing lithium carbonate was based on encouraging data collected using laboratory animals in which the medication decreased cannabinoid-associated withdrawal symptoms [31]. Bowen et al. [13] and Winstock et al. [130] conducted open-label trials of the effects of lithium carbonate (500–900 mg/d) on cannabis withdrawal. In general, the researchers reported that the medication reduced withdrawal severity for most study participants, but both studies contained important limitations that decrease the generality of the findings. For example, the non-controlled nature of these experiments may have increased expectancy effects, i.e., the researchers' and the participants' knowledge that participants were receiving an active treatment medication influenced participants reported cannabis withdrawal intensity

Another strategy tested for efficacy in attenuating human marijuana withdrawal is the administration of oral $\triangle^9$-tetrahydrocannabinol. In a recently reported study, Haney and coworkers [54] investigated the effects of oral $\triangle^9$-tetrahydrocannabinol (0, 10 mg), administered five times per day, on marijuana withdrawal symptoms. The primary reason for evaluating the effects of oral $\triangle^9$-tetrahydrocannabinol on marijuana withdrawal was based on the idea of substituting a longer-acting pharmacologically equivalent drug for the abused substance, stabilizing the individual on that drug, and then gradually withdrawing the substituted drug. In this way, the likelihood of precipitating abstinence symptoms is decreased. Nicotine replacement therapies have been used extensively in this capacity for the treatment of tobacco-related withdrawal, as has methadone for opioid withdrawal. Haney et al. [54] found that oral $\triangle^9$-tetrahydrocannabinol markedly reduced symptoms associated with marijuana abstinence including self-reported ratings of marijuana craving, anxiety, misery, and sleep disturbance. The medication also reversed the withdrawal-associated psychomotor performance decrements as well as the anorexia and weight loss associated with marijuana withdrawal. It is important to note, too, that these effects occurred at an oral $\triangle^9$-tetrahydrocannabinol dose indistinguishable from placebo (i.e., like placebo, active $\triangle^9$-tetrahydrocannabinol produced no apparent subjective effects), highlighting the pharmacological specificity of marijuana withdrawal. Budney and colleagues [21] replicated and extended these findings by demonstrating that oral $\triangle^9$-tetrahydrocannabinol (30 and 90 mg/d) dose-dependently suppressed cannabis withdrawal in an outpatient environment. Together, these results are consistent with findings that showed acute $\triangle^9$-tetrahydrocannabinol administration substantially assuaged precipitated cannabinoid withdrawal in laboratory animals [83, 127]; more importantly, they indicate that oral $\triangle^9$-tetrahydrocannabinol might be beneficial in the treatment of marijuana dependence.

Several limitations of the above studies should be noted. First, most of the studies employed only one active dose of the treatment medication. Perhaps more cannabis-related

withdrawal symptoms would have been alleviated if a wider range of medication doses were examined. This point is particularly relevant for the study that examined nefazodone because the tested active dose (450 mg/d), which was lower than doses regularly used clinically to treat anxiety and depression, showed a trend toward improved withdrawal symptomatology. Second, most study participants were seeking treatment to abstain from cannabis use. Because the study of cannabis-related effects in humans requires the administration of carefully controlled doses of smoked marijuana, ethical considerations dictate that research volunteers not only have current cannabis use histories, but that they are also not seeking treatment for their cannabis use [41]. Thus, it is possible that the above results may not generalize to persons who are requesting treatment for cannabis dependence. A related limitation is that although adolescents are more likely than adults to exhibit clinical features of cannabis dependence and experience difficulties abstaining from cannabis use [25], none of the above studies included participants younger than 21 years of age. This was done because the studies involved the administration of smoked marijuana (a drug of abuse); thus it was believed inappropriate to expose children to smoked marijuana in the laboratory, even if the potential participant had reported previous use. Nonetheless, in light of the fact that a large proportion of cannabis-dependent persons under the age of 21 report using cannabis to alleviate withdrawal symptoms [27], it may be important study the effects of potential treatment medications in older adolescents.

There are at least two issues of potential concern related to treating cannabis-dependent adolescents with medications such as oral $\triangle^9$-tetrahydrocannabinol: (1) administration of a psychoactive drug to individuals whose brains are still developing can potentially hamper development, especially in areas like the prefrontal cortex, which is slower to develop than other cortical regions [69]; and (2) replacement of one psychoactive drug with abuse potential with another drug that has abuse potential. While these concerns deserve serious consideration, it is important to note that the route of administration is a critical determinant of neurochemical consequences associated with drug administration, in part because neurochemical effects depend on the rate of rise of drug concentrations and the maximum drug concentrations achieved [43]. Thus, administration of $\triangle^9$-tetrahydrocannabinol via the oral route would be expected to produce less deleterious neuronal consequences than smoked marijuana. Regarding concerns about the abuse potential of oral $\triangle^9$-tetrahydrocannabinol, data from a recent study completed in our laboratory showed that the drug produced low rates of self-administration in a sample of marijuana smokers, suggesting that the abuse potential of oral $\triangle^9$-tetrahydrocannabinol is limited [62]. Note also that oral $\triangle^9$-tetrahydrocannabinol, unlike smoked marijuana, is not associated with an increased risk of lung toxicity. Hence, from a risk-benefit perspective, oral $\triangle^9$-tetrahydrocannabinol appears to be a safer therapeutic option. It should be noted that Gray et al. [47] recently assessed oral $\triangle^9$-tetrahydrocannabinol (0, 2.5, 5, 10 mg/d) for tolerability in older adolescents (ages 16–21 years). They found that the drug produced dose-related increases in euphoria without producing significant effects on cardiovascular measures, psychomotor performance, or "negative" subjective-effect ratings. Another limitation worth noting is that the same group of researchers has collected most of the published data in this research area, which highlights the need for replication of previous results and additional data.

The above limitations notwithstanding, the data obtained in human research participants demonstrate that while a growing number of medications have been tested, few show promise as potential treatment strategies for the amelioration of cannabinoid withdrawal symptoms. Findings from studies of bupropion and divalproex were discouraging, as these medications failed to assuage many marijuana withdrawal symptoms. In some cases, symptoms were worsened by the medication. Of the agents tested, clearly, oral $\triangle^9$-tetrahydrocannabinol produced

the most promising results. In addition, the limited results obtained in adolescents indicate that oral Δ^9-tetrahydrocannabinol is well tolerated and suggest further study of this medication in adolescent marijuana abusers. Although no study has investigated the effects of benzodiazepines on human cannabis withdrawal symptoms, data obtained in laboratory animals suggest that future studies should examine the ability of agents such as clonazepam or oxazepam to lessen severity of the withdrawal syndrome.

Relapse Prevention Medications

Drug self-administration procedures provide a reliable method for evaluating the reinforcing effects of psychoactive agents. Under these procedures, laboratory animals are provided an opportunity to self-administer intravenously doses of a drug contingent upon an operant response (e.g., lever pressing). These procedures have been used extensively not only to assess drug-related abuse liability, but they have also been used to evaluate the usefulness of potential pharmacotherapies in treating substance use disorders. If a potential treatment medication, for example, decreases self-administration of the abused drug in laboratory animals, then perhaps the treatment medication would be effective in curtailing human abuse of the drug. Although data from the majority of earlier studies showed that cannabinoids did not reliably maintain self-administration behavior in laboratory animals tested (e.g., [57, 78, 86, 100]; for review, see also [117]), findings from recent studies demonstrate clearly that cannabinoids produce dose-related reinforcing effects in rats and squirrel monkeys [38, 74, 116]. The success of recent attempts to obtain reliable self-administration in laboratory animals has been attributed to the employment of lower Δ^9-tetrahydrocannabinol doses that were injected more rapidly than those previously investigated.

Because of the demonstration that Δ^9-tetrahydrocannabinol reliably serves as a reinforcer, Goldberg and colleagues have begun testing the ability of potential marijuana treatment medications to alter marijuana self-administration in squirrel monkeys. In the first study, monkeys were given an opportunity to self-administer Δ^9-tetrahydrocannabinol (2, 4 μg/kg) during sessions [116]. Both doses robustly maintained self-administration; when active Δ^9-tetrahydrocannabinol was substituted with vehicle, responding significantly decreased. Following the demonstration of Δ^9-tetrahydrocannabinol self-administration, the researchers then assessed the effects of the cannabinoid antagonist rimonabant, administered one hour before experimental sessions, on Δ^9-tetrahydrocannabinol as well as cocaine self-administration. The administration of rimonabant markedly reduced Δ^9-tetrahydrocannabinol self-administration, but had no effect on cocaine self-administration, indicating the selective involvement of the cannabinoid system in Δ^9-tetrahydrocannabinol reinforcing effects. These findings were recently extended when this group of investigators demonstrated that rimonabant blocked cue- and Δ^9-tetrahydrocannabinol-induced reinstatement of Δ^9-tetrahydrocannabinol self-administration by squirrel monkeys [76]. The finding that rimonabant suppressed Δ^9-tetrahydrocannabinol self-administration is an important one with respect to cannabis treatment medications development efforts. It suggests that cannabinoid antagonism might be a useful strategy for decreasing cannabis dependence in humans. In fact, Huestis et al. [67] reported that rimonabant (90 mg, by mouth) blocked the acute subjective and cardiovascular effects of smoked marijuana in human research volunteers. An important caveat to the above findings is that an acute rimonabant dosing regimen was employed in those studies. Because individuals undergoing treatment for cannabis dependence may require repeated administration of pharmacological agents, the clinical utility of rimonabant is unclear. In addition, while rimonabant-like medications may present an alternative option for individuals who do not want to be maintained on cannabinoid agonists, it is important to note that lack of compliance has been a major problem

with antagonist therapy used in treating other substance use disorders (e.g., naltrexone for opioid dependence). Despite these concerns, the above data suggest that further study of rimonabant-like medications in the treatment of marijuana dependence is warranted.

In another study by this group of researchers, Justinova et al. [75], using similar procedures, evaluated the effects of naltrexone, an opioid antagonist, on $\triangle^9$-tetrahydrocannabinol self-administration behavior in monkeys. The rationale for the use of naltrexone stemmed from accumulating evidence obtained in laboratory animals, which suggests a reciprocal functional interaction between central nervous system cannabinoid and opioid systems [87]. Opioid antagonists, for example, have been demonstrated to precipitate withdrawal symptoms in rats dependent on cannabinoids [79, 93]. Moreover, pretreatment with the opioid antagonist naloxone has been shown to decrease self-administration behavior maintained by cannabinoid agonists in rodents [14, 15, 94]. Justinova et al. [75] replicated and extended the self-administration data by demonstrating that $\triangle^9$-tetrahydrocannabinol self-administration behavior in monkeys was significantly decreased in the presence of naltrexone. The dampening effect of naltrexone on $\triangle^9$-tetrahydrocannabinol self-administration behavior was not as robust as those produced by the cannabinoid antagonist (described above). While these data are congruent with the hypothesis that the endogenous opioid system modulates central nervous system cannabinoid effects and are suggestive of the idea that naltrexone might be useful in preventing relapse to marijuana use, data obtained using human research participants indicate that naltrexone does not alter marijuana-associated antinociceptive or subjective effects (e.g., [48, 129]). Indeed, Haney et al. [53] reported that naltrexone pretreatment (50 mg, oral) significantly increased "positive" subjective effects (e.g. ratings of "Good Drug Effect") of oral $\triangle^9$-tetrahydrocannabinol (30 mg). Naltrexone also produced a moderate increase in choice to self-administer $\triangle^9$-tetrahydrocannabinol, although this effect was not significant. More recently, Haney [55] investigated the effects of a lower, more selective dose of naltrexone (12 mg, oral) on response to oral $\triangle^9$-tetrahydrocannabinol (0–40 mg) in non-marijuana and marijuana smokers. Naltrexone-related effects varied as a function of marijuana use history: in non-marijuana smokers, $\triangle^9$-tetrahydrocannabinol-associated intoxicating effects (2.5 mg) were enhanced and $\triangle^9$-tetrahydrocannabinol-associated anxiety (10 mg) was decreased, whereas, in marijuana smokers, $\triangle^9$-tetrahydrocannabinol-associated intoxicating effects (20 mg) were reduced and $\triangle^9$-tetrahydrocannabinol-associated anxiety (40 mg) was increased. The apparent lack of correspondence between data obtained using laboratory animals and those obtained with human research participants emphasize the importance of not only testing potential marijuana pharmacotherapeutic agents in laboratory animals, but also evaluating the utility of these medications in human research participants.

In contrast to the large database describing the effects of relapse prevention medications in treating human alcohol and cocaine dependence (for review, see [58]), research evaluating potential cannabis pharmacotherapies is scarce. Of the few studies that have been published, most have focused primarily on the ability of the test medication to alter physiological and subjective effects of marijuana. Cone et al. [29], for instance, showed that clonidine pretreatment reduced marijuana-related increase in heart rate, but had no effect on marijuana-related subjective effects, and as mentioned above, Huestis et al. [68] found that rimonabant pretreatment attenuated both the increased heart rate and intoxicating effects associated with smoked marijuana. Maintenance on a cannabinoid agonist has also been reported to decrease the intoxicating effects and increase heart rate following smoked marijuana [68, 72]. These data indicate that some of marijuana-associated effects can be altered by various medications.

While modification of subjective and cardiovascular effects produced by marijuana provides important information, the behavior of major

interest for the treatment of cannabis dependence is drug-taking. To date, only a few published studies have measured cannabis-taking behavior by human research volunteers while being maintained on a potential pharmacotherapeutic agent. The first study was a within-participant design, residential laboratory study during which the influence of oral Δ^9-tetrahydrocannabinol maintenance (0, 10, 20 mg four times daily, each dose administered for three consecutive days) on choice to self-administer smoked marijuana was evaluated [60]. Hart et al. [60] reasoned that because Δ^9-tetrahydrocannabinol had been demonstrated to play an integral role in the behavioral effects of smoked marijuana (e.g., [59]) and because agonist therapies have been demonstrated to be effective in decreasing self-administration of other drugs of abuse (e.g., [10, 28]), marijuana-related reinforcing and subjective effects could be significantly attenuated during oral Δ^9-tetrahydrocannabinol maintenance. Yet, choice to self-administer marijuana was not significantly altered by either of the two active Δ^9-tetrahydrocannabinol maintenance conditions, although some marijuana-associated "positive" subjective effect ratings (e.g., "Good Drug Effect") were reduced when participants were maintained on oral Δ^9-tetrahydrocannabinol. There exist several possible reasons why oral Δ^9-tetrahydrocannabinol maintenance did not alter marijuana self-administration, but two are of particular importance. First, the Δ^9-tetrahydrocannabinol maintenance regimen involved only three consecutive days of active treatment, which may have been an insufficient time frame to reduce marijuana self-administration by frequent marijuana users (prior to study enrollment, participants reported smoking an average of 7 marijuana cigarettes per day). Second, none of the study participants were seeking treatment to abstain from marijuana use, further decreasing the likelihood of observing alterations in marijuana self-administration behavior. Given these observations, as well as the fact that some of marijuana's subjective effects decreased, the effect of longer oral Δ^9-tetrahydrocannabinol maintenance on self-administration of marijuana by different populations of marijuana-dependent individuals warrants further investigation.

In another laboratory study, Haney et al. [56] determined the effects of oral Δ^9-tetrahydrocannabinol (60 mg/d), lofexidine (2.4 mg/d), and the combination on symptoms of marijuana withdrawal and relapse, defined as a return to marijuana use after a period of abstinence. Oral Δ^9-tetrahydrocannabinol decreased most withdrawal symptoms, which replicates previous findings (e.g., [20, 54]), but did not decrease marijuana relapse. Lofexidine was sedating and did not lessen withdrawal, but improved sleep and decreased marijuana relapse. The Δ^9-tetrahydrocannabinol-lofexidine combination most robustly improved sleep and attenuated marijuana withdrawal, craving, and relapse. These findings argue that the Δ^9-tetrahydrocannabinol-lofexidine combination should be examined further for its potential as a marijuana dependence treatment medication.

In a pilot outpatient trial, Levin et al. [82] tested divalproex as a marijuana abuse relapse prevention medication. This 12-week study utilized a double-blind placebo-controlled, crossover design, during which 25 individuals were initially randomized to either divalproex (average dose: 1673 mg/d) or placebo. Self-reported marijuana use and quantitative Δ^9-tetrahydrocannabinol urine levels were the primary outcome measure. Divalproex was not found to be more efficacious at curtailing marijuana use than placebo. In addition, divalproex, at doses tested, did not appear to be well tolerated, as compliance on the medication was poor. Together with the finding that divalproex was ineffective at decreasing symptoms of marijuana withdrawal [54], these results suggest that divalproex is not a viable therapeutic option for marijuana dependence.

McRae et al. [89] used an open-label design to test buspirone (10–60 mg/d) as a potential marijuana dependence treatment medication. The rationale for testing buspirone was based on its ability to decrease anxiety, a symptom sometimes associated with cannabis withdrawal. This 12-week study enrolled 11 participants, but only

two completed. The researchers reported that buspirone produced moderate reductions in self-reported marijuana craving and irritability and urine samples positive for marijuana metabolites. A major limitation associated with this study is that it was conducted under non-blind conditions. As a result, the generality of the findings is limited.

In another open-label trial, the attention deficit hyperactivity disorder medication atomoxetine was investigated [119]. Tirado et al. [119] reasoned atomoxetine would be an excellent candidate medication because impairments in attention, memory, executive function and response inhibition seen in marijuana smokers resemble deficits seen in individuals with attention deficit hyperactivity disorder. During this 11-week trial, 13 cannabis dependent treatment seekers were administered a flexible dose of atomoxetine (from 25 to 80 mg/day) depending upon individual tolerability and self-reported cannabis use and use verified via urine toxicology were assessed. Self-reported cannabis use was decreased during medication treatment, but this was not confirmed by urine toxicology as the number of tetrahydrocannabinol-positive urine screens did not vary as a function of treatment condition. In addition, atomoxetine was associated with significant adverse gastrointestinal symptoms (nausea, vomiting, dyspepsia and diarrhea).

A growing number of clinical laboratory studies have demonstrated that the physiological and subjective effects of cannabis can be reduced by different classes of medications. Cannabis-related effects on heart rate are attenuated by the α_2-receptor agonist clonidine and by the cannabinoid antagonist rimonabant; cannabis-related intoxicating effects are dampened by rimonabant and by the cannabinoid agonist $\triangle^9$-tetrahydrocannabinol. Such findings are encouraging, but clearly more research is needed to determine the clinical utility of these medications for cannabis dependence. Of the limited number of studies evaluating the effects of relapse prevention medications on cannabis-taking behavior by humans, one has shown a medication to decrease marijuana relapse; the $\triangle^9$-tetrahydrocannabinol-lofexidine combination seems to be the most encouraging. The finding might ultimately prove beneficial in decreasing relapse to cannabis use in a treatment seeking population of cannabis-dependent individuals, but further studies using different doses are needed to confirm data from the single available study.

Future Directions in Medication Development for Cannabis Dependence

In recent years, there has been an increase in the popularity of smoking "blunts," marijuana wrapped in tobacco paper from inexpensive cigars such as Phillies Blunts or Dutch Masters [46]. Anecdotally, blunt smokers report that the combination of nicotine, derived from the tobacco wrapping, and marijuana enhances the psychoactive pleasurable effects of marijuana. Although there is currently a lack of scientific evidence substantiating this claim in humans, Valjent et al. [124] found that $\triangle^9$-tetrahydrocannabinol-induced hypothermia, antinociception and hypolocomotion were markedly facilitated by nicotine in mice. Consistent with these results, Solinas et al. [107] demonstrated that selective alpha7 nicotinic acetylcholine receptor antagonists disrupted the discriminative stimulus and reinforcing effects of cannabinoid receptor 1 agonists. They also found that selective alpha7 nicotinic acetylcholine receptor antagonists decreased $\triangle^9$-tetrahydrocannabinol-induced dopamine elevations in the shell of the nucleus accumbens. In general, the above results are in line with a recent report indicating that symptoms of cannabis dependence are worsened by the combination of tobacco and marijuana smoking [103]. Together, these findings suggest that endocannabinoid and acetylcholinergic activity may produce synergetic effects and should be target for future medication development efforts for cannabis dependence.

Several new nicotinic acetylcholine receptor agonists are now in human clinical development for a variety of cognitive disorders and smoking cessation. Recently, varenicline, a nicotinic acetylcholine receptor partial agonist, was approved for smoking cessation with efficacy superior to nicotine replacement therapies and bupropion. Because of the overlap between nicotine and cannabis in terms of dependence and similarity in withdrawal symptoms [126], pharmacotherapies, like varenicline and transdermal nicotine, may reduce the withdrawal effects associated with cannabis, particularly if the cannabis-dependent individuals are also dependent on tobacco.

In summary, research investigating the use of pharmacotherapies for cannabis use disorders continues to be refined. A growing number of medications have been shown to alleviate cannabinoid withdrawal symptoms in laboratory animals and may provide clues to the underlying neuronal mechanisms of cannabinoid dependence. The majority of these findings, however, have not been tested in humans, as only $\triangle^9$-tetrahydrocannabinol and the $\triangle^9$-tetrahydrocannabinol-lofexidine combination have been demonstrated to ameliorate substantially human symptoms of cannabis withdrawal. Fewer studies have assessed the effects of potential cannabis treatment medications on cannabinoid-related physiological, subjective, and reinforcing effects. In laboratory animals, only rimonabant has been shown to be particularly promising; in humans, a small number of medications have been demonstrated to decrease physiological and subjective effects of cannabis (clonidine, oral $\triangle^9$-tetrahydrocannabinol, and rimonabant), and the $\triangle^9$-tetrahydrocannabinol-lofexidine combination has been demonstrated to most effectively reduce relapse to cannabis use.

Acknowledgements This research was supported by the National Institute on Drug Abuse grant #DA-03746. We gratefully acknowledge the efforts of Michaela Bamdad and Catalina Saldaña, who read an earlier version of the manuscript and made helpful suggestions.

Hallucinogens

John H. Halpern, Joji Suzuki, Pedro E. Huertas, and Torsten Passie

Contents

Historical Perspectives

Psychoactive substances derived from botanicals have been ritualistically used for millennia [63, 73]. Developments during the second half of the twentieth century in neuroscience and in synthetic organic chemistry recast natural and synthetic intoxicants into a new biological and clinical light [52]. These chemicals, referred to improperly as "hallucinogens", alter psychoneurobiological behavior in ways both subtle and overt. The term "hallucinogen" suggests the induction of hallucinations, a symptom of psychosis well-known within clinical psychiatry, but this is not the case with most hallucinogens and some closely related substances (i.e., entactogens such as 3,4-methylenedioxymethamphetamine), which do not induce major sensory alterations. The terms "psychotomimetics" (psychosis-mimicking) and "psychedelics" have also been used. "Psychotomimetic" only rarely appears anymore in the scientific literature, since, much like with "hallucinogen", these substances are not primarily psychotogenic, whether mimicking or otherwise, though hallucinogens can exacerbate or contribute to worsening the mental health of those vulnerable to a formal thought disorder. The term "psychedelic", first offered by the psychiatrist Humphrey Osmond [55], may be the most commonly used lay term for hallucinogens, and it used to be an accepted alternate descriptor in the scientific literature.

Albert Hofmann first synthesized lysergic acid diethylamide in 1938 and accidentally ingested it in 1943. Publishing on these findings heralded much research in the 1950s where hallucinogens became the focus of intense interest in psychiatric research and stimulated the discovery of the neurotransmitter systems and their functions in the brain [39].

Over 10,000 subjects received lysergic acid diethylamide (and other hallucinogens) in controlled research settings in studies published from 1951 to the late 1960s, resulting in more than 1,000 clinical papers, dozens of books, and six international conferences on their use as aids in psychotherapy [11, 24, 48, 56].

A number of substances have been categorized as hallucinogens or hallucinogen-like:

(1) the classical hallucinogens (e.g., mescaline, psilocybin, lysergic acid diethylamide, dimethyltryptamine), (2) the entactogenic phenethylamines (3,4-methylenedioxyamphetamine, 3,4-methylenedioxymethamphetamine, 3,4-methylenedioxyethylamphetamine, methylbenzodioxolylbutanamine), (3) the anticholinergic delirants (atropine, hyoscyamine, scopolamine), and (4) dissociative anesthetics/miscellaneous (N_2O, ketamine, phencyclidine, salvinorin A). This chapter focuses on the more commonly used classical and entactogenic hallucinogens, but will mention the other substances where appropriate or necessary.

Epidemiology

The Substance Abuse and Mental Health Services Administration's National Survey on Drug Use and Health estimated that among Americans aged 12 or older in 2006, close to 4 million used hallucinogens that year, with 1.1 million trying one for the first time ever, and some 35.3 million Americans have tried one at least once in their lifetime [60]. 380,000 Americans over age 12 were estimated to meet *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition criteria for hallucinogen abuse or dependence in 2006 (out of a total of 23.6 million persons classified with any substance abuse or dependence that year) [60]. The Substance Abuse and Mental Health Services Administration's Drug Abuse Warning Network data estimated that 16,408 emergency room visits for the entire United States in 2005 involved a hallucinogen (not including phencyclidine: 7,535), with 10,752 for the entactogen 3,4-methylenedioxymethamphetamine and less than 1,900 for the classical hallucinogen lysergic acid diethylamide (out of a total of 1.45 million drug-related visits) [61].

Among high school students, the Monitoring the Future data have shown a continuous decline since the late 1990s in the lifetime, annual, and past-month use of hallucinogens [43]. In 2006, 8.3% of 12th graders in the United States reported lifetime use of hallucinogens, a drop from 15.1% in 1997 [43].

Taken together, these numbers indicate that the prevalence of hallucinogen use still is lower compared with other substances of abuse in the United States and is significantly lower in morbidity and mortality. The prevalence of the various hallucinogen-related disorders is not known.

Basic Pharmacology

Table 1 lists some of the more commonly known hallucinogens. As shown by the table, the various hallucinogens are wide-ranging in dosage and duration. In general, hallucinogens exert their effects by sympathomimetic actions on the central nervous system. This activation may be due to agonist properties on different neurotransmitter-modulated brain systems that are adrenergic, dopaminergic, and, perhaps most importantly, serotonergic. The brain contains approximately 40,000 serotonergic neurons, mainly located in the dorsal raphe nucleus of the mid-brain. This tiny population of neurons maintains a widely distributed network throughout the brain, which modulates nearly every kind of brain activity.

Despite heterogeneity, most classical hallucinogens appear to exert pharmacologic action through agonist effects on 5-HT_{2A}/c receptors [52]. Hallucinogens have high affinity for serotonin receptors [21, 59], and genetic or pharmacologic inactivation of 5-HT_{2A} receptors blocks behavioral effects in preclinical models as well as subjective effects in humans [16, 21, 22, 72]. Rapid tolerance develops due to receptor down-regulation, and repeated administration leads to markedly diminished effects within several days [52].

It remains unclear as to whether a specific pattern of alterations of brain functioning is involved in hallucinogens' psychoactive effects. Neurometabolic studies to date point to activation of the frontal cortex, limbic/paralimbic structures, and the right hemisphere [23, 38, 58, 71].

Table 1 The common hallucinogens (partial list)

Class	Chemical name	Common or street name	Source	Dosage	Route	Duration of action	Major neurobiological target	Notes
Indole-alkylamines	Lysergic acid diethylamide	LSD, Acid, Blotter	Synthesis	50–200 μg	By mouth	8–14 h	5-HT_{2A} partial agonist	Distributed on small squares of blotting paper, drops of liquid, gel-caps, small pills
	Psilocybin	Magic mushrooms, Shrooms	Psilocybe cubensis, Psilocybe azurescens, and many other subspecies, Synthesis	10–50 mg, 1–5 g dried mushroom; quite variable	By mouth	4–8 h	5-HT_{2A} partial agonist	Psilocybin is converted in the body to psilocin, the actual active hallucinogen. Continued shamanic use in Mexico. Bruising of mushroom turns blue.
	Dimethyltryptamine	DMT, Yopo, Cohoba	Psychotria viridis, Anadenanthera peregrina, Mimosa hostilis, and many other natural sources, Synthesis	5–40 mg	Smoked, inhaled snuff	30–60 min	5-HT_{2A} partial agonist	Continued Amazonian shamanic use
	Dimethyltryptamine + monoamine oxidase inhibitors (harmala beta-carbolines)	Ayahuasca, yaje, Hoasca, Daime, "vine of the soul"	Psychotria viridis (dimethyl-tryptamine) + Banisteropsis caapi (monoamine oxidase inhibitor)	Variable	By mouth	2–4 h	5-HT_{2A} partial agonist	Brewed as a tea; religious sacrament
	Ibogaine	Ibogaine	Tabernathe iboga	200–300 mg	By mouth	12+ h	Likely 5-HT_{2A} partial agonist	Religious sacrament; long-acting metabolites may contribute to purported anti-opiate withdrawal benefits.
Phenyl-alkylamines	3,4,5-trimethoxy-phenylethylamine	Mescaline, Peyote, San Pedro	Lophophora williamsii, Echinopsis panachoi, other cacti, Synthesis	200–500 mg, 10–20 g or 5–10 dried peyote buttons, 1 kg fresh E. pachanoi	By mouth	6–12 h	5-HT_{2A} partial agonist	Religious sacrament

Table 1 (continued)

Class	Chemical name	Common or street name	Source	Dosage	Route	Duration of action	Major neurobiological target	Notes
Entactogenic phenyl-alkylamine	3,4-methylenedioxy-methamphetamine	MDMA, Ecstasy, X, XTC, Rolls, Molly	Synthesis	80–150 mg	By mouth	4–6 h	Serotonin release and depletion	Mildly hallucinogenic at high doses
	3,4-methylenedioxy-amphetamine	MDA, Love drug, Adam	Synthesis	75–160 mg	By mouth	4–8 h	Serotonin release and depletion	
	4-bromo-2,5-dimethoxy-phenethylamine	2C-B, Nexus	Synthesis	5–30 mg	By mouth	4–8 h	Unknown	
	4-chloro-2,5-dimethoxy-amphetamine	DOC	Synthesis	1–5 mg	By mouth	4–8 h	Unknown	Has been found on blotting paper
	4-methyl-2,5-dimethoxy-amphetamine	DOM, STP	Synthesis	1–10 mg	By mouth	14–20 h	Unknown	Higher doses used in the 1960s resulted in many ER visits then.
Dissociative	Ketamine	Ketamine, Special K, Vitamin K, K hole	Synthesis	25–50 mg (intramuscularly), 50–100 mg (by mouth or snorted)	Intramuscularly, by mouth, snorted	1–2 h (intramuscularly), 1–4 h (by mouth)	*N*-methyl-*D*-aspartate antagonist	Sub-anesthetic dose: lost sense of time, space, verbal skills, balance, drooling
	Dextromethorphan	DXM, Robo, DM	Synthesis	100–600 mg	By mouth	4–8 h	*N*-methyl-*D*-aspartate antagonist	
	Phencyclidine	PCP, Angel dust	Synthesis	3–10 mg	By mouth	8–24 h	*N*-methyl-*D*-aspartate antagonist	

Table 1 (continued)

Class	Chemical name	Common or street name	Source	Dosage	Route	Duration of action	Major neurobiological target	Notes
Other	Salvinorin A	Salvia, Sally D, Diviner's sage	Salvia divinorum	250–750 mg (smoked), 2–10 g dried leaves (by mouth)	Smoked, by mouth	30–60 min (smoked), 1–3 h (by mouth)	Kappa-opioid selective agonist	Atypical hallucinogen; no longer found in the wild
	Scopolamine and atropine	Datura, Jimson weed, loco weed, Thorn apple, Angel's trumpet, belladonna, deadly nightshade	Datura stramonium, Atropa belladonna, many related species	Highly variable	By mouth	12–48 h	Competitive muscarinic acetylcholine antagonist	Plants of the Solanaceae family contain various ratios of scopolamine to atropine; blurred vision
	Muscimol (5-(aminomethyl)-3-isoxazolol)	Fly agaric, Amanita	Amanita muscaria, Amanita pantherina	1–30 g dried mushrooms	By mouth	5–10 h	Gamma-aminobutyric acid-A agonist glutamate	Shamanic use in eastern Siberia; over 600 species of agarics—easy to misidentify. Some are extremely poisonous, such as "death cap" A. phalloides; mushrooms also contain ibotenic acid—as it dries/ages, decarboxylation of ibotenic acid creates muscimol.

Entactogenic substances, such as 3,4-methylenedioxyamphetamine and 3,4-methylenedioxymethamphetamine, differ from classical hallucinogens by inducing a marked release of serotonin from serotonin-containing neurons and (to a lesser extent) dopamine release from dopamine-containing neurons [70]. Their neurometabolic actions show minor deactivation of cortical regions and limbic activation [23] as well as deactivation of the left amygdala [18]. The latter may be responsible for their most prominent effect: the decrease of emotional tension and anxiety.

Psychological and Biological Effects

Intoxication with hallucinogens, commonly referred to as "tripping", may induce some physiologic effects quite subtle to observation and a wide variety of behavioral, emotional, and cognitive effects (Table 2) [29, 42]. The visual images experienced are usually not true hallucinations but illusions, such as the perception of geometric patterns or scenic dream-like visions appearing before closed eyes, perception of movement in stationary objects, and synesthesias. The content of visual and most emotional phenomena most often reflects the psychodynamics of the user [27, 45]. Colors may appear intensified, and humans (self and others) and animals may be viewed as altered or exaggerated directly or in mirrored reflection [69]. Hallucinogens amplify affectivity and may cause significant changes of mood, with possible rapid changes from euphoria to depression or anxiety or vice versa [67]. In extreme cases, especially with higher order overdoses, psychotic-like reactions may be experienced. In short, the psychological effects of hallucinogens are highly variable and strongly influenced by the individual's psychological state at the time

Table 2 Hallucinogen[a] physical and psychological effects

Intoxication may include a cluster of the following	
Physical effects[b]	Psychological effects
Regular (mild to very mild): Tachycardia, palpitations, hypertension or hypotension, diaphoresis, hyperthermia, motor incoordination, tremors, hyperreflexia, altered neuroendocrine functioning *Regular (mild to strong):* Mydriasis, arousal, insomnia *Occasional:* Nausea, vomiting, diarrhea, blurred vision, nystagmus, piloerection, salivation	Intensification and/or lability of affectivity with euphoria, anxiety, depression, and/or cathartic expressions Dream-like state Sensory activation with illusions, pseudo-hallucinations, hallucinations[c], synesthesias Altered experience of time and space Altered body image Increased suggestibility Acute neuropsychological/cognitive impairments with loosening of associations, inability for goal-directed thinking, memory disturbances Paranoid/suicidal ideation Impaired judgment Megalomania, impulsivity, odd behavior Lassitude, indifference, detachment Psychosomatic complaints Derealization, depersonalization Mystical experiences Sense of profound discovery/healing

[a] Indolealkylamine and phenylalkylamine hallucinogens only (see Table 1)

[b] Some effects are reactionary to psychological content (e.g., increased heart rate and nausea due to anxiety), and complaints can be dependent on factors such as mindset, setting, dose, and supervision. Intoxicated individuals may also deny physical impairment and/or claim increased energy, sharpened mental acuity, and improved sensory perception

[c] A subject experiencing "pseudo-hallucinations" retains the capacity to recognize that these perceptions are transient and drug induced, as opposed to true hallucinations in which no such discernment from reality is possible

of ingestion (mind-set) as well as the social and physical setting [75].

Toxicity of lysergic acid diethylamide, psilocybin, and other classical hallucinogens is very low. Overdosing leads to psychological complications to psychological crises or (rarely) psychotic symptoms. However, no case of lethal overdose is known, and there is no evidence of toxicity beyond the acute state of intoxication [33]. A recent review of the harmful consequences of drugs of abuse found that the classical (and the most used, by far) hallucinogen lysergic acid diethylamide is near the bottom in a ranking of risk to users and society [53].

Hallucinogen Use Disorders

Hallucinogen abuse and hallucinogen dependence are organized in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition much like most other listed substance use disorders. Both are characterized by patterns of compulsive and repeated drug use despite the knowledge of significant harm caused by this use. Hallucinogen use only virtually never leads to the development of classic dependence syndromes as seen with opiates or alcohol [54]. By far the most typical pattern is for users to experiment with a few doses of a hallucinogen and then discontinue further use [41]. Users do not experience withdrawal symptoms as seen with other substances of abuse, and so this symptom is not a criterion in diagnosing hallucinogen dependence. Note that tolerance rapidly increases, in general, when hallucinogens are used with frequency, which strongly limits their use on a regular basis.

Hallucinogen-Induced Disorders

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition allows for the diagnosis of numerous substance-induced disorders. Specific to hallucinogens are: hallucinogen intoxication, hallucinogen persisting perception disorder, and hallucinogen-induced psychotic, mood, anxiety, delirium, or "not otherwise specified" disorder. These disorders arise in the context of substance use and may manifest during intoxication, during withdrawal, or long after the drug has been ingested and the acute effects have subsided [7]. The diagnosis of a hallucinogen-induced psychotic, mood, anxiety, or delirium disorder is made only if the symptoms are in excess of what is expected from intoxication or withdrawal [7].

Assessment and Treatment

Hallucinogen Intoxication

The *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, Fourth Edition criteria for hallucinogen intoxication are presented in Table 3.

Assessment

An individual will most often present for treatment because he or she is experiencing an acute panic and/or depressive reaction (sometimes combined with temporary delusional ideation), commonly referred to as a "bad trip". Symptoms begin any time after the onset of effects and may include marked anxiety or fears of "going insane" [17, 65]. Paranoid ideation, feelings of being manipulated, or feelings of being in a situation without any escape may also occur. Hallucinogen intoxication should be suspected when a patient or his or her friends report recent ingestion of a hallucinogen and the patient presents with a characteristic constellation of sympathomimetic findings with a clear sensorium. Since laboratory testing is generally not available in most acute settings, obtaining an accurate history and clinical examination is critical in establishing this diagnosis. Since illicit drugs often contain various substances, the actual identity of the offending substance ingested may not be known. However, hallucinogens in general produce similar effects, which

Table 3 *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, fourth edition criteria (292.89): Hallucinogen intoxication

A. Recent use of hallucinogen
B. Clinically significant maladaptive behavior or psychological changes (e.g., marked anxiety or depression, ideas of reference, fear of losing one's mind, paranoid ideation, impaired judgment, or impaired social or occupational function) that developed during or shortly after, hallucinogen use.
C. Perceptual changes occurring in a state of full wakefulness and alertness (e.g., subjective intensification of perceptions, depersonalization, derealization, illusions, hallucinations, synesthesias) that developed during, or shortly after, hallucinogen use.
D. Two (or more) of the following signs, developing during, or shortly after, hallucinogen use:
(1) pupillary dilatation
(2) tachycardia
(3) sweating
(4) palpitations
(5) blurring vision
(6) tremors
(7) incoordination
E. The symptoms are not due to a general medical condition or are not better accounted for by another mental disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, fourth edition (Copyright 2000). American Psychiatric Association

should be carefully assessed. Signs and symptoms of hallucinogen intoxication are reviewed in the previous section (see Table 2). Physical examination will also provide important clues that can help support the diagnosis of hallucinogen intoxication (in particular, widely dilated pupils that do not rapidly/tightly constrict to accommodate bright light). Although duration of action can vary considerably among hallucinogens, the acute reaction typically lasts less than 12–24 h; persisting reactions will require further investigation to rule out other etiologies.

Differential Diagnosis

Since polysubstance ingestion is common, history should be sought on whether other substances were also recently consumed. Urine toxicology should also be performed, but tests for specific hallucinogens are specially ordered and results typically will not be available for a few days. Anticholinergic intoxication should be considered in individuals with a suggestive history (i.e., ingestion of jimson weed, or Datura) and findings of hyperthermia, delirium, dry mouth, urinary retention, headache, and blurred vision. Delirium due to alcohol, sedative, or hypnotic withdrawal will present with sympathomimetic findings, but will also present with confusion, seizures, tremors, and visual, auditory, or tactile hallucinations. Stimulant psychosis, a psychosis in the setting of a clear sensorium induced by chronic stimulant abuse, presents with paranoid delusions and visual or auditory hallucinations, and the stimulant abuser may report compulsive fascination with and performance of complex, stereotyped repetitive behaviors known as "punding" [15]. Phencyclidine, ketamine, or dextromethorphan intoxication may present similarly to hallucinogen intoxication, but differentiates with additional symptoms, including ataxia, horizontal nystagmus, rage, erythema, amnesia, and dry skin [19, 20]. Dextromethorphan intoxication will also produce a distinctive, plodding "zombie-like" gait abnormality [10]. In addition, phencyclidine overdose can prolong the toxic effects to 3 days owing to its long half-life [3].

If mood, anxiety, and psychotic symptoms warrant clinical evaluation, then hallucinogen-induced mood, anxiety, or psychotic disorder, respectively, should be considered. Psychiatric diagnoses, including affective psychoses, schizophrenia, anxiety, and dissociative disorders, also can present with varying degrees of acute dysphoria, depersonalization, and hallucinations. Medical causes of perceptual disturbances and mental status change should

be ruled out, including adverse medication reaction, metabolic disturbance, infection, dementia, stroke, seizure, central nervous system tumor, and Charles Bonnet syndrome. Collection of a careful history and physical, collateral information from family and friends, where appropriate, as well as laboratory data, will be needed for narrowing to the correct working diagnoses.

Treatment

The "talk down" (more accurately the "talk through") is usually the only intervention indicated in these situations [68]. Recommendations include placing the patient in a low-stimulus environment—i.e., a quiet space with dimmed lights and minimal distractions—and providing emotional support. Arrange for a reliable sitter (a non-intoxicated family member or friend) to remain with and attend to the patient. The sitter can help keep him or her calm and oriented by providing a sympathetic presence. In addition, provide reassurance to the patient that the experience is generally non-hazardous, drug-induced, and time-limited and will resolve with full recovery. The patient should not be left alone until the effects of the drug wear off [67].

Hallucinogens rapidly absorb in the gastrointestinal tract. Therefore, unless ingestion occurred within 30 min of presentation, gastric lavage is unlikely to remove additional undigested drug. The patient's mental state will invariably worsen if gastric lavage is forcefully attempted; therefore, it should be avoided.

If severe agitation does not respond to redirection and if concerns of safety remain for the patient and/or others, benzodiazepines are quite effective in reducing anxiety and panic [3]. Many authorities recommend diazepam or lorazepam as drugs of choice, by mouth if possible, but intramuscular and intravenous administrations are more effective [13]. In any case, avoid physical restraints, if possible, and limit the use of neuroleptics since paradoxical effects have been reported with chlorpromazine [65], and hallucinogen persisting perception disorder symptoms have been reported to worsen after receiving phenothiazines [1, 64] and 5-HT_{2A} antagonists such as risperidone [2, 50]. Haloperidol may be considered in rare cases of severely agitated patients who require further acute interventions after benzodiazepines have not proven to be sufficient. Great caution must be exercised, however, since neuroleptics lower the seizure threshold and may also induce hypotension [67].

Once acute symptoms subside, patients usually are able to return home accompanied by a family member or friend [65]. It is important to advise patients that subsequent ingestion of hallucinogens may precipitate similar reactions and (especially after bad trips) the risk for uncontrolled re-experience ("flashback") of some element(s) of the altered state is heightened. These flashbacks usually last for seconds, but may be longer if an actual hallucinogen (or cannabis) is re-ingested (see below). If symptoms persist for longer than 24 h or there are accompanying severe mood or psychotic symptoms that warrant further clinical attention, hospitalization may be appropriate [66].

Hallucinogen Abuse and Dependence

The *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, Fourth Edition criteria for hallucinogen abuse are presented in Table 4.

Assessment

For hallucinogen abuse and dependence, evaluation and treatment should proceed similar to those of patients diagnosed with hallucinogen intoxication. Hallucinogen abuse should be diagnosed when individuals report using hallucinogens despite evidence and knowledge of related harm. Hallucinogen dependence should be considered when the pattern of use appears to be out of control, such as when using larger amounts than intended or when there is an inability to cut down on the frequency of use [7].

Table 4 *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, fourth edition criteria (305.30): Hallucinogen abuse

A. A maladaptive pattern of hallucinogen use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:
  (1) recurrent hallucinogen use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to the substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
  (2) recurrent hallucinogen use in situations in which it is physically hazardous
  (3) recurrent hallucinogen-related legal problems
  (4) continued hallucinogen use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance
B. The symptoms have never met the criteria for Substance Dependence for this class of substance.

Overall rates of abuse and dependence are estimated to be low compared with other substances [43, 74]. In clinical settings, individuals often present as polydrug users; therefore, a complete history is always needed to assess for other drug use.

Differential Diagnosis

With polydrug use being common, a differential diagnosis must always list other substance use or substance-induced disorders. In addition, a significant portion of illicit drugs sold as lysergic acid diethylamide (or some other hallucinogen) may contain other substances such as amphetamines or phencyclidine [67]. Therefore, diagnosis of amphetamine or phencyclidine abuse and dependence should be included for consideration and further data gathering. Alcohol is likely the drug that is most commonly abused comorbidly, and this should be assessed especially carefully in this population [14]. Schizophrenia, schizophreniform disorder, bipolar disorder, and schizoaffective disorder should be ruled out in these individuals by assessing the longitudinal course of the constellation of symptoms and their temporal relation to hallucinogen ingestion.

Treatment

General principles of substance abuse and dependence treatment apply to treating these individuals [14]. Motivational interviewing, detoxification, relapse prevention, intensive outpatient counseling, and family therapies are examples of interventions that may be individualized to the person presenting. Treatment should target all other substance abuse and dependence, whether or not they are thought to be contributing to the presenting disturbances. Moreover, treatment should be provided with a dual diagnosis approach, such that any underlying psychiatric disorder(s) will receive concurrent attention. No controlled trials have been conducted to evaluate the efficacy of pharmacotherapies.

Hallucinogen Persisting Perception Disorder

The *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, Fourth Edition criteria for hallucinogen persisting perception disorder (i.e., flashbacks) are presented in Table 5.

Assessment

Diagnosis of hallucinogen persisting perception disorder requires differentiation into two kinds of phenomena. The International Statistical Classification of Diseases and Related Health Problems, 10th Revision, describes symptoms as the re-emergence of fragments, scenarios, and/or altered states of consciousness and mood that are similar to those experienced during the hallucinogen intoxication. This implies a re-experience ("flashback") of the initial

Table 5 *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, fourth edition criteria (292.89): Hallucinogen persisting perception disorder (flashbacks)

A. The re-experiencing, following cessation of use of a hallucinogen, of one or more of the perceptual symptoms that were experienced while intoxicated with the hallucinogen (e.g., geometric hallucinations, false perception of movement in the peripheral visual fields, flashes of color, intensified colors, trails of images of moving objects, positive afterimages, halos around objects, macropsia, and micropsia).
B. The symptoms in Criterion A cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The symptoms are not due to a general medical condition (e.g., anatomical lesions and infections of the brain, visual epilepsies) and are not better accounted for by another mental disorder (e.g., delirium, dementia, schizophrenia) or hypnopompic hallucinations.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, fourth edition (Copyright 2000). American Psychiatric Association

intoxication. These "flashbacks", as they are often nonspecifically called, may (in some rare cases) occur intermittently over weeks, months, or years after the hallucinogen intoxication. Some people intentionally try to induce these re-experiences (with specific music/surroundings), describing them as "free trips". Flashback episodes are very short-lived (usually seconds) but may extend longer with additional cannabis intoxication. There is no documented case in the literature of a flashback leading to real danger or suicide [40].

Different from flashback phenomena is the hallucinogen persisting perception disorder phenomena as described by Abraham [1] and specified in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition. They are nearly all visual in nature (including flashes of color, geometric images, and afterimages of moving objects, or "trails") [14], and appear to be continuous phenomena starting in the days to weeks after hallucinogen consumption. Hallucinogen persisting perception disorder is a rare disorder that may afflict individuals who, in particular, report anomalous visual disturbances (such as "floaters" or episodes of micropsia/macropsia) premorbid to hallucinogen exposure and who did eventually try lysergic acid diethylamide [14]. One Web-based survey of purported hallucinogen users estimated hallucinogen persisting perception disorder prevalence at 0.17–4.1% of users [9].

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition diagnostic criteria require that the individual not be intoxicated with other substances [34]. As such, urine toxicology screens should be performed routinely.

Differential Diagnosis

Hallucinogen-induced psychotic disorder should be considered in patients experiencing significant psychotic symptoms shortly after their use of hallucinogens, but it is important to note that the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition does not list a diagnosis for hallucinogen-induced *persistent* psychotic symptoms. However, very rare cases of a prolonged post-lysergic acid diethylamide psychosis have been reported but also, tellingly, have been more likely in patients with schizophrenia [65]. Psychotic disorders, including schizophrenia and bipolar disorder, should be ruled out by careful psychiatric examination and review of history. Medical causes of intermittent perceptual disturbances should also be considered, including adverse medication reaction, metabolic disturbance, migraine, temporal lobe epilepsy, ocular disease, stroke, or primary or secondary cancer of the central nervous system.

Treatment

Simple reassurance that symptoms do not reflect brain damage, and that the complained-about symptoms typically resolve over more time, can prove tremendously effective in an anxious patient with hallucinogen persisting perception disorder. A variety of treatments have been

reported in several case series to ameliorate symptoms as well as the distress associated with hallucinogen persisting perception disorder, including the use of benzodiazepines, clonidine, haloperidol, olanzapine, carbamazepine, psychotherapy, behavior modifications, and sunglasses [34]. Some case reports note worsening hallucinogen persisting perception disorder symptoms after trials of risperidone [2], phenothiazines [1], and selective serotonin reuptake inhibitors [47]. Clearly, avoiding further hallucinogen use is recommended. In addition, other substances, particularly cannabis, may also trigger hallucinogen persisting perception disorder symptoms. Avoiding triggering drugs (e.g. cannabis) is an important element of treatment. Those providing treatment should take into account the need for symptom relief while also remaining vigilant for benzodiazepine abuse and dependence (when such drugs are chosen for pharmacological intervention), as polysubstance abuse and dependence is common in this patient population [14].

Hallucinogen-Induced Psychotic Disorder

The *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, Fourth Edition criteria for substance-induced psychotic disorder are presented in Table 6.

Assessment

Hallucinogen-induced psychotic disorder is considered in individuals with recent ingestion of a hallucinogen who also present with marked psychotic symptoms and who are often lacking insight that their symptoms are related to this hallucinogen use. While this reaction may be a more severe form of the "bad trip", the diagnosis is made in the setting where a patient's psychotic symptoms are more severe than what would be expected to extend from hallucinogen intoxication. The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition lists modifiers to indicate whether hallucinations or delusions are prominent features [7]. Hallucinogen-related psychotic reactions usually end once the effects of the drug wear off.

Differential Diagnosis

Differential diagnosis includes diagnoses considered for any acute psychosis. Since toxicology screens do not routinely test for hallucinogens, obtaining a thorough history and physical examination is critical. Collateral information from families and friends will aid in narrowing the possible diagnoses. As is stressed several times above, evaluation must include a careful review of the use of other substances of abuse and their frequency of ingestion, including information gained from sources other than the patient. Formal thought disorders and affective psychoses should be considered, with relevant historical information sought to help rule in or out a primary psychiatric illness for the presenting condition. Any evidence for delirium needs careful continued evaluation and management, including infection, adverse medication reaction, metabolic disturbance, central nervous system tumor, stroke, and head injury. Finally, diagnosis should be distinguished from hallucinogen persisting perception disorder, which represents a re-experiencing of the perceptual disturbances of past hallucinogen intoxication (see above).

Treatment

Procedures for the treatment of recent hallucinogen intoxication should be followed as described above, and underlying etiologies for psychosis should be further investigated. In rare occurrences, the patient may require hospitalization as the prolonged reaction can persist for days.

Hallucinogens as Treatment Tools for Addiction?

Past research indicated a use for lysergic acid diethylamide in the treatment of alcoholism and drug dependence [4, 5, 8, 28, 37, 44, 51, 62].

Table 6 *Diagnostic and Statistical Manual of Mental Disorders*, Text Revision, fourth edition criteria: Substance-induced psychotic disorder

A. Prominent hallucinations or delusions, Note: Do not include hallucinations if the person has insight that they are substance induced.
B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):
(1) the symptoms in Criterion A developed during or within a month of substance intoxication or withdrawal
(2) substance use is etiologically related to the disturbance
C. The disturbance is not better accounted for by a psychotic disorder that is not substance induced. Evidence that the symptoms are better accounted for by a psychotic disorder that is not substance induced might include the following: the symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent non-substance-induced psychotic disorder (e.g., a history of recurrent non-substance-related episodes).
D. The disturbance does not occur exclusively during the course of delirium.
Note: This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.
Code specific substance-induced psychotic disorder.
292.11: amphetamine (or amphetamine-like substance), with delusions;
292.12: amphetamine (or amphetamine-like substance), with hallucinations;
292.11: hallucinogen, with delusions;
292.12: hallucinogen, with hallucinations.
Specify:
With onset during intoxication: if criteria are met for intoxication with the substance and the symptoms develop during the intoxication syndrome.
With onset during withdrawal: if criteria are met for withdrawal from the substance and the symptoms develop during, or shortly after, a withdrawal syndrome.

This promising research collapsed under the weight of federal de-funding, decreased access to test compounds, and political hostility to research involving drugs thought to foment the public unrest of the era [25].

In the 1980s, the indolealkylamine hallucinogen ibogaine was patented as a treatment of addiction [46], but it has remained an "underground" tool in America and elsewhere, with only limited research published to date [6, 49]. Ayahuasca, which contains dimethyltryptamine, has been proposed to help those seeking recovery within the religious practices of the União do Vegetal [26] and the Santo Daime Church [36], as well as to possibly "inoculate" teen members from engaging in the addictive use of drugs of abuse [12]. Similarly, anecdotal evidence exists that sacramental peyote taken within the prayer ceremonies of the Native American Church by Native Americans may assist in recovery from drug dependence and alcoholism [30, 31, 32, 35].

There is an ongoing, desperate need for effective treatments for alcoholism and other drug abuse and dependence disorders. The long-standing and continued religious use of hallucinogens suggests that some hallucinogens (combined with psychotherapeutic and socio-therapeutic procedures) may well be an effective psychopharmacologic intervention for these disorders. As research to evaluate hallucinogens for therapeutic use is no longer a major area of investigation, the few legitimate research groups in the United States and elsewhere will hopefully re-evaluate hallucinogens' potential for addictions as well as continue to encourage more colleagues to return to this field. It is also hoped that future research will avoid methodological flaws, which unfortunately made the studies of the 1950s and 1960s less reliable from today's perspective [5, 32, 57]. Without current, clearly favorable clinical research findings, hallucinogen "treatments" for drug dependence hold only aging speculative "promise"

and are not accepted for any medical indication, including for those seeking treatment for their problematic drug use.

Acknowledgments The authors greatly appreciate the editing assistance of medical student Sean Doherty of Cardiff University School of Medicine.

Molecular Genetics and the Treatment of Addiction

Lara A. Ray and Kent E. Hutchison

Contents

Overview

Substance use disorders represent complex phenotypes that result from the intricate interplay of genetic variation, neurobiological mechanisms, psychosocial variables, and environmental variables. To date, one of the least studied factors has been genetic variation. However, basic research on the human genome is progressing at a rapid pace, and investigations of genetic factors that influence the etiology and treatment of substance use disorders are now much more common. The promise of this research is that it may help scientists optimize the success of treatments by matching specific treatments with individuals who have specific genetic vulnerabilities. The ability to match a specific treatment with an individual who is most likely to benefit from that treatment is especially exciting because, while a number of treatment alternatives exist, the overall effectiveness of these treatments is quite modest and there are currently no objective criteria that can be used to match an individual with the treatment that is most likely to be effective. It is only a matter of time before much of the genetic variation that contributes to the risk of addiction is uncovered and, likewise, only a matter of time before clinicians begin to utilize genetic information to match individuals with the treatment that is safest and most likely to benefit them.

This chapter provides a critical review of the expanding literature with respect to molecular genetics and the treatment of addiction. First, we present a brief overview of key concepts in the genetics of addictions. Second, we provide a more extended review and discussion of pharmacogenetics and pharmacogenomics applied to addiction medicine. Recent studies of genetic differences and responses to pharmacological, and to a lesser degree psychosocial, treatments for addictions will be reviewed for various substances of abuse, including alcohol, nicotine, cocaine, and opiates. Third, we discuss practical

and ethical issues in the translation of pharmacogenetics science into clinical practice. Fourth, we outline several future directions for the field of molecular genetics applied to the treatment of addictions. Finally, we present a summary and some concluding remarks.

Genetics and the Treatment of Addictions

Twin and adoption studies have suggested that approximately 50% of the variance in risk for developing alcohol dependence can be explained by genetic factors [24, 44]. Likewise, studies have demonstrated that genetic factors account for a significant portion of variance in drug use, abuse, and dependence [7, 27, 28, 45, 48, 92, 93]. The progression from initial use to abuse or dependence for substances such as marijuana and cocaine also appears to be largely due to genetic factors [46, 47].

Just as the etiology of substance use disorders appears to be under moderate genetic control, so does the response to pharmacotherapies. Broadly speaking, evidence for heritability of medication effects in psychiatry dates as far back as 1967, when heritable variation in plasma concentration of the tricyclic antidepressants, desipramine and nortriptyline, were first shown in twin and family studies [2, 30]. More recent research has also documented the heritability of response to typical antipsychotics [98], including differences in antipsychotic response among ethnic groups [1, 21]. As discussed in detail below, genetic factors also seem to play a role in response to pharmacotherapies, and perhaps psychosocial treatments, for substance use disorders.

After determining that genetic variation plays a substantial role in the etiology of addictive disorders and the response to treatment through family, twin, and adoption studies, the next step in genetics research often consists of identifying specific genetic variations that contribute to the etiology and response to treatment for these disorders. In many ways, research on genetics of addiction has already transitioned from establishing that genetic variables contribute to the variance in a disorder to identifying the specific genetic variables that actually contribute to the disorder.

Currently, there are two basic approaches to the identification of genetic variations that influence substance use disorders and/or treatment outcomes. The first is a hypothesis-driven approach, in which investigators develop a priori hypotheses based on what is known about the genetic variation and the neurobiology of the disorder or the mechanism of action for a specific treatment. For example, one might hypothesize that a specific genetic variation that influences the mu-opioid receptor expression might also predict acute responses to alcohol [8, 74] and the effects of a medication (e.g., naltrexone) that targets this receptor [3, 66, 78].

In many cases, it is more common to work with a gene for which function variations have yet to be identified. In this situation, a variation on the approach described above is to hypothesize that a gene is related to a specific aspect of a substance use disorder or the effects of a medication and then use special analytic approaches to probe genetic variation across the entire gene. This approach is commonly known as a haplotype-based approach, and is designed to capture most of the genetic variation across the gene even when the function variations have not been identified. To that end, "tag single nucleotide polymorphisms" are often used as they allow scientists to capture genetic variation in various loci by genotyping fewer, but informative, markers. More specifically, tag single nucleotide polymorphisms are selected on the basis of patterns of linkage disequilibrium that indicate whether several polymorphisms are highly correlated, in which case, instead of having to genotype all markers, scientists can identify a few that strongly predict genetic variation in a given area or locus. This approach has become increasingly accessible due to the availability of bioinformatics resources, most notably results from the International HAPMAP Project, which have been made publicly available in the user-friendly HAPMAP Project Web site (http://www.hapmap.org/). The next step after

identifying tag single nucleotide polymorphisms for areas of interest is often to build haplotypes, which describe common patterns of DNA sequence variation. In fact, the objective of the HAPMAP Project is to develop a haplotype map of the human genome, which in turn can aid scientists in finding genes affecting health, disease, and responses to medications and environment [22, 41, 90]. A detailed review of haplotype-based techniques in pharmacogenetics is beyond the scope of this chapter and can be found elsewhere [57].

Finally, a more recent approach is to conduct exploratory genome-wide analyses to identify genetic variation that influences substance use disorders or responses to medications. The genome-wide association study is currently in vogue and represents one of the most cutting-edge approaches in terms of identifying sources of genetic variation that may eventually be used to predict response to treatment. A genome-wide association study utilizes a high-density single nucleotide polymorphism array to generate data on more than one million genetic markers (e.g., using the Illumina 1 M array). This vast array of genetic data can then be analyzed in combination with a set of phenotypes. A number of reviews have been published recently on the advantages, disadvantages, limitations, and recommendations associated with this approach [11, 68, 89]. One obvious problem with this approach is the sheer number of statistical tests and the resulting increase in Type I error that may lead to false positives. A corollary is the requirement of strict statistical corrections and the need for massive sample sizes. To date, there have been a number of genome-wide association study reports in the psychiatric genetics literature, including major depressive disorder [9], bipolar disorder [19], and schizophrenia [65], but only one that involves a substance abuse disorder, namely nicotine dependence [95]. While genome-wide association is the approach du jour and has generated much excitement in the field, it is important to note that genome-wide association studies represent a transition to even more difficult and time-consuming work. Once new genetic variations are identified, models will need to be developed and hypothesis-driven research will be needed to translate the effect of genetic variation uncovered in the genome-wide association studies regarding the effect of the genetic variations from the molecular level, to the cellular level, to the systems level, and to the behavioral level in order to understand the implications of these findings for the etiology, prevention, and treatment of substance use disorders. This translation will likely lead to new findings on as yet unknown neuronal mechanisms that influence the development of substance use disorders and lead to new targets for pharmacotherapies as well as generating information about which individuals will be most likely to respond to those new pharmacotherapies.

Pharmacogenetics and Pharmacogenomics

Pharmacogenetics is a field of research that seeks to understand individual differences in the metabolism and efficacy of medications. As described by Vogel [97], pharmacogenetics is the study of heritable differences in the metabolism and activity of exogenous agents, including medications and environmental toxins. Current pharmacogenetics research focuses on identifying genetic factors that account for variability in pharmacotherapy effects, in terms of both pharmacodynamics and efficacy [16, 61]. In recent years, the term pharmacogenomics has been defined [81] as the application of genomics to the study of pharmacogenetics. In brief, the distinction between the two terms refers to the methodological and theoretical approach such that pharmacogenetics investigations are generally hypothesis driven and focus on a few loci at a time. Conversely, pharmacogenomics investigations include the use of high-throughput genotyping and genome-wide association approaches to understanding genetic determinants of pharmacotherapy response. In essence, the objective of pharmacogenomics is the same as pharmacogenetics, which is to elucidate genetic variants that influence the efficacy and safety of

pharmacotherapies. For simplicity, we will refer simply to pharmacogenetics in this chapter.

The field of pharmacogenetics has grown rapidly and has greatly benefited from advancements in molecular genetics tools for identifying gene polymorphisms, developments in bioinformatics and functional genomics, and new findings from the human genome project. The foremost goal of this line of research is to optimize pharmacotherapy by identifying genetic factors that predict who is more likely to respond to certain pharmacotherapies and who will not respond, thereby matching individuals to medications on the basis of genetic factors. Genetic factors can account for individual differences in medication toxicity and response in many ways. Genetic polymorphisms may lead to functional differences in medication metabolism and disposition, such as functional differences in enzyme activity or medication transporters. Alternatively, genetic polymorphisms may impact the target of a medication, such as a particular receptor. An example of the first case is a polymorphism of the CYP2D6 gene, which is involved in the availability of specific medication-metabolizing enzymes associated with one's response to opioid painkillers, such as codeine or morphine. Individuals who are homozygous for the nonfunctional CYP2D6 alleles were found to be resistant to the analgesic effects of opioid painkillers [70].

On the other hand, genetic polymorphisms involved in a medication's target may also impact one's response to pharmacotherapy. For example, polymorphisms of the dopamine D4 receptor gene (DRD4) have been associated with differential response to antipsychotic medications [10]. There is also a growing literature on the pharmacogenetics of antidepressant medications [49]. Specifically, research has suggested that the functional polymorphism of the serotonin transporter gene located in the 5′ upstream regulatory region consisting of a 44-base pair insertion/deletion, which results in a long or short variant, predicts response to various selective serotonin reuptake inhibitors, including fluoxetine [71], fluvoxamine [88], and paroxetine [99]. Carriers of the long allele of the serotonin transporter promoter polymorphism have better clinical response to antidepressant medications compared with individuals who are homozygous for the short allele, which results in two-fold decreased expression and transport activity of the receptor in vitro [32]. These results suggest that pharmacogenetics may soon inform a more targeted use of antidepressant medications. In addition to medications' efficacy, pharmacogenetics research has focused on identifying susceptibility loci contributing to adverse effect profiles and medications' toxicity, thereby enhancing the safety profile of pharmacotherapies. Next, we will review pharmacogenetic studies in the field of addictions to various substances of abuse.

Alcohol

Several studies to date have investigated genetic polymorphisms in the context of pharmacotherapies for alcohol dependence. Naltrexone, a mu-opioid receptor antagonist, is one of the very few pharmacotherapies currently approved for the treatment of alcoholism by the United States Food and Drug Administration. From a pharmacogenetics perspective, there has been recent interest in the gene coding for mu-opioid receptors (OPRM1), as they represent a primary target of naltrexone. More specifically, studies have focused on the Asn40Asp mutation of the OPRM1 gene, given evidence that this nonsynonymous mutation leads to an amino acid change, which in turn codes for more potent receptors. Human laboratory studies have shown that the Asp40 allele of the OPRM1 gene is associated with greater sensitivity to the reinforcing effects of alcohol [74] and greater neural activation in the mesocorticolimbic structures following a priming dose of alcohol [20].

In a pharmacogenetic study of naltrexone, Oslin and colleagues [66] found that the Asn40Asp allele of the OPRM1 gene was associated with clinical response to naltrexone for the treatment of alcohol dependence. The relationship was such that individuals with at least one copy of the Asp40 variant showed lower relapse rates and longer time to return to heavy

drinking when treated with naltrexone, as compared with homozygotes for the Asn40 allele [66]. These findings have been recently replicated and extended in the multisite COMBINE Study, such that carriers of the Asp40 allele of the OPRM1 gene had better clinical response to naltrexone, in combination with medication management, as compared with homozygotes for the Asn40 allele [3]. A double-blind, placebo-controlled laboratory trial of naltrexone (50 mg) found that carriers of the Asp40 allele of the OPRM1 gene showed significantly greater naltrexone-induced blunting of the alcohol "high", as compared with individuals who were homozygous for the Asn40 allele [78]. These findings suggest that the differential clinical response to naltrexone may be due to differential blunting of alcohol-induced reward as a function of genotype and propose a mechanism for this important pharmacogenetic relationship. Nevertheless, there have been null findings regarding the association between this functional polymorphism and the efficacy of naltrexone for alcoholism [33] such that further work is necessary before these findings can be translated into clinical practice.

Limitations notwithstanding, the pharmacogenetics of naltrexone and the putative moderating effects of a functional single nucleotide polymorphism of the OPRM1 gene represent an interesting line of work that is both promising and exciting from a pharmacogenetics perspective. In this case, functional variation in a gene coding for a medication (i.e., naltrexone) target, namely mu-opioid receptors, may be used to predict the efficacy of a pharmacotherapy. This case most likely represents an exception, rather than the rule, in pharmacogenetics research as most pharmacotherapies do not have such targeted neurobiological effects and the functional significance of most single nucleotide polymorphisms are not well characterized.

Using a similar hypothesis-driven approach, a series of pharmacogenetic studies have tested the association between olanzapine, a medication that targets dopamine receptors, alcohol craving, and a polymorphism of the dopamine D4 receptor gene (DRD4 variable number tandem repeat) [37–39]. One study found an association between the 7-repeat allele of the DRD4 variable number tandem repeat polymorphism and increased craving for alcohol after a priming dose of alcohol [36]. Another study found that olanzapine decreased craving after a priming dose of alcohol in a non-clinical sample of college drinkers [39]. Finally, results from a recent clinical trial revealed that the efficacy of olanzapine in the treatment of alcohol dependence was moderated by this genetic variation, such that individuals with at least one copy of the long allele showed greater reductions in cue-elicited craving and greater decreases in alcohol consumption during the 12-week clinical trial, as compared with individuals who were homozygous for the short allele [37]. This genetic variation has also been associated with increased activation of mesocorticolimbic regions during the presentation of alcohol cues [20]. Together these series of laboratory and clinical trials have established a relationship between a polymorphism of the DRD4, craving for alcohol in the laboratory, and response to a medication that targets dopamine receptors.

The approach in this series of studies of olanzapine for alcoholism was theory driven and focused on intermediate phenotypes for alcoholism, in this case alcohol craving, rather than the diagnostic phenotype of alcohol dependence per se. There are important advantages to a theory-driven pharmacogenetics approach, such as the ability to answer more specific questions about the mechanisms of action of pharmacotherapies, genetic variants, and biobehavioral risk makers of complex disorders, such as alcoholism. Importantly, theory-driven approaches can be complementary to data-driven pharmacogenomics investigations, which are likely to become increasingly accessible given recent advances in DNA genotyping technology.

Nicotine

Currently, there are two non-nicotine pharmacotherapies approved by the United States

Food and Drug Administration for the treatment of nicotine dependence, namely bupropion hydrochloride and varenicline. In addition, there are five Food and Drug Administration-approved nicotine replacement therapies, which vary mostly in terms of their delivery kinetics; these include transdermal patch, gum, lozenge, inhaler, and nasal spray. Several candidate genes have been subjected to pharmacogenetic studies, mostly those of nicotine replacement therapies and bupropion as described in recent reviews of the pharmacogenetics of smoking cessation [6, 64, 80]. Specifically, pharmacogenetic studies of nicotine dependence have examined genes underlying the metabolism of nicotine, focusing primarily on the cytochrome P450 2A6 gene (CYP2A6). This gene codes for the primary enzyme that converts nicotine to cotinine and cotinine to 3-hydroxycotinine. In a study of transdermal patch and nasal spray nicotine replacement therapies, at the same levels of nicotine replacement, carriers of CYP2A6 alleles coding for a slower metabolism were found to have higher plasma nicotine concentrations following 1 week of the nicotine patch than normal metabolizers [59]. Those differences were not seen using the nasal spray, and at 6-month follow-up, slow metabolizers had higher quit rates in the transdermal patch condition, as compared with normal metabolizers [54]. However, the results have not been consistent, and a study found that slow metabolizers had higher relapse rates when treated with the nicotine patch [67].

Nicotinic receptor genes have also been subjected to pharmacogenetic investigations. Nicotine binds to nicotinic acetylcholine receptors, which are ligand-gated ion channels for which there are several subunits. Allelic variation in the gene coding for the nicotinic acetylcholine receptor's α4 subunit (CHRNA4) has been associated with nicotine dependence [18, 56]. More recent molecular work has suggested that certain single nucleotide polymorphisms in the CHRNA4 gene are functional and related to smoking cessation during nicotine replacement therapy [35]. Although promising, these findings await replication. Likewise, a series of studies have examined the role of functional genetic variation in the DRD2 in response to bupropion and nicotine replacement therapy [42, 52]. Results revealed that the DRD2–141C Ins/Del genotype was associated with treatment response to bupropion, such that smokers homozygous for the Ins C allele had a more favorable response to treatment compared with those carrying the Del C allele. Conversely, regardless of nicotine replacement therapy type, those carrying the Del C allele had higher quit rates from nicotine replacement therapy compared with those homozygous for the Ins C allele [52]. Additional polymorphisms that have received attention as putative genetic moderators of smoking cessation in response to nicotine replacement therapies and bupropion include dopaminergic genes (e.g., the Val/Met single nucleotide polymorphism of the catechol-*O*-methyltransferase gene) [53], opioidergic genes (e.g., Asn40Asp single nucleotide polymorphism of the OPRM1 gene) [55, 79], and serotonergic genes (e.g., the serotonin transporter promoter polymorphism) [63].

Perhaps one of the more exciting new developments in the pharmacogenetics of smoking cessation is a series of genome-wide association studies of smoking cessation with bupropion and nicotine replacement therapy [95]. These studies revealed that genetic variants in quit-success were likely to alter cell adhesion, enzymatic, transcriptional, structural, and protein-handling functions. The genes identified through these genome-wide association studies had modest overlap with genes associated with addictions and memory processes. Clearly, as noted above, there are limitations to the genome-wide association approach, and these results should be interpreted with caution until replicated in an independent sample.

Cocaine

Currently, there are no Food and Drug Administration-approved pharmacotherapies for the treatment of cocaine dependence; nor have there been any compelling findings with respect to specific genetic variations that influence the

trajectory of cocaine dependence or treatment outcomes. However, several pharmacotherapies are currently under study for stimulant use disorders, and some of the most promising ones include gamma-aminobutyric acid agents (e.g., topiramate, tiagabine, baclofen, and vigabatrin) and agonist replacement agents such as modafinil and methylphenidate [43]. Nevertheless, much work has yet to be done in identifying efficacious pharmacotherapies for cocaine and stimulant dependence before pharmacogenetic investigations can take place.

Opiates

Opiate addiction is treated pharmacologically through opiate agonists, antagonists, and partial agonists; for a review see [29]. The first medication for opioid addiction was methadone, a selective synthetic opioid agonist [12]. Buprenorphine is another synthetic opiate that functions as a partial agonist at mu-opioid receptors and an antagonist at kappa-opioid receptors [51]. Both methadone and buprenorphine are equally effective for maintenance treatment of heroin dependence [60]. Methadone and buprenorphine are metabolized by CYP3A4; however, buprenorphine is metabolized to a much lesser degree than methadone by CYP2D6. Studies have found that Caucasians who lack CYP2D6 function have a poor metabolizer phenotype, which in turn is protective against opiate dependence [94]. Nevertheless, when slow opioid metabolizers go on to develop opioid addiction, they tend to respond well to methadone treatment, whereas opioid-dependent individuals with the CYP2D6 genotype coding for the "ultra rapid" opioid metabolism are less responsive to the withdrawal relief afforded by methadone maintenance therapy [69] and respond better to buprenorphine, which is not as significantly metabolized by CYP2D6. The case of pharmacogenetics of opioid addiction is an interesting one in that what was learned about the pharmacogenetics of responsiveness to opiates for pain management purposes (described above) has informed the clinical literature on the use of opiates for the treatment of opiate addiction and has ultimately led toward the optimization of pharmacotherapy for opioid dependence.

An Intermediate Phenotype-Driven Pharmacogenetics Approach

Recent research has increasingly recognized the heterogeneity of diagnostic phenotypes and argued for the development of more discrete and homogeneous phenotypes, or intermediate phenotypes, for psychiatric disorders of complex genetics [25, 26], including addictions [13, 34]. Recently, intermediate phenotypes have been further refined as translational phenotypes, which emphasizes the role of the phenotype in translating the effect at the genetic level to the clinical level [40]. An ideal translational phenotype is one that is narrowly defined and biologically based with a plausible link to the gene as well as the clinical presentation of the disorder. The use of intermediate phenotypes for disorders of complex genetics has allowed for progress in genetic association studies, and importantly, this approach not only increases power to detect genetic effects but also allows scientists to ask different research questions about the neurobiology and mechanisms underlying disease processes and pharmacotherapy response. When applied to pharmacogenetics research, intermediate or translational phenotypes often involve examining mechanisms of medication response that go beyond clinical outcomes. Examples of intermediate phenotypes for substance use disorders include craving for a substance, withdrawal mechanisms, substance-induced reward, reinforcing value of the substance, and response inhibition processes, to name a few.

Based on the literature on intermediate phenotypes for addictions and their potential to advance etiological and treatment approaches to these disorders, a conceptual model that integrates translational addiction phenotypes, genetic factors, and pharmacological treatments

for addictions is clearly warranted [77]. In this model, phenotypes, such as subjective responses to alcohol, represent an important translational link between genetic variations and the effects of medications and clinical outcomes. More specifically, this theoretical framework may be used to improve our understanding of pharmacotherapies for addictions in several ways (Fig. 1). First, intermediate phenotypes for alcoholism, such as alcohol craving and subjective responses to alcohol, have been shown to predict drinking behavior and the risk for developing alcohol use disorders [34, 36, 73, 83, 91]. Second, medications found to operate at the level of intermediate phenotypes, such as craving and subjective responses to alcohol [62, 75], may ultimately be effective in reducing drinking. In a recent example of this approach, a laboratory study found that aripiprazole increased the sedative effects of alcohol and decreased its euphoric and stimulant properties; those effects, in turn, are thought to capture the mechanisms of action of aripiprazole for alcoholism [50]. Third, genetic variants appear to underlie the expression of alcohol phenotypes such as craving [36, 58, 96] and subjective responses to alcohol [31, 74, 82]. Fourth, genetic variants associated with alcohol intermediate phenotypes may, in turn, be used to predict responses to pharmacotherapies thought to affect those phenotypes [36, 37, 74, 75].

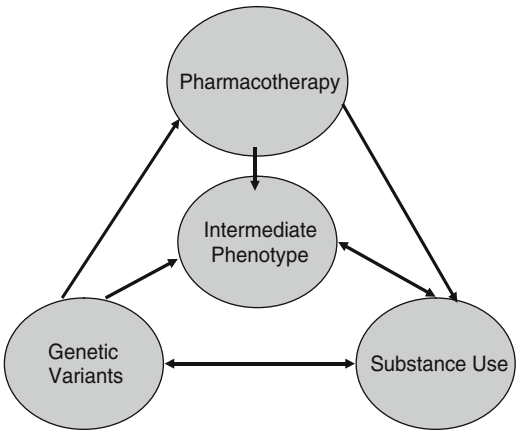

Fig. 1 An intermediate phenotype-driven pharmacogenetics model for addiction treatment

In sum, we have proposed that a theory-driven pharmacogenetic approach can be used to enhance the pharmacological treatment of alcoholism [77]. This approach is interdisciplinary and translational by definition, as it integrates aspects of behavioral genetics, pharmacology, and clinical and experimental science. Focusing on theory-driven addiction intermediate phenotypes and the genetic and neurobiological factors underlying these phenotypes may help us elucidate the mechanisms of action of pharmacotherapies, as well as moderators of response. Most importantly, this approach has the potential to enhance the translation of basic science to treatment, as it more directly connects translational phenotypes and genetic variants to pharmacotherapies for addictions. The intermediate phenotype-driven pharmacogenetics model described herein offers a potentially useful framework for better understanding how addiction phenotypes and genetic factors concomitantly influence responses to pharmacotherapies. Similar approaches may be useful in optimizing psychosocial interventions by targeting more specific and narrowly defined components of the risk for substance use disorders (i.e., prevention efforts) or the clinical syndrome itself (i.e., treatment efforts).

Optimizing Psychosocial Treatments Through Genetics

Molecular genetics may also inform psychosocial treatments for substance use disorders. In a recent example of the application of behavioral genetics to optimizing treatment, Bauer and colleagues [5] reported that variation within the GABRA2 gene, thought to increase the risk for alcoholism [14], predicted the response to the psychosocial interventions tested in Project MATCH. Specifically, the low-risk allele was associated with more robust differences in drinking outcomes in the trial, enhancing the superiority of 12-step facilitation over cognitive behavioral therapy and motivational enhancement therapy [5]. A recent study examined the

DRD4 variable number tandem repeat polymorphism, previously linked to alcohol use and cue reactivity [36], possibly through an underlying impulsivity phenotype [15, 72], and response to a brief motivational intervention [17]. The findings suggested that heavy-drinking college students who were carriers of the long allele of the DRD4 variable number tandem repeat polymorphism were more impulsive and less likely to benefit from the brief motivational intervention for drinking problems. In summary, these results indicate that the assessment of genetic liability may also be important to studies of the efficacy of psychosocial interventions. More broadly, these results allude to the importance of integrating biological and psychosocial variables to capture more fully the clinical phenomenon of addiction and its treatment.

Translating Pharmacogenetic Approaches into Practice

In anticipation of the translation of pharmacogenetic approaches into practice, issues of physicians' attitudes and training have received recent attention, particularly in the field of smoking cessation, a highly prevalent chronic condition and public health concern. In a national mailed survey study of 2,000 primary care physicians in the United States, the self-reported likelihood that physicians would offer a new test to tailor smoking cessation treatment ranged between 69 and 78%, across various scenarios [87]. Describing the test as genetic versus non-genetic decreased the likelihood of physicians offering the test across all scenarios. Moreover, physicians were less likely to offer the test when the scenario indicated that the same genotypes used for treatment tailoring may identify individuals at risk for other conditions (e.g., cocaine or alcohol addiction), differed in allele frequency by race, and may also predict individuals predisposed to become addicted to nicotine [87]. The authors concluded that physicians' responses may reflect an assumption of greater complexity in genetic testing, as compared with other laboratory tests, for example. A broader survey of genetic testing in clinical practice, non-specific to addictions, revealed that physicians serving minority patients were less likely to use, and refer for, genetic testing in their practice [85]. In short, it has been suggested that several steps are necessary to facilitate the translation of pharmacogenetics science to practice, especially in primary care, including issues such as physicians' training and experience, organizational-level policy, and infrastructure, including reimbursement for pharmacogenetic testing and protections of privacy and against discrimination [84, 86]. Those practical and ethical issues warrant further attention as they are critical to the integration of pharmacogenetic treatment strategies for addiction.

Future Directions of Molecular Genetics and Addiction Treatment

In many ways, the future impact of genetic research on addiction medicine will depend on the substance use disorder in question. For example, there are currently no medications approved for cocaine dependence but a number that have been approved for alcohol dependence. The opportunity to make progress with respect to identifying genetic variation that influences treatment effectiveness for cocaine dependence is limited by the lack of approved medications for cocaine dependence. Additional directions for future research include:

a) There is great need and opportunity to develop robust brain-based translational phenotypes for each substance use disorder, thereby examining specific mechanisms of genetic risk and therapeutics for various substances of abuse [40]. Brain-based translational phenotypes may also be informative in investigations of pharmacotherapies for addictions as they can advance the knowledge on the neuropharmacological mechanisms of medications' efficacy as well as help identify

genetic factors that may operate at the neural level, leading to differential clinical response to a given pharmacotherapy.

b) Genome-wide association studies with refined behavioral and brain-based phenotypes are necessary to isolate important sources of genetic variation. These initial findings of genome-wide association studies can lead to more refined genetic analyses, including custom genetic panels designed based on the more consistent findings of genome-wide association studies.

c) Laboratory-based studies of candidate medications using behavioral and brain-based translational phenotypes are needed to inform large-scale clinical trials and address more specific and mechanistic questions regarding medications' efficacy. Specifically, these phenotypes not only enhance power to detect genetic effects, they also allow scientists to answer more nuanced questions regarding the pathophysiology of addictive disorders and their pharmacological treatment [76].

d) According to recent research, genotypes used to tailor the pharmacological treatment of alcohol and nicotine dependence may vary in allele frequencies across populations [23]. For instance, the Asn40Asp allele of the OPRM1 gene, thought to predict clinical response to naltrexone for the treatment of alcoholism, has a minor allele frequency of approximately 20–25% in individuals of European ancestry, 50% in Asians, and <5% in African-Americans [4]. If treatment recommendations are to be developed based on genetic variants, careful attention to issues of allele frequency across racial and ethnic groups is essential in ensuring that appropriate recommendations are made and that the ethical principle of beneficence is upheld across populations.

e) Clinical scientists need to integrate multiple pieces of information to determine which medications have promise, which genetic variables are likely to predict the effectiveness of those medications, and for which population. Clearly, much work has yet to be done before these findings are translated into clinical practice.

f) Educating and training physicians to implement pharmacogenetic treatment strategies in clinical practice is critical to the translation of science into practice. As discussed above, much work remains to be done in the area of physicians' training and education before pharmacogenetic findings for addictions can be disseminated into clinical practice [84, 87].

Summary and Conclusions

Translational approaches such as the ones described in this chapter have the potential to inform clinical practice by identifying individuals who are more likely to benefit from a given pharmacotherapy on the basis of genetic factors. At present, efforts at optimizing pharmacotherapy on the basis of genetic factors, often referred to as personalized medicine, remain incipient, and considerable research is required before these findings can be translated into clinical practice. Important issues such as the differential frequency of certain gene variants among various ethnic groups and the clinical significance of these differential treatment responses must be evaluated carefully in future pharmacogenetic trials and before translating these findings to clinical practice. Likewise, as the technology for high-throughput genotyping becomes increasingly accessible, the use of genomic approaches to the study of pharmacotherapy response will become more widespread, hopefully leading to more consistent findings that can be more rapidly translated into clinical practice. Limitations notwithstanding, research efforts in pharmacogenetics and pharmacogenomics hold considerable promise for optimizing treatment for a host of medical and psychiatric disorders, including addiction.

Introduction

The effects of chronic ingestion of alcohol and other substances of abuse vary considerably and depend on the concentration and dose, together with various other factors, such as nutritional status, gender, and ethnicity. The present chapter analyzes the main medical consequences related to substance abuse, particularly alcohol, nicotine, opioids, cocaine, amphetamine, and benzodiazepines. The effects of these substances on the liver, gut, pancreas, nervous system, cardiovascular system, and endocrine system will be discussed. The link between substance abuse disorders and tumors will also be reported, as well as the relationship between substances of abuse and nutrition and body composition.

Liver

Alcohol

Alcoholic liver disease is one of the major medical complications of alcohol abuse [185]. In particular, 80% of heavy drinkers develop steatosis, 10–35% develop alcoholic hepatitis, and approximately 10% will develop cirrhosis [185]. Steatosis represents an abnormal retention of lipids accumulated in vesicles that displace the cytoplasm of the hepatocytes. Although liver function is usually normal, if alcohol abuse continues steatosis may progress to cirrhosis [185] (Table 1).

It has been suggested that 15–20 years of alcohol abuse are necessary to develop alcoholic hepatitis, which usually results in cholestasis [185]. When alcohol abuse is persistent for a long period and generally follows a regular pattern, an individual can often develop cirrhosis. Alcoholic liver disease represents the most common cause of liver cirrhosis in the Western world [177, 178]. Liver damage is related to the toxicity of alcohol being linked to its metabolism via alcohol dehydrogenase. Alcohol dehydrogenase converts nicotinamide adenine dinucleotide to nicotinamide adenine dinucleotide-reduced form, which contributes to hyperuricemia, hypoglycemia, and hepatic steatosis by inhibiting lipid oxidation and promoting lipogenesis [118]. Another pathway of ethanol metabolism is the microsomal ethanol oxidizing system. The activity of its main enzyme, cytochrome P4502E1 (CYP2E1), and its gene are increased by chronic consumption, resulting in metabolic tolerance to ethanol [118]. Twin studies suggest a genetic component to disease susceptibility [94]. In white people, associations between alcoholic liver disease risk and polymorphisms of the genes encoding the cytochrome P-450 have been shown [185]. The activity of the cytochrome P4502E1 is also associated with the generation of free radicals, with resulting lipid peroxidation and membrane damage as well as depletion of mitochondrial reduced glutathione and its ultimate precursor—methionine activated to *S*-adenosyl-*L*-methionine [118]. The involvement of free radical mechanisms in the pathogenesis of alcoholic liver disease is demonstrated by the detection of lipid peroxidation markers in the liver and the serum of alcohol-dependent individuals, as well as by experiments in alcohol-fed rodents that show a relationship between alcohol-induced oxidative stress and the development of liver pathology [9, 15, 19]. In particular, oxidative stress promotes hepatocyte necrosis as well as a pro-apoptotic action via tumor necrosis factor-alpha. Furthermore, oxidative mechanisms can contribute to liver fibrosis by triggering the release of pro-fibrotic cytokines and collagen gene expression in hepatic stellate cells [19]. From a clinical point of view, alcohol-related damage can be present without any apparent symptoms or signs of liver disease. Otherwise, non-specific clinical features can include nausea, vomiting, or fatigue. When liver cirrhosis is present, typical cirrhosis-related signs and symptoms can include jaundice, ascites, encephalopathy, or upper gastrointestinal bleeding. Although two meta-analyses suggest that corticosteroids are beneficial in improving short-term survival in individuals with severe alcoholic hepatitis [96], the utility of using corticosteroids in the treatment of

Table 1 Main hepatic features in subjects with substance abuse or dependence

Substance	Main feature(s)	Other feature(s)
Alcohol	Enzyme induction; steatosis	Chronic liver disease; acute liver failure; liver cirrhosis
Nicotine	Enzyme induction	Risk factor for: gallstones; PSC; HCC
Opioids	Hepatotoxicity	High risk factor for hepatitis viruses, especially HCV
Cocaine	Hepatotoxicity	Impaired hepatic perfusion
Amphetamine	Hepatotoxicity	Chronic liver disease; acute liver failure
Benzodiazepines	Enzyme induction	Hepatotoxicity

PSC primary sclerosing cholangitis, *HCC* hepatocellular carcinoma, *HCV* hepatitis C virus

advanced alcoholic liver disease is still debated. In particular, while the short-term mortality is reduced, the benefits in terms of long-term mortality are still unknown. Propylthiouracil has also been proposed because it abolishes the ethanol-induced increase in liver oxygen consumption after long-term alcohol consumption [38]. S-adenosyl-L-methionine dietary supplement therapy has been used in alcoholic liver disease as it replenishes liver mitochondrial glutathione levels [49]. Acute alcohol hepatitis can be present in some cases of acute alcohol intoxication. Based on the assumption that tumor necrosis factor has a role in the pathogenesis of alcoholic liver disease, some recent studies have suggested a role of infliximab and pentoxifylline in alcoholic liver disease. Infliximab is an anti-tumor necrosis factor antibody [176], while pentoxifylline is a non-selective phosphodiesterase inhibitor that has a moderate anti-cytokine effect attributed to reduced transcription of the gene that encodes tumor necrosis factor [165]. However, further studies are needed to confirm these preliminary results. Orthotopic liver transplantation represents an option when liver cirrhosis is present. Survival after a liver transplant for alcoholic cirrhosis is similar to—or even better than—that for other end-stage liver diseases [176, 185]. Abstinence for at least 6 months before transplantation is required. However, several ethical concerns are still present due to the limited availability of liver transplants and the risk of relapse after the transplantation [176, 185]. Independent of the stage of disease, abstinence from alcohol is the cornerstone of management. Accordingly, total alcohol abstinence can improve the histology and/or survival of individuals with alcoholic liver disease [176] and the clinical outcome of all stages of alcoholic liver disease [59]. Persistent alcohol intake in those with alcoholic cirrhosis is associated with a significant risk ratio of death [150] due to bleeding esophageal varices, infection, renal failure, and/or hepatic failure [191]. In recent decades, several medications able to reduce alcohol craving and, consequently, to increase abstinence and prevent alcohol relapse have been evaluated—i.e., naltrexone, acamprosate, and topiramate [10, 11]. However, trials investigating anti-craving medications typically exclude individuals with high levels of transaminases and/or advanced liver disease [24, 72]. Furthermore, naltrexone is contraindicated in those with liver disease due to its hepatic metabolism and reports of medication-related hepatic injury [27]. A more recent compound that is potentially useful in the treatment of alcohol dependence is the gamma-aminobutyric acid-B agonist baclofen [13]. Baclofen is mainly eliminated by the kidney. No hepatic side effects have been reported in treated individuals. A recent trial demonstrated the efficacy and safety of the gamma-aminobutyric acid-B baclofen in the treatment of alcohol-dependent individuals affected by liver cirrhosis [14]. This last study suggested that baclofen is effective at promoting alcohol abstinence in alcohol-dependent individuals with liver cirrhosis and is well tolerated [14]. Due to the lack of hepatic side effects, baclofen may have an important role in the treatment of these individuals [73].

Nicotine

Several preclinical studies suggest an influence of nicotine on the hepatic enzymatic systems. For example, the chronic exposure of rats to cigarette smoke does not alter hepatic biotransformation processes [81].

However, in a rat model of cirrhosis, a reduction of nicotine metabolism has been observed and linked to the decreases in cytochrome P450 and flavin-containing mono-oxygenase protein expression levels [137]. Clinical studies have often been performed considering both smoking and alcohol consumption. Whitehead et al. [187] evaluated a large population of 46,775 men and showed a joint effect of cigarette smoking and alcohol consumption in increasing the levels of gamma-glutamyl transferase, while alcohol but not cigarette smoking was related to an increase of transaminases [187]. In other words, nicotine is able to modify the hepatic enzymatic system but not to induce liver damage. Consistently, smoking does not appear to be a risk factor for cirrhosis of the liver [25].

On the other hand, a link between smoking and hepatocellular carcinoma has been suggested since constituents of cigarette smoke are hepatic carcinogens in animals [193]. Cigarette smoking has been suggested as an important risk factor for primary sclerosing cholangitis and gallstones, although in the latter case other co-factors should be taken into account, such as gender, alcohol consumption, overweight, etc. [25]. Finally, there is growing interest in the role of nicotine in those individuals with liver disease who are undergoing surgical procedures, particularly orthotopic liver transplantation. In a recent study [62], 60% of orthotopic liver transplantation recipients reported a lifetime history of smoking, with 15% reporting smoking post-orthotopic liver transplantation. Of smokers who quit before orthotopic liver transplantation, 20% reported relapse to smoking post-orthotopic liver transplantation. This observation has been subsequently confirmed by DiMartini and colleagues [60], who showed that individuals with alcoholic liver disease resume smoking early post-orthotopic liver transplantation, increase their consumption over time, and quickly become tobacco dependent.

Opioids

Preclinical studies show that opioid substances, such as morphine, heroin, meperidine, and methadone at therapeutic doses, do not usually produce irreversible damage to human hepatocytes, while opiate doses during tolerance or abuse may be a cause of liver dysfunction [79]. However, it has also been noted that chronic use at therapeutic doses of opioids such as tramadol and, most of all, morphine for the management of chronic pain increases liver damage via oxidative stress and induction of apoptosis [148]. Consistent with the preclinical findings, intravenous drug abusers are commonly found to have altered transaminases [186]. However, from a clinical perspective, the most important implications of opioid abuse and dependence are related to the high prevalence of hepatitis infection. In fact, over 90% of intravenous heroin addicts carry the hepatitis C virus [171]. Accordingly, a hepatitis C virus-related elevation of the liver enzyme can be present, along with several stages of liver damage leading to cirrhosis [171]. Furthermore, several extrahepatic clinical features can be present (e.g., immune suppression, collagen diseases, lymphoma, and leukemia) and included in the so-called "hepatitis C virus syndrome" [171]. The hepatitis B virus may hold a similar chronic and degenerative course [171].

Cocaine

Animal data show cocaine-induced liver damage including periportal and portal damage and elevated transaminases [153]. In subjects using cocaine, acute hepatotoxicity and hepatocellular necrosis have been described [80], perhaps via oxidative stress [163]. However, because cocaine is a sympathomimetic, impaired hepatic perfusion potentially may be a contributing factor together with other conditions (e.g., rhabdomyolysis) that are often present in subjects with cocaine abuse [163]. Interestingly, the concurrent use of cocaine and alcohol produces another psychoactive substance called cocaethylene and can induce significant liver damage [23].

Amphetamine

Methylenedioxymethamphetamine (ecstasy) and amphetamine abuse can be associated with serious liver clinical features. Intoxication with amphetamine or methylenedioxymethamphetamine can be associated with severe hepatotoxicity [100]. Also, chronic abuse of amphetamines/methylenedioxymethamphetamine can be associated with either subclinical liver damage [102] or cholestatic chronic liver damage [100]. Histologic features include confluent necrosis and ballooning degeneration in centrilobular zones [102]. The use of steroids has been suggested according to a possible immune-mediated component of amphetamine-related hepatic damage, while the benefit/risk ratio of

orthotopic liver transplantation for fulminant hepatic failure is still controversial [100].

Benzodiazepines

Liver alterations can be present in subjects abusing benzodiazepines, especially those with a liver metabolism like diazepam and chlordiazepoxide. Subjects with benzodiazepine abuse or dependence can present with an increase of gamma-glutamyl transferase, reflecting the chronic enzymatic induction [91]. With a much lower frequency, benzodiazepines such as diazepam and chlordiazepoxide can induce cholestatic hepatotoxicity by a hypersensitivity mechanism [163]. Furthermore, the use of benzodiazepines needs to be evaluated carefully in those alcohol-dependent individuals with liver damage, taking into account the possibilities of both dual substance abuse (alcohol and benzodiazepines) and the need to administer benzodiazepines to treat alcohol withdrawal symptoms.

Gut and Pancreas

Alcohol

The effects of alcohol on the gastrointestinal apparatus include those on the esophagus, stomach, small bowel, colon, and pancreas. Excess alcohol ingestion at the esophageal level is able to induce the Mallory-Weiss syndrome due to vomiting. In the Mallory-Weiss syndrome, 60–80% of patients are seen to have consumed important amounts of alcohol in the hours before [36]. Gastroesophageal reflux is also facilitated in these individuals for the existence of esophageal peristaltic dysfunction, making easier the development of esophagitis and/or Barrett esophagus [172]. Furthermore, alcohol is able to cause direct damage of the mucosa via alterations in epithelial transport, intercellular junction disorders, and impairment of the mucosal barrier [36]. Both superficial and chronic atrophic gastritis are common in alcoholics. For example, 25.8% of alcohol-dependent individuals enrolled in detoxification programs present with superficial gastritis, and 24.2% have chronic atrophic gastritis. In healthy subjects, the incidence is 10.7% for superficial gastritis and 3% for chronic atrophic gastritis. A recent study indicates that moderate consumption of wine and beer (approximately 7 units/week) protects against *Helicobacter pylori* infection [136]. However, more generally it seems that chronic *Helicobacter pylori* infection, and not alcohol per se, is the major causative agent of chronic gastritis in alcohol-dependent individuals [172]. Consistently, epidemiological studies have concluded that both acute and chronic alcohol consumption are not associated with an increase in the risk for a gastric or duodenal ulcer [172]. In the small intestine, acute and chronic alcohol misuse impairs the barrier function of the gastrointestinal mucosa, resulting in increased permeability and translocation of macromolecules. Bacterial overgrowth in the small intestine has been also demonstrated in individuals with chronic alcohol abuse. These bacteria may cause mucosal damage and contribute to malabsorption [155]. Exposure of the mucosal side of the small intestine to alcohol inhibits the active transport of numerous macro- and micronutrients across the epithelial layer, such as folate and others. Moreover, alcohol affects the metabolism of carbohydrates and lipids in the brush border membrane of the small intestinal mucosa by damaging the villi, where lactase and sucrase are located. The activities of both enzymes are reduced, which may exacerbate lactose intolerance. However, the activities of lactase and sucrase return to normal within weeks of abstinence [155]. Acute alcohol reduces impending wave motility and increases propulsive wave motility; this may result in reduced transit time to the colon and diarrhea [155]. Conversely, chronic alcohol misuse may induce a reversible prolonged orocecal transit time [2]. Both abnormalities could contribute to diarrhea as shortened transit reduces absorption while prolonged transit predisposes to bacterial overgrowth. In contrast to the organs of the upper gastrointestinal tract, the mucosa of

Table 2 Main gastrointestinal and pancreatic features in subjects with substance abuse or dependence

Substance	Main feature(s)	Other feature(s)
Alcohol	Gastric and intestinal motility disorders; malabsorption; pancreatitis	Esophagitis; Mallory-Weiss syndrome; esophageal varicosities; acute and chronic gastritis; peptic ulcer disease; bacterial overgrowth; acute and chronic pancreatitis
Nicotine	Peptic ulcer disease; risk factor for pancreatic carcinoma	Gastroesophageal reflux disease; atrophic gastritis; reduced risk of developing UC; detrimental effect on CD
Opioids	Inhibition of gastric and intestinal motility	Nausea; constipation; increased sphincter of Oddi tonicity; pancreatitis
Cocaine	Bowel ischemia	"Candy-cane" esophagus; intestinal perforations; ischemic colitis
Amphetamine	Decreased gut motility	Constipation; teeth damage
Benzodiazepines	Gastric and gut motility disorders	Vomiting; nausea; diarrhea; epigastric distress; abdominal pain; gaseous distension; dysphagia

UC ulcerative colitis, *CD* Crohn's disease

the large bowel is exposed only to alcohol concentrations corresponding to those in the blood [33]. However, due to the low aldehyde dehydrogenase activity of the colonic mucosa, acetaldehyde accumulates in the colon and may contribute to the pathogenesis of alcohol-induced diarrhea and colon cancer. The morphology of the rectum is altered by chronic alcohol misuse; rectal biopsies often show crypt destruction, inflammation, and proliferation of epithelial cells. Abnormal cellular proliferation is the hallmark of malignant neoplasia [154]. Pancreatitis due to alcohol abuse is a very painful and potentially fatal condition. About one-third of acute pancreatitis cases in the United States are related to alcohol, and 60–90% of pancreatitis patients have a history of chronic alcohol consumption. It is estimated that drinking more than 80 g of alcohol per day for a minimum of 6–12 years is required to produce symptomatic pancreatitis. However, other factors, including environment, genetics, race, and concomitant risk factors such as cigarette smoking, are also involved [46]. Possible mechanisms involved in the pathophysiology of alcoholic pancreatitis include inhibition of secretion from acini, microtubular dysfunction, induction of oxidative stress, production of pro-inflammatory cytokines, alteration of cell permeability, increased lysosomal fragility, inhibition of apoptosis, and enhancement of necrosis [46]. Finally, an increased risk of pancreatitis is present in individuals with acute alcohol intoxication and secondary hyperlipidemia. This hyperlipidemia, together with hemolytic anemia and the consequent increase of bilirubin, is called Zieve's syndrome (Table 2).

Nicotine

Smoking could worsen gastroesophageal reflux disease; specifically, nicotine might be responsible for lower esophageal sphincter pressure [173]. Epidemiological data show that cigarette smoking increases both the incidence and relapse rate of peptic ulcer disease and delays ulcer healing in humans [122]. Nicotine may tilt the balance between aggressive and defensive factors of the gastric and duodenal mucosal integrity, favoring aggressive factors (e.g., gastric acid secretion, *Helicobacter pylori* infection, pepsinogen secretion) and attenuating defensive factors. In particular, *Helicobacter pylori* infection is more common in smokers and eradication therapy is less effective. In fact, nicotine potentiates the vacuolating toxin activity of *Helicobacter pylori* in gastric cells [138]. Regarding the effects of nicotine on the gut, nicotine is an important factor in inflammatory bowel disease, with differing effects in ulcerative colitis and Crohn's disease. Several epidemiological studies show a reduced risk of developing ulcerative colitis in cigarette smokers

when compared with non-smokers. Intermittent smokers often find their symptoms actually improved with smoking. Moreover, a dose-response relationship exists between a decreased risk of ulcerative colitis and increasing amounts of cigarettes smoked [190]. Therefore, nicotine, a major component of tobacco, has been examined as a possible pharmacological agent in the treatment of ulcerative colitis. Various mechanisms have been considered to explain the beneficial effect of nicotine on ulcerative colitis, including effects on the epithelial mucus (increased mucin synthesis), gut motility (reduction of circular muscle activity), eicosanoid metabolism, inhibition of pro-inflammatory cytokine production, and parasympathetic nervous system [173]. On the other hand, smoking has a detrimental effect on the course of Crohn's disease. The reason for the opposite association with smoking status compared with ulcerative colitis is still unclear. A hypothesis is that this opposite effect could be related to smoking's immunosuppressive effects on macrophages, which might further compound any deficiency in the host response to luminal bacteria (a possible mechanism of the pathogenesis of Crohn's disease). Finally, epidemiological evidence shows an association between cigarette smoking and pancreatic diseases. The mechanism is perhaps mediated by signal transduction pathways in the pancreatic acinar cell, leading to enhanced levels of intracellular calcium release and thereby resulting in cytotoxicity and eventual cell death [45]. Also, the induction of pancreatic injury by nicotine may involve the activation and expression of the proto-oncogene H-ras, which may lead to the development of pancreatic carcinoma in cigarette smokers [45].

Opioids

Opioid-induced gastrointestinal dysfunctions are well known. In particular, nausea and vomiting are severe adverse effects of opioids. Among individuals being treated with opioids, 8–35% have reported nausea while 14–40% have suffered from vomiting [128]. Opioids act at the chemoreceptor trigger zone (area postrema in the medulla), triggering emetic mechanisms mediated by the vomiting center in the medulla. By an action on mu receptors, opioids result in inhibition of gastric motility and a delay in gastric emptying, leading to gastroesophageal reflux/heartburn [189]. The inhibitory effect of opioids on the ileocecal sphincter and defecation reflexes contributes to opioid-induced constipation. Opioids do not seem able to induce detrimental effects on the gastrointestinal mucosa. Conversely, it has been suggested that morphine protects against stress-induced gastric ulceration in a dose-dependent manner [44]. Opioids can increase sphincter tonicity and result in sphincter of Oddi dysfunction [134]. Sphincter of Oddi dysfunction may be manifested clinically by alteration of liver tests, pancreaticobiliary pain, and pancreatitis. For example, a study conducted in a group of 91 hospitalized heroin addicts evidenced hyperamylasemia in 19% of the individuals [88]. However, it also has been suggested that hyperamylasemia after heroin usually arises from sources other than the pancreas.

Cocaine

Gastrointestinal complications of cocaine abuse occur less frequently than those in the cardiovascular and nervous systems. Esophageal lesions are characterized by alternating pink and white linear bands imparting a "candy-cane" appearance to the mucosa. The injury produces chest pain, as well as dysphagia, odynophagia, and abdominal pain. However, when individuals with candy-cane esophagus have chest pain, myocardial ischemia should remain the first possible diagnosis. Smoking cocaine has been reported to induce intestinal perforations. These perforations occur in a predominantly male population of drug addicts who are 8–10 years younger than the usual group of individuals with pyloroduodenal perforations. *Helicobacter pylori* infection may be a contributing factor to these perforations [77]. Cocaine injected intravenously has

been shown to cause bowel ischemia without evidence of thrombosis, embolism or atherosclerosis [69]. The intestinal vasculature contains alpha-adrenergic receptors, which are stimulated by norepinephrine, leading to mesenteric vasoconstriction and focal ischemia [77].

Amphetamine

Amphetamines act as an indirect sympathomimetic amine and may include decreased gut motility with consequent constipation [162]. Cocaine- and amphetamine-regulated transcript peptides are found in areas of the intestine and are thought to be responsible for regulating the sympathetic nervous system effects. Typically, misuse of "crystal meth", the smokable form of methamphetamine hydrochloride, can have an important effect on teeth. In a few months, healthy teeth can turn greyish-brown, twist, and begin to fall out. The mechanism is due to the dry mouth caused by amphetamine sympathomimetic action, which in turn makes users thirsty and crave sugary soft drinks. The problem is aggravated by caustic substances used in the drug preparation, such as lithium and red phosphorus [57].

Benzodiazepines

Oral benzodiazepine poisoning produces minimal effects on the gastrointestinal tract. However, vomiting, nausea, diarrhea, epigastric distress, abdominal pain, gaseous distension, and dysphagia can occur after the administration of high doses of benzodiazepines [84]. Conversely, several studies have evidenced possible protective effects of benzodiazepines against ethanol-induced gastric mucosa damage and stress-induced gastric ulcerations for the involvement of central-type benzodiazepine receptors located in the stomach [21]. Finally, peripheral benzodiazepine receptors are expressed also in human pancreatic islets, and prolonged binding to peripheral benzodiazepine receptors may cause human beta-cells functional damage and apoptosis [125].

Nervous System

Alcohol

Alcohol abuse is often related to brain defects and associated cognitive, emotional, and behavioral impairments. Interestingly, it has recently been suggested that the right hemisphere may be more vulnerable to the effects of alcohol than the left [143]. The regions particularly vulnerable to damage and dysfunction in individuals with chronic abuse are the frontal lobes, limbic system, and cerebellum [144]. The alterations of the frontal lobes in alcoholics are related to a decreased neuronal density, a reduction of the regional blood flow, reduced amplitude of event-related potentials, and a low glucose metabolism. These alterations generally determine some aberrations of emotion and personality including disinhibition, impulsivity, and antisocial trait. The alterations of the limbic system in alcoholics are related to dysfunction in the amygdala, a reduction of the hippocampal volume, and damage to the mammillary bodies of the hypothalamus. Clinical consequences include alterations in the control of major emotions, memory deficits (anterograde amnesia), and learning impairments. The alterations in the cerebellum in alcoholics are related to a reduction of the white matter volume of the vermis, a disruption of the fronto-cerebellar circuitry [41]. Clinical consequences include walking alterations, ataxia, and alterations of executive function [41]. Moreover, a 36% reduction in Purkinje cell number in the cerebellar vermis has been correlated to Korsakoff's syndrome in alcoholics [30]. Korsakoff's syndrome is characterized by anterograde and retrograde amnesia, disorientation, and impairment of recent memory coupled with confabulation [16]. This

syndrome is often associated with Wernicke's encephalopathy. The typical signs of Wernicke's encephalopathy are ocular motility disorders, ataxia, and mental changes (confusion, drowsiness, obtundation, clouding of consciousness, pre-coma, or coma) [16, 174]. These two disorders are usually termed the Wernicke-Korsakoff syndrome and considered as a single clinical manifestation [16]. The prevalence of Wernicke-Korsakoff syndrome is 8–10 times higher in alcoholics than in the general population (12.5 and 0.8%, respectively) and is caused by thiamine (vitamin B_1) deficiency in these individuals [174]. Moreover, thiamine deficiency is probably the basis of the cause of polyneuropathy often present in alcoholics, although the pathogenesis of alcoholic neuropathy is still unclear [107]. Alcoholic peripheral neuropathy is characterized by an asymmetric polyneuropathy pattern with greater involvement of the lower extremities, via distal axonal degeneration that involves both myelinated and non-myelinated fibers [107] (Table 3).

Nicotine

Among the 4,700 compounds found in tobacco smoke, many are associated with brain toxicity, including vinyl chloride, a risk factor for brain cancer. Other components are associated with negative effects on the pulmonary system, with secondary effects on the central nervous system. Several animal and human studies demonstrated that chronic nicotine exposure induces an increase in the number of central nervous system nicotinic acetylcholine receptors [157]. Nicotinic acetylcholine receptors are highly represented in the thalamus and cerebellum. Both acute and chronic nicotine exposure can induce changes in the central nervous system. Cerebral responses to acute administration of nicotine or smoking include reduction in global brain activity, activation of the prefrontal cortex, thalamus, and visual cortex during visual cognitive tasks, and increased dopamine concentration in the ventral striatum/nucleus accumbens. Responses to chronic nicotine exposure include decreased monoamine oxidase A and B activity in the basal ganglia and a reduction in alpha-4-beta-2 nicotinic acetylcholine receptor availability in the thalamus and putamen [167]. Ultimately, nicotine is able to induce free radicals, to deplete antioxidants, and to increase markers of oxidative stress in neural cells, inflammatory response, and atherosclerosis [167]. Smoking history represents a reliable risk factor for preclinical brain changes, such as accelerated risk for incident silent brain infarct, reduction of gray matter volumes and densities in the prefrontal cortex, in left dorsal anterior cingulated cortex, and in cerebellar gray matter. From a clinical perspective, it has been reported that continuous smoking is associated with an increased risk of cognitive impairment [26] and dementia [131].

Opioids

Chronic opiate abuse can modify several neurotransmitter systems of the central nervous system. In particular, chronic opiate abuse has been associated with marked changes in the

Table 3 Main neurological clinical symptoms in subjects with alcohol abuse or dependence

Symptoms	Area(s) mainly involved
Disinhibition, impulsivity, antisocial trait	Frontal lobes
Control emotions altered, memory deficits, learning impairments	Limbic system
KS: walking alterations, ataxia, executive function alterations	Cerebellum
Polyneuropathy: nociception alteration, painful symptoms	PNS
WKS: ocular motility disorders, ataxia, confusion, drowsiness, obtundation, pre-coma, coma	Cerebellum, Thalamus, Hypothalamus

KS Korsakoff's syndrome, *WKS* Wernicke-Korsakoff syndrome, *PNS* peripheral nervous system

brain density of mu-opioid receptors [129]. Interestingly, although methadone is used as a substitute for heroin in the treatment of opiate-dependent individuals, the long-lasting effects of these two opiates differ. Methadone administered in a maintenance regimen results in an up-regulation of the mu-opioid receptors, which persists even after detoxification from opiates [55]. Conversely, post-mortem analyses of chronic heroin users have shown a down-regulation of the mu-opioid receptors [70]. Regarding monoamine neurotransmission, chronic opiate abuse has been associated with reduced densities in noradrenaline (α2) and dopamine (D2) receptors [70]. The effects on the dopamine system overall in opiate users are less pronounced than in stimulant users [105]. From a clinical perspective, heroin vapor inhalation induces leukoencephalopathy, or "chasing the dragon" syndrome, characterized by progressive neurological deficits such as altered levels of consciousness, spastic paraparesis, ataxia, bradykinesia, and dysarthria [142]. Intravenous injection of heroin also can induce permanent neuropathies. Rhabdomyolysis and myopathy have been attributed to toxicity and ischemia or a gluteal compartment syndrome, whereas the associated neuropathy could have been caused by compression [139].

Cocaine

Within the central nervous system, frontal lobes represent the areas most affected by cocaine abuse [71]. For example, imaging results show volumetric deficits in multiple frontal areas in cocaine users, including the anterior cingulate and orbitofrontal cortex as well as the insula and temporal cortex [126]. Chronic cocaine users often present with poor performance on experimental and neuropsychological tasks that probe working memory function [71]. This feature is consistent with the observations that many of these compromised cognitive functions involve the dopaminergic neurons of the dorsolateral prefrontal and orbitofrontal regions [71]. In cocaine abusers, some cerebral vascular alterations have also been recognized [139]. In particular, cerebral hemorrhage and ischemic stroke have been reported. Silent ischemia has been suggested as a possible mechanism for the cerebral atrophy and consequent encephalopathy often present in cocaine abusers [147]. Either ischemic or hemorrhagic stroke can lead to *ex novo* seizures or exacerbate a pre-existing seizure disorder [115]. However, seizures can also occur in the absence of vascular disorders when high blood concentrations of cocaine are present, suggesting a direct toxicity [139]. Cocaine can also induce transient movement disorders, characterized by choreoathetosis, akathisia, parkinsonian tremor, and multifocal tics, and can aggravate the symptoms of individuals with Tourette's syndrome [146]. Furthermore, some cocaine abusers experience an acute severe migrainous headache, which can be attributed to either acute use or withdrawal of the drug [58].

Amphetamine

Methamphetamine-induced neurotoxicity involves several neurotransmitter systems, mostly by altering the function of the dopamine fronto-striato-thalamocortical loops [39]. Both high doses and chronic administration of methamphetamine can result in a depletion of dopamine and destruction of dopamine nerve terminals [47]. Several mechanisms have been implicated in methamphetamine-induced neurotoxicity, including production of reactive oxygen and nitrogen species, hyperthermia, and the triggering of an apoptotic cascade dependent upon mitochondria [47]. Acute effects of methamphetamine use are mediated by the sympathetic branch of the autonomic nervous system and include hypertension, tachycardia, hyperthermia, increased breathing rate, and constriction of blood vessels. Cognitive and emotional effects include euphoria, enhanced energy and alertness, a surge in productivity, and an increase in libido

[47]. Chronic methamphetamine use can result in pulmonary hypertension, acute aortic dissection, myocardial infarction, and ischemic and hemorrhagic strokes. In addition, some physical and mental consequences can occur, including sleep deprivation, affective distress, psychiatric disorders, and an increased risk of depression and suicidal ideation [47]. Furthermore, methamphetamine may induce seizures, delirium, and coma, especially if used in combination with other drugs [139]. Either hemorrhagic [192] or ischemic stroke [192] may also occur. Finally, in chronic methamphetamine addicts, a transient movement disorder named "jerking syndrome" has been described. The "jerking syndrome" is probably caused by a basal ganglia disorder and is characterized by constant automatic involuntary choreiform movements, stereotyped dystonic facial movements, and/or chewing-gum movements [139].

Benzodiazepines

In individuals with benzodiazepine abuse, many studies have demonstrated a down-regulation of the benzodiazepine binding sites, although the affinity is usually unchanged [95]. Symptoms of benzodiazepine withdrawal are time-limited, usually occurring for only 1 or 2 weeks after the discontinuation of the drug, but the duration varies according to the drug and the individual subject [141]. During withdrawal, the original anxiety symptoms often return in a more intense form, a phenomenon known as "rebound anxiety" [95]. Rebound anxiety can include psychological and physiological symptoms such as anxiety, apprehension, irritability, insomnia, dysphoria, tremor, palpitations, mild systolic hypertension, dizziness, sweating, muscle spasm, and gastrointestinal disturbances [95] (Table 4).

Cardiovascular System

Alcohol

Alcohol abuse has been associated with several cardiovascular diseases, such as hypertension, cardiomyopathy, coronary artery disease, and stroke [121]. However, low-to-moderate ethanol consumption has been linked to a reduced cardiovascular risk, with a J-shaped dose-response curve. Although red wine consumption and the related compounds (i.e., polyphenols) were considered important in the so-called "French paradox", alcohol itself seems to hold the major benefits [121]. On the other hand, chronic alcohol abuse induces several alterations in the cardiovascular system, including: low-grade systemic inflammation, hyperuricemia, dyslipidemia, hyperhomocysteinemia, increased oxidative stress with enhanced lipid peroxidation,

Table 4 Main neurological clinical symptoms in subjects with substance abuse or dependence

Substance	Neurological features
Alcohol	Disinhibition, impulsivity, antisocial trait, control emotions altered, memory deficits, learning impairments, KS, WKS, polyneuropathy
Nicotine	Atherosclerosis, stroke vigilant, attention and memory, cognitive decline, dementia
Opioids	Neuropathies, rhabdomyolysis, myopathy, altered levels of consciousness, spastic paraparesis, ataxia, bradykinesia, dysarthria
Cocaine	Hemorrhagic stroke, ischemic stroke, encephalopathy, seizure disorder, choreoathetosis, akathisia, parkinsonian tremor, multifocal tics, Tourette's syndrome symptoms, headache
Amphetamine	Ischemic stroke, hemorrhagic stroke, euphoria, enhanced energy, alertness, increase in libido, sleep deprivation, affective distress, psychiatric disorders, increased risk of depression and suicidal ideation, jerking syndrome
Benzodiazepines	Benzodiazepine withdrawal: "rebound anxiety", anxiety, apprehension, irritability, insomnia, dysphoria, tremor, palpitations, dizziness, sweating, muscle spasm, hypersensitivity to light, sound or touch body pains, headache, generalized seizure

KS Korsakoff's syndrome, *WKS* Wernicke-Korsakoff syndrome

impaired glucose tolerance with insulin resistance, endothelial dysfunction, arterial hypertension, and alcoholic cardiomyopathy [121, 151]. From a clinical point of view, all the mentioned mechanisms are able to modify the pathophysiology of atherosclerosis. Atherosclerosis is a diffuse disease, and its clinical presentation varies depending upon the vascular bed in which it occurs. Moreover, long-term heavy alcohol consumption (of any beverage type) is the leading cause of a non-ischemic dilated cardiomyopathy called alcoholic cardiomyopathy [151]. The exact pathogenesis of alcoholic cardiomyopathy is still unclear. Alcohol induces several changes in the myocardial structure by inducing myocyte loss, intracellular organelle dysfunction, and contractile protein alterations, and influencing calcium homeostasis. These changes can alter several aspects of myocyte function and, therefore, may lead to myocyte dysfunction and alcoholic cardiomyopathy. Symptoms often appear late, and the diagnosis could be difficult since the symptoms are close to those of chronic heart failure. Alcohol abstinence often results in at least partial recovery of the myocyte damage, with a consequent improvement in cardiac function. The term "holiday heart syndrome" was coined by Ettinger et al. [63] and defined as "an acute cardiac rhythm and/or conduction disturbance associated with heavy ethanol consumption in a person without other clinical evidence of heart disease and disappearing, without evident residual, with abstinence". In sum, although numerous studies have described a J-shaped or U-shaped curve to describe the relationship between alcohol intake and total and cardiovascular mortality, these studies have been observational and epidemiological in nature. Prescribing alcohol for those who do not drink and the use of alcohol as a cardioprotective strategy are not recommended [106] (Table 5).

Nicotine

Smoking is associated with an increased risk of atherosclerotic vascular disease, hypertension, myocardial infarction, unstable angina, sudden cardiac death, and stroke [188]. Acute and chronic cigarette smoking impairs nitric oxide synthase-mediated relaxation of large blood vessels. Smoked tobacco, in fact, contains high levels of free radicals and pro-oxidant agents. There is considerable evidence that cigarette smoking can result in both morphologic and biochemical disturbances to the endothelium both *in vivo* and in cell culture systems. However, a consensus of the causal relationship between cardiovascular disorders and the consumption of smokeless tobacco has not yet been established [83]. An acute hypertensive effect has been shown, up to 90 minutes after smoking tobacco. In particular, absorbed nicotine stimulates the release of catecholamines; the subsequent activation of alpha-adrenoceptors in vascular smooth muscle cells contracts vascular tissues and elevates blood pressure. Free radicals and aromatic compounds diminish the endothelial synthesis of nitric oxide, causing impaired endothelium-dependent relaxation of arteries, the earliest clinical sign of endothelial dysfunction, and they injure the arterial endothelium, promoting atherogenesis [83]. The increased oxidation of low-density lipoprotein in smokers has synergetic effects to promote

Table 5 Main cardiovascular features in subjects with substance abuse or dependence

Substance	Cardiovascular features
Alcohol	Hypertension, alcoholic cardiomyopathy, coronary artery disease, stroke
Nicotine	Atherosclerosis, hypertension, myocardial infarction, angina, sudden cardiac death, stroke
Opioids	Bradycardia/bradyarrhythmias, hypotension, pulmonary edema, endocarditis
Cocaine	Severe hyper-/hypotension
Amphetamine	Arrhythmias (supraventricular/ventricular), chest pain/myocardial infarction, acute heart failure, dilated cardiomyopathy/chronic heart failure, endocarditis
Benzodiazepines	Bradycardia, myocardial infarction (?)

monocyte adhesion and monocyte migration into the subintimal space. Continued stimulation of intimal cells by oxidized low-density lipoprotein leads to the development of atherosclerosis. Smokeless tobacco use has been linked to impotence [101], acute myocardial infarction, congestive heart failure [156], and ischemic stroke [75]. In particular, diseases of the cardiovascular system and their final or lethal states occur 3 to 4 times more frequently than lung cancer in heavy smokers [83].

Opioids

The cardiovascular effects of opioids are directed to the vasomotor center to increase parasympathetic activity, reduce sympathetic activity, and release histamine from mast cells. These combined effects produce bradycardia and hypotension [119]. Acute cardiac effects of opioid abuse are represented by drug-induced bradycardia [119]. The reduction in the heart rate increases the automaticity in ectopic electrical myocardial activity, leading to atrial fibrillation, idioventricular rhythm, or potentially lethal ventricular tachyarrhythmias [119]. Some opioids (such as dextropropoxyphene) have additional sodium channel-blocking effects, which further contribute to the pro-arrhythmic and myocardial depressant effects, leading to acute left ventricular dysfunction and cardiogenic pulmonary edema. Overdose of narcotic analgesics can also cause acute non-cardiogenic pulmonary edema. This may be related to an anaphylactic reaction to the drug, to an increase in pulmonary capillary hydrostatic pressure resulting from pulmonary vasoconstriction induced by hypoxia, or to disruption of alveolar capillary membrane integrity. Apart from the well described central nervous system and respiratory depressant effects, there also may be profound cardiovascular collapse or arrhythmias after narcotic analgesic overdose [76]. Chronic consequences of intravenous opioids injection include the risk of infection of the injection site, along with the risk of bacterial endocarditis, which usually affects the right-sided heart valves and may be associated with pulmonary abscess formation [164]. Since the abused drug is rapidly metabolized, the majority of arrhythmias are short-lived. Compared with abusers of other drugs, opioids abusers show a low prevalence of coronary artery disease [124]. On this point, the binding of morphine to opioid receptors before induction of an infarction in a rat model results in smaller infarcts, with protection of cardiomyocytes mediated by peripheral opioid receptors [76]. Moreover, in humans, long-term exposure to opioids is associated with decreased severity of coronary artery disease, with a decreased incidence of fatal myocardial infarctions. One possible explanation is that narcotics may decrease inflammation [54], which is associated with atherogenesis and plaque disruption [116].

Cocaine

Cocaine affects the cardiovascular system, predominantly via activation of the sympathetic nervous system [76]. Cocaine acts indirectly as a sympathomimetic drug inhibiting the reuptake of noradrenaline and dopamine at the sympathetic nerve terminals. Cocaine can also act through central pathways to release noradrenaline from the adrenal medulla [43]. At high doses, cocaine can impair myocyte electrical activity and contractility by blocking fast sodium and potassium channels and inhibiting calcium entry into myocytes [133]. Furthermore, cocaine has a short serum half-life of approximately 30–80 minutes, but some of its metabolites are more cardiotoxic than the parent compound [89]. Cocaethylene, for example, is formed when cocaine is taken with alcohol and has an important cardiotoxic effect [89]. The clinical symptoms related to the cocaine-induced sympathetic activation include tachycardia, vasoconstriction, unpredictable blood pressure effects, and arrhythmias, depending on the dose and the possible presence of a coexisting cardiovascular disease. Hypertension is common, but severe hypotension (due to a paradoxical central sympathetic suppression) can also occur [133]. Chest pain, myocardial ischemia, and infarction can be

produced by various mechanisms, such as diffuse or local coronary artery spasms [132]. A pro-coagulant effect that is able to facilitate a thrombotic coronary occlusion can also occur by decreasing the concentrations of protein C and antithrombin III, activating platelets, and potentiating thromboxane production. Chronic use of cocaine can induce repetitive episodes of coronary spasm and paroxysms of hypertension, which may result in endothelial damage, coronary artery dissection, and subsequent acceleration of atherosclerosis. Prolonged administration of cocaine may be associated with an irreversible dilated cardiomyopathy, related to subendocardial ischemia and fibrosis and myocyte necrosis produced by exposure to excessive catecholamine concentrations or repeated episodes of myocarditis. Myocardial cellular injury can also occur in association with exposure to infectious agents or heavy metals, such as manganese, that contaminate street preparations of cocaine. A wide and unpredictable range of supraventricular and potentially lethal ventricular tachyarrhythmias can be precipitated by such a sympathomimetic stimulation. Moreover, cocaine can impair cardiac conduction, inducing a wide range of bradyarrhythmias such as sinus arrest and atrioventricular block. Sudden cardiovascular collapse may occur as a result of myocardial ischemia and infarction, arrhythmias, acute heart failure, or mechanical complications. Benzodiazepines attenuate the cardiac and central nervous system toxicity of cocaine and should be given in sedative dosages, also to manage hypertensive and cardiovascular complications, in addition to nitrates [93]. Cocaine-induced chest pain should be treated initially with oxygen, aspirin, and benzodiazepines. If the ischemia damage continues, then the use of additional vasodilators such as nitrates or phentolamine to reverse residual coronary spasm may be necessary.

Amphetamine

As a consequence of acute amphetamine intoxication, cardiovascular symptoms, including chest pain, palpitations, and dyspnea, are common [20]. Cardiovascular effects of amphetamine are similar to those induced by cocaine and include hypertension, supraventricular tachyarrhythmias, ventricular arrhythmias, myocardial ischemia and infarction, acute heart failure, chronic heart failure, and endocarditis [76]. Similar principles should be applied to the management of the cardiovascular complications associated with these recreational drugs, although the duration of treatment will vary depending on the half-life of the agent taken.

Benzodiazepines

Benzodiazepines, particularly diazepam, are usually considered primarily to exert a cardiodepressant effect, which is a consequence of a centrally mediated decrease in cardioregulatory outflow of the sympathetic nervous system [40]. On the other hand, some studies report that diazepam produces positive inotropic effects on the myocardium, which have been related to catecholamines released from sympathetic nerve terminals located in the heart [17]. Moreover, it has also been shown that diazepam potentiates the positive inotropic effect of both noradrenaline and adrenaline, as well as that of the endogenous noradrenaline-releasing agent tyramine in electrically driven right ventricular strips of rat, by directly inhibiting the enzyme cyclic nucleotide phosphodiesterase [123]. Diazepam overdose can produce cardiac sympathomimetic-like effects on atrioventricular conduction. Recently, it has been shown that peripheral-type benzodiazepine receptors are almost ubiquitous (i.e., platelets, erythrocytes, lymphocytes, and mononuclear cells) and are abundant in the cardiovascular system (endothelium, striated cardiac muscle, vascular smooth muscles, and mast cells) and in intracellular locations (mitochondria) [182]. The exact function of peripheral-type benzodiazepine receptors is still unclear, but they seem to take part in some responses to trauma such as ischemia. The irreversible peripheral-type benzodiazepine receptor

antagonist, SSR180575, was found to reduce the ischemia-related damage [182]. Diazepam is often found to be a substance of abuse that is able to induce a myocardial infarction secondary to coronary spasm, mostly in teenagers.

Oncology

Alcohol

The alcohol-associated risk for the development of cancers varies from low to moderate to high, depending on the type of organ affected as well as the amount of alcohol consumed. Statistically significant relative risks for the development of cancers from the consumption of 100 g of alcohol per day were reported for the oral cavity, pharynx, esophagus, larynx, breast, liver, ovary, colon, rectum, and stomach [29]. Among the possible mechanistic pathways, the formation of acetaldehyde seems to be the most important [99]. Twenty-five percent to 80% of upper aerodigestive tract cancers are attributable to alcohol acetaldehyde. For example, individuals heterozygous for inactive ALDH2 are at increased risk for upper aerodigestive tract cancers because of the accumulation of acetaldehyde after alcohol consumption [154]. The pooled alcohol-associated risks for colorectal cancer range from 1.08 for 25 g of alcohol consumed per day to 1.18 for 50 g/day to 1.38 for 100 g/day [29]. A daily alcohol consumption of $\geq$30 g/day was associated with an increased risk of proximal colon cancer, distal colon cancer, and rectal cancer. An association between alcohol abuse and gastric cancer has not been clearly shown [104]. While the association between cirrhosis and the development of hepatocellular carcinoma is well documented, a direct correlation between ethanol consumption and the development of hepatocellular carcinoma remains debatable. Among individuals with alcoholic cirrhosis, the annual incidence of hepatocellular carcinoma is 1–2% [127]. Similarly, while heavy alcohol consumption represents a major cause of chronic pancreatitis and a risk factor for type 2 diabetes mellitus (both of which are linked to pancreatic cancer), there is little or no support for a direct causal relationship between light and moderate alcohol use and risk of pancreatic cancer [78]. Alcohol consumption is associated with increased risk for breast cancer in both premenopausal and postmenopausal women, regardless of the type of alcoholic beverage consumed. The proportion of breast cancer cases attributable to alcohol consumption among U.S. women is 2.1%, accounting for about 14,000 women per year [181]. The role of alcohol drinking in the etiology of non-Hodgkin's lymphoma is still debatable. Some studies have suggested that alcohol consumption reduces the risk of non-Hodgkin's lymphoma, whereas others have found increased non-Hodgkin's lymphoma risk among alcohol drinkers, or no relationship [169] (Table 6).

Nicotine

Cigarette smoke contains 4,800 identified chemicals, including at least 61 products (e.g., benzene, polonium, polycyclic aromatic hydrocarbons, nitrosamines, aromatic amines, etc.) able to cause cancer [86]. Moreover, tobacco components have been recognized to induce immunosuppression, which may play an important role in the development of malignant cells [169]. The unequivocal role of cigarette smoking in causing lung cancer is one of the most thoroughly documented causal relationships in biomedical research. Using an attributable risk approach, the annual number of deaths caused in the U.S. by smoking-related lung cancer from 1995 to 1999 was 122,800. The risk for lung cancer among cigarette smokers increases with the duration of smoking and the number of cigarettes smoked per day. Genetic factors can also contribute. For example, it has recently been shown that a common variant in the nicotinic acetylcholine receptor gene cluster on chromosome 15q24 with an effect on smoking quantity confers a risk of lung cancer [175]. Regarding upper

Table 6 Pathways and related effects on the basis of the link between cancers and substances of abuse

Possible pathways involved in alcohol-related cancer	Effects
Alcohol contacts-related local effects	Cancer of: UADT, stomach, colon
Alcohol's solvent effects on tobacco and other carcinogens	Cancer of: UADT, stomach, colon, pancreas
Induction of microsomal enzymes involved in carcinogen metabolism	Cancer of: UADT, stomach, colon, liver, pancreas
Generation of oxygen radicals and lipid peroxidation products	Cancer of: UADT, stomach, colon, liver, pancreas
Nutritional deficiency	Cancer of: colon, breast, blood
Suppressed immune function	Cancer of: UADT, stomach, colon, liver, pancreas, breast, NHL
Acetaldehyde-induced carcinogenesis	Cancer of: UADT, stomach, colorectal, liver
Decreased hepatic retinoic acid	Cancer of: liver
Iron overload	Cancer of: liver
Perturbation of estrogen metabolism and response	Cancer of: breast
Down-regulated BRCA1 expression	Cancer of: breast
Possible pathways involved in tobacco component-related cancer	**Effects**
Increasing mean leukocyte counts Decreasing serum concentration of immunoglobulins Decreasing NK-cells Decreasing CD41/CD81 ratio Altering T-cell function	Cancer of: lung, larynx, mouth, esophagus, bladder, pancreas, kidney, cervix uteri, stomach, breast, blood
Possible pathways involved in opioid-related cancer	**Effects**
Decreased natural and adaptive immunity	Worsening of cancer in animal models
Possible pathways involved in cocaine-related cancer	**Effects**
Vasoconstriction irritating to the respiratory epithelium of the nasal airway	Nasal SFT
Possible pathways involved in amphetamine-related cancer	**Effects**
Suppresses neutrophil phagocytosis Suppresses production of TNF-alpha and IL1 Suppresses circulating lymphocyte numbers Alters T-cell function	Reduced tumor surveillance

UADT upper aerodigestive tract, *NHL* non-Hodgkin's lymphoma, *SFT* solitary fibrous tumor, *NK-cells* natural killer cells, *TNF* tumor necrosis factor, *IL1* interleukin-1

aerodigestive tract cancers, the risk of laryngeal cancer in smokers is on the order of 10 relative to non-smokers and >15 for heavy smokers, and the risk seems stronger for glottic than for supraglottic neoplasms. Smokers are at a dramatically increased risk for oral carcinoma, particularly squamous-cell cancer. Studies also have demonstrated a dose-response effect of intensity and duration of smoking [109] on this risk. Epidemiological studies report a two- to five-fold increase in the risk of esophageal cancer among smokers. A dose-response increased risk of squamous-cell carcinoma of the esophagus with increased intensity and duration of smoking and a decline in risk after smoking cessation have been repeatedly demonstrated. Smoking is also responsible for a two- to three-fold increased risk of adenocarcinoma of the esophagus, and risk relates to the intensity of smoking [109]. Relevant cohort and case-control studies that have examined the relationship between tobacco smoking and stomach cancer show an up to two-fold increase in risk for smokers compared with non-smokers. A positive dose-response relationship with intensity and duration of smoking was demonstrated in most studies. A large number of case-control and cohort studies have reported an increased

risk for liver cancer in smokers. Smoking is associated with an approximate two- to four-fold increased risk of pancreatic cancer. The proportion of pancreatic cancer attributable to cigarette smoking was 29% in blacks and 26% in whites [109]. Furthermore, an increased risk of kidney and renal pelvis cancers has also been reported in smokers compared with non-smokers [109]. During the last four decades, many epidemiological studies and reviews have consistently shown that cigarette smoking substantially increases the risk of bladder cancer. A positive dose-response relationship has been found with both the number of cigarettes smoked per day and the number of years smoking. Age at first exposure and cessation of cigarette smoking were inversely associated with bladder cancer risk. The role of human papillomavirus in cervical tumors in women is well known. Accordingly, recent cohort and case-control studies have investigated the association between tobacco smoking and the incidence of invasive cervical cancer, cervical intraepithelial neoplasia, and cervical cancer in situ using analyses adjusted for human papillomavirus status or restricted to human papillomavirus-positive women. In these studies, the association between tobacco smoking and cervical cancer was present and remained even after adjustment for a series of other potentially confounding factors. The association between smoking and breast cancer risk remains controversial despite >100 epidemiological studies conducted over the past three decades. The results of these studies overall suggest that smoking probably does not decrease risk and indeed suggest that there may be an increased risk with smoking, particularly heavy smoking of long duration. Recent cohort studies found statistically significantly positive associations between smoking of long duration and breast cancer risk among non-drinkers in their populations. Finally, among hematological tumors, the available literature on tobacco smoking and leukemia indicates that there is an association between tobacco smoking and myeloid leukemia, with an increased risk with higher intensity and longer duration of smoking. In recent years, a direct relationship between tobacco smoking and the risk of non-Hodgkin's lymphoma has been suggested. Compared with those who have never smoked, current smokers had a 10–40% higher risk of developing non-Hodgkin's lymphoma. The association seemed stronger for follicular and high-grade lymphomas [169]. On the contrary, Nieters et al. [140] showed an elevated risk of Hodgkin's lymphoma in relation to smoking but did not find any association between tobacco smoking and risk of non-Hodgkin's lymphoma. However, the latter study was based on a small sample size.

Opioids

There are few data on this topic; the most important pertain to the immunomodulatory activities of morphine and the related potential risk of carcinogenesis [158]. Moreover, injecting opioids also exposes an individual to an indirect risk of cancer, considering the impairment of the immune system in human immunodeficiency virus/acquired immune deficiency syndrome subjects [111].

Cocaine

Also in this case, few data are available. Reactive vascular lesions of the nasal septum simulating angiosarcoma have been reported in chronic cocaine abusers [18]. Cocaine that is snorted is vasoconstricting and locally irritating to the respiratory epithelium of the nasal airway. An anecdotal report also described a solitary fibrous tumor of the nasal cavity in an individual with a long-standing history of cocaine inhalation [18].

Amphetamine

Both animal and human studies demonstrated that amphetamine, particularly methylenedioxymethamphetamine, has immunosuppressive actions that can play a role in reducing tumor

surveillance. However, it is difficult to predict the impact of methylenedioxymethamphetamine-induced immunosuppression on disease susceptibility, particularly cancer onset risk [50].

Benzodiazepines

For the majority of benzodiazepines, results of genotoxicity and carcinogenicity tests recommended by current guidelines are difficult to retrieve [34]. In some instances, an agent for which there is inadequate evidence or no data in humans but limited evidence of carcinogenicity in experimental animals, together with supporting evidence from other relevant data, may be placed in Group 2B. On the basis of these indications, three drugs might be considered as possibly carcinogenic to humans: oxazepam, already classified by the International Agency for Research on Cancer in Group 2B, and, tentatively, midazolam and zopiclone due to sufficient evidence of carcinogenicity in experimental animals. Three other drugs—brotizolam, quazepam, and zolpidem—might be tentatively classified as probably not carcinogenic to humans (Group 4). All the other benzodiazepines, on the basis of available data, should be considered not classifiable as to their carcinogenicity to humans (Group 3), including diazepam, doxefazepam, estazolam, prazepam, ripazepam, and temazepam [34].

Endocrinology

Alcohol

Alcohol abuse can often be associated with several endocrine disorders. Among them, the thyroid gland seems to be typically affected. Most studies have shown a reduction in peripheral thyroid hormones and/or blunted thyroid-stimulating hormone response to thyrotropin-releasing hormone in alcohol-dependent individuals [90]. Consistently, in these individuals, both ultrasound and autopsy studies have shown a significant reduction of the thyroid gland volume. Decreased thyroid hormones might result from damage to the thyroid gland or from alterations of the hypothalamic-pituitary-thyroid axis due to chronic alcohol intake. Interestingly, thyroid hormone dysfunction has been associated with some behavioral features of alcohol dependence, such as the severity of withdrawal, negative mood status, and an increased risk of alcohol relapse and alcohol craving, especially in its compulsive component [113, 145]. This last feature is of interest and in line with other similar findings found with other hormones and peptides able to modulate food intake, such as leptin [92], ghrelin [12], and insulin [114]. Alcohol-dependent individuals may show a chronic activation of the hypothalamic-pituitary-adrenal axis, with increased concentrations of cortisol during periods of heavy intake [120]. Recent abstinent alcoholics also show a blunted adrenocorticotropin response to corticotropin-releasing hormone, possibly caused by a direct pituitary effect of chronic ethanol exposure. Alcohol-dependent individuals tend to relapse more rapidly when they have smaller cortisol responses to public stress or in response to alcohol cues in a cue exposure procedure. Consistent with these data, the involvement of other stress hormones in alcoholism has been shown. For example, alcohol drinking is known to cause hyperprolactinemia in both humans and laboratory animals after acute and chronic ethanol exposure, with a consequent normalization during abstinence [110]. Accordingly, women addicted to alcohol suffer from menstrual cycle irregularities, amenorrhea, and infertility because hyperprolactinemia is able to increase the dysfunction of the pituitary-ovarian axis, as caused directly by alcohol. Consistent with the involvement of the hypothalamic-pituitary-adrenal axis in alcohol addiction, a significant decrease in aldosterone levels during abstinence, as well as its potential role in mediating alcohol craving, has been suggested [112]. With regard to the link between alcohol and diabetes, a recent meta-analysis showed that a moderate alcohol intake was associated with a reduced risk of type 2

diabetes compared with low consumption or abstinence, while high consumption of alcohol was associated with an increased risk of type 2 diabetes compared with moderate consumption [37]. Chronic moderate use of alcohol has no deleterious effect on metabolic control in individuals with diabetes. The relationship between alcohol use and insulin sensitivity is J-shaped, with the lowest fasting insulin levels and the lowest insulin resistance index values in moderate drinkers and higher values in both abstainers and heavy drinkers. Finally, some sexual dysfunctions also can be present in alcohol-dependent individuals. In fact, alcohol impairs testicular production of testosterone as well as hypothalamic pituitary secretion of gonadotropin-releasing hormone and the two gonadotropins, follicle-stimulating hormone and luteinizing hormone. Also, acute alcohol intoxication increases sexual desire but inhibits sexual performance. On the other hand, chronic alcohol consumption is associated with the risk of an erectile dysfunction, in a J-shaped manner, with moderate consumption conferring the highest protection and higher consumption conferring fewer benefits [42]. In alcoholic females, several gynecologic problems such as gonadal dysfunction, loss of libido, and infertility are frequent. Consistently, various studies have shown that alcohol consumption increases estrogen levels in the pre-ovulation and luteal phases of the menstrual cycle [28] (Table 7).

Nicotine

Smoking is a risk factor for Graves' hyperthyroidism, and especially for Graves' ophthalmopathy, due to both a tissue hypoxia and an immune-mediated effect [183]. Consistently, the response to the treatment in individuals with ophthalmopathy is delayed and markedly poorer in smokers. Furthermore, in individuals with Graves' disease, smoking may promote the development of thyreotoxicosis. Cigarette smoking has been found to be negatively associated with thyroid cancer, a feature probably due to both the lower thyroid-stimulating hormone levels that reduce thyroid cell proliferation and a smoking-related anti-estrogen effect. With regard to hypothyroidism, a meta-analysis has suggested that Hashimoto's thyroiditis, postpartum thyroid dysfunction, and non-toxic goiter are associated with smoking [183]. Smoking acutely increases the plasma levels of prolactin, adrenocorticotropin, cortisol, growth hormone, and arginine vasopressin without significant changes in thyroid-stimulating hormone, luteinizing hormone, and follicle-stimulating hormone [103]. These effects are directly proportional to the nicotine content of cigarettes. Four potential mechanisms may cause these effects: nausea induced by smoking via the stimulation of the emetic center; nicotine-stimulated cyclic adenosine monophosphate production; stress per se, and a direct effect of nicotine on the anterior pituitary or hypothalamus. In chronic smokers, however, inhibition of prolactin secretion occurs, and it depends on a nicotinic release of dopamine acting as a prolactin-inhibitory factor [180]. Chronic smoking stimulates plasma renin activity and raises plasma aldosterone levels. Higher levels of androstenedione and dehydroepiandrosterone sulfate are found in smokers. Plasma adrenaline and noradrenaline levels rise after smoking. Cigarette smoking has an anti-estrogenic effect in women. This is probably due to increased production of 2-hydroxyestrogen compounds with minimal estrogenic activity [170]. Some physiological estrogen-dependent processes, such as the menstrual cycle, are affected by the risk of anovulation and the consequent decreased fertility. Menopausal symptoms such as hot flashes are experienced more commonly among smokers. Cross-sectional studies have also shown increased insulin resistance in smokers vs. non-smoking controls [65]. The reduced insulin sensitivity seen in smokers could be due to the increase in counter-regulatory hormones such as growth hormone, cortisol, and catecholamines, which all raise blood glucose levels. Calcium absorption is lower in smokers vs. non-smokers, a feature probably related to the lower parathyroid hormone and serum calcitriol levels seen in smokers. An association between smoking

Table 7 Main endocrine features in subjects with substance abuse or dependence

Substance	HPT axis	HPA axis	HPG axis	Sexual dysfunction(s)	Other(s)

and erectile dysfunction has also been suggested. Smokers were 1.5 times more likely to suffer erectile dysfunction than non-smokers [61], and the significant association of smoking with erectile dysfunction was strengthened as the number of cigarettes smoked increased. Smoking results in alterations of the male sex hormones and is a key cause of and contributor to erectile dysfunction. Smoking may cause erectile dysfunction by several mechanisms, including adversely affecting intrapenile blood flow caused by endothelial dysfunction. A decrease in sperm quality and a reduced response to fertility treatments have also been reported in male smokers.

Opioids

Opiate users who inject heroin, or those on methadone maintenance treatment, may exhibit adrenal insufficiency and atypical circadian patterns of hypothalamic-pituitary-adrenal hormone secretion [64]. Opiate use increases corticosteroid-binding globulins, which can mask adrenal dysfunction. During chronic administration of opioids, the acute stimulatory effect on prolactin, growth hormone, and thyroid-stimulating hormone secretion is abolished, whereas adrenocorticotropin is inhibited and luteinizing hormone remains suppressed. The inhibition of

adrenocorticotropin release can be explained by the concomitant release of beta-endorphin. A lower, but substantial, percentage of individuals may develop hypocorticism. This condition should be properly diagnosed and treated to avoid Addisonian crises. Growth hormone deficiency may affect an equivalent number of individuals. Methadone dose showed a significant direct correlation with increased orgasm dysfunction, both before and after adjusting for duration of treatment [35]. Heroin addiction influences sexual function negatively. Although opiate addicts often equate the drug experience with sexual orgasm, diminished libido and impaired sexual performance such as erectile dysfunction are common sequelae of chronic use. Substitution therapy by sex steroids restored libido in most men and women and improved their quality of life. A clear and significant suppression of luteinizing hormone and testosterone in virtually all males and a similar decrease in luteinizing hormone secretion with a disrupted menstrual cycle in females were found in a recent study [56].

Cocaine

There is evidence from brain imaging studies that the pituitary gland is larger in men who abuse cocaine chronically than in controls [130]. Chronic cocaine abuse can be associated with hyperprolactinemia. Prolactin release is pulsatile. Hyperprolactinemic cocaine abusers have higher average prolactin peak heights than controls or normoprolactinemic cocaine abusers, and they have higher average prolactin levels between peaks than the other groups. Intravenous cocaine administration is usually followed by an increase in adrenocorticotropin and a subsequent increase in cortisol in human males [130]. When cocaine was administered intranasally, a change in adrenocorticotropin was not detected, but there was a significant increase in cortisol levels [87]. Peak plasma cocaine levels were coincident with the peak increase in plasma adrenocorticotropin levels; adrenocorticotropin peak amplitude and height increased significantly after intravenous cocaine administration, and pulse frequency remained unaltered. These data are consistent with the hypothesis that the reinforcing properties of cocaine may occur as a consequence of its effects on dopaminergic neural systems, which co-modulate corticotropin-releasing hormone release in the brain. Cocaine also reduces renin secretion and increases arginine vasopressin. Acute administration of cocaine intravenously or intranasally was followed by a significant increase in luteinizing hormone. Clinical effects include increases in sexual feelings and energy as well as intense euphoria. The adverse effects of cocaine on reproductive function include disorders of menstrual cycle duration and impairments in folliculogenesis, ovulation, and luteal phase adequacy. Compared with placebo, both luteinizing hormone and, to a lesser degree, follicle-stimulating hormone levels increased significantly after cocaine administration [87]. Chronic cocaine abuse is associated with erectile dysfunction, perhaps due to endothelial dysfunction [85]. Finally, several reports have associated priapism with intranasal, intraurethral, intracavernous, and topical recreational use of cocaine [135].

Amphetamine

Cocaine- and amphetamine-regulated transcript is suggested to be involved in the regulation of the hypothalamic-pituitary-thyroid axis. Co-secretion of cocaine- and amphetamine-regulated transcript with thyrotropin-releasing hormone into the portal pituitary circulation, therefore, may have an important modulatory influence on the effect of thyrotropin-releasing hormone on pituitary hormone secretion [66]. D-amphetamine resulted in poor prolactin suppression in normo- and hyperprolactinemic subjects. Methylenedioxymethamphetamine use can cause neurochemical, behavioral, and endocrine alterations, similar to those produced by exposure to acute stress, suggesting its

possible role as a "chemical stressor" [32]. In humans, acute methylenedioxymethamphetamine treatment results in a rise in cortisol plasma concentrations, supporting the hypothesis of methylenedioxymethamphetamine-induced release of corticotropin-releasing hormone from the median eminence of the hypothalamus and subsequent hypothalamic-pituitary-adrenal axis and sympathetic nervous system activation. A recent study showed that amphetamine or methylenedioxymethamphetamine abusers were prone to having increased sexual desire, erectile dysfunction, and increased ejaculation latency [31].

Benzodiazepines

While benzodiazepines produce inconsistent effects on basal hormone secretion, they have potent effects on the inhibition of adrenocorticotropin, cortisol, thyroid-stimulating hormone, and prolactin secretion in response to stressful and pharmacological stimuli [97]. However, it is still unclear whether benzodiazepines reduce thyroid hormones. Acute diazepam administration causes stimulation of growth hormone secretion, but individuals taking this medication regularly over periods of years have an impaired growth hormone response or no response at all (tolerance). Benzodiazepines may act on the gamma-aminobutyric acid-coupled benzodiazepine receptors at the hypothalamus or other brain regions to reinforce the effects of endogenous gamma-aminobutyric acid. Nevertheless, some neuroendocrine effects of benzodiazepines are mediated through actions on benzodiazepine receptors in the pituitary gland. Plasma testosterone and 11-hydrocorticoid levels are increased by benzodiazepine ligands in humans [74]. In males, testosterone modulates peripheral-type benzodiazepine receptor density in the genital tract. The peripheral-type benzodiazepine receptor density is increased in the human ovary proportional to greater cell maturation and differentiation. Finally, individuals with benzodiazepine abuse can present with significant sexual dysfunctions such as erectile dysfunction [68], including a complete loss of libido.

Nutrition and Body Composition

Alcohol

There is some controversy about the effect of ethanol on body weight and about the contribution of alcohol energy to body mass. In fact, several studies have shown a positive, a negative, or no relationship between alcohol consumption and body composition alterations. These discrepancies are at least partially related to the different sample of subjects evaluated (healthy social drinkers, alcohol abusers, or subjects affected by chronic alcoholism) (Table 8).

According to Cordain et al. [52], the intake of small quantities of alcohol by social drinkers seems to have no effect on body composition or metabolism. On the other hand, in a study carried out in Italy, the caloric intake from alcohol in males was related to a significant increase in body mass and in the waist-to-hip ratio value, indicating a greater body fat distribution in the intra-abdominal region [159], which is considered as "harmful fat" for hypertension. These differences could be related to several factors, including age, gender, and the kind of alcoholic beverage used. Consistently, Addolorato et al. [3] have recently reported no significant modifications of body weight, fat mass, fat-free mass, or total body water in healthy social drinkers. However, while fat-free mass and fat mass were unmodified in the control group, fat mass increased in subjects drinking beer and wine and decreased in subjects who drank liquor. Fat-free mass was stable in beer and wine drinkers and increased in subjects who drank liquor.

On the other hand, the intake of large amounts of alcohol is related to several nutritional disorders. According to Lieber [117], long-term consumption of up to 2,000 calories/day in the form of alcohol does not produce the expected

Table 8 Main nutritional and metabolic features in subjects with substance abuse or dependence

Substance	Nutritional features	Metabolic features
Alcohol	Reduced BMI, reduced FM, increased ECW	Increased REE, lower carbohydrate oxidation, higher lipid oxidation
Nicotine	Reduced BMI, increased WHR	Increased lipid oxidation and lipolysis, decreased lipoprotein lipase activity
Opioids	Reduced BMI, reduced FM	Normal REE
Cocaine	Reduced BMI, reduced FM	Normal REE
Amphetamines	Loss of appetite	Indirect fat-mobilizing action, through an endogenous catecholamine release, and exercise-promoting effects, increasing EE
Benzodiazepines	Hyperphagia, enhanced palatability	

BMI body mass index, *FM* fat mass, *ECW* extracellular water, *WHR* waist-to-hip ratio, *REE* resting energy expenditure, *EE* energy expenditure

gain in body weight. Chronic alcohol abuse deeply affects nutritional status, first due to the fact that ethanol may supply more than 50% of the dietary energy in alcoholics partly because of the high caloric content of ethanol (7.1 kcal/g), its appetite suppressant action, and its promotion of a satiety effect by inhibiting gastric motility. Moreover, chronic intake of heavy amounts of alcohol may cause malabsorption of intestinal origin, steatorrhea, and pancreatic disorders, together with impaired hepatic metabolism of nutrients [117]. In recent years, a set of studies performed in our laboratory were aimed at evaluating the effect of chronic alcohol abuse on energy metabolism and substrate oxidation in alcoholics without clinical or laboratory evidence of liver disease or malabsorption. Alcohol-dependent individuals seem to have a high resting energy expenditure, thus consuming, even at rest, more energy than social drinkers and producing heat instead of storing energy in response to food or liquid intake as happens in normal metabolic pathways [1]. The increased resting energy expenditure in these individuals is related in part to the induction of the microsomal ethanol oxidizing system caused by chronic alcohol abuse [3]. Ultrastructural abnormalities of mitochondria have also been shown in alcohol-dependent individuals, with formation of giant mitochondria and functional alterations characterized by increased thermogenesis with dissipation of heat [117]. A further loss of energy by thermogenesis may be related to increased catecholamine levels [166]. Chronic heavy amounts of ethanol exposure in individuals without malabsorption also produce a lower body weight with respect to control groups and induce a preferential utilization of lipids as energy substrate and a lower carbohydrate oxidation, as indicated by a significantly lower non-protein respiratory quotient measured by indirect calorimetry assessment [2, 3]. These alterations cause alcoholics to have a lower body mass index and fat mass and a similar fat-free mass value with respect to controls as measured by dual-energy X-ray absorptiometry [3, 4, 8]. The alterations in body composition and metabolism seem to be completely reversible, at least in alcohol-dependent individuals who do not have severe alcohol-related disease, after 3 months of complete alcohol abstinence without pharmacotherapy or nutritional supplementation [3, 6]. With regard to body fluid distribution, alcohol-dependent individuals show an increase in the extracellular water compartment, with a higher extracellular water/total body water ratio compared with controls [7]. The mechanism responsible for this increase remains unclear. It could be hypothesized that the increased extracellular water/total body water ratio in alcoholics is a result of an increased leak of vacuolar fluid into the interstitial space caused by endothelial damage that occurs due to ethanol-induced vasoconstriction [22] and/or a direct toxic effect of ethanol on the cellular membrane [4]. Finally, compared with non-cirrhotic subjects, alcoholics affected by liver cirrhosis, and especially those with ascites, show a more impaired nutritional

status, with not only increased resting energy expenditure, preferential lipid oxidation, and a reduction in fat mass, but also a reduction in fat-free mass [5, 82, 161]. This could be due to the low protein intake with the diet, aggravated by ascites gastric compression and consequent anorexia, and impaired enteric absorption due to portal hypertension [161].

Nicotine

Chronic nicotine administration and its withdrawal produce significant effects on body weight and food intake. Several studies have reported a significantly lower weight and body mass index in cigarette smokers than in non-smokers. However, the former had a significantly higher waist-to-hip ratio than the latter [179], indicating that cigarette smoking could have harmful effects on the pattern of distribution of body fat. According to Perkins et al. [149], an acute intake of nicotine significantly increases energy expenditure, slightly at rest and more significantly during physical exercise. On the other hand, chronic administration of nicotine seems to be not associated with increased resting energy expenditure [98]. However, changes in body weight could be related to enhanced fat oxidation [98] and increased lipolysis and, over time, decreased lipoprotein lipase activity [168], suggesting an alternative mechanism by which nicotine modifies body weight despite changes in food intake.

Opioids and Cocaine

Data available in the literature focus overall on the metabolic and nutritional alterations in subjects with opioid and/or cocaine abuse and dependence. According to Santolaria-Fernandez et al. [160], drug addicts, especially those with heavier consumption, are undernourished. Poor nutritional status is mainly related to female sex, intensity of drug addiction, anorexia, and disturbance of the social and familial networks. Consistently, in a small cohort of opioid-addicted subjects evaluated before and after 4 years in a methadone maintenance program, weight loss and decreased body mass index were observed in the women, whereas the men experienced an increase in body mass index [108]. Drug dependence, especially when parenteral, is frequently complicated by infections, which are particularly harmful when affecting a previously malnourished person. Repeated infections, such as the hepatitis B virus, staphylococcal phlebitis, endocarditis, sepsis, systemic yeast infections, etc., contribute through the enhancement of catabolism to the development of undernutrition [160]. Moreover, human immunodeficiency virus infection may be a main cause of malnutrition (wasting syndrome) in drug addicts. Among human immunodeficiency virus-infected individuals with a high prevalence of drug use, females have lower average weight, body mass index, and fat mass than non-users. In particular, women with "heavy drug use" have lower whole body fat in both absolute and percentage amounts and higher lean mass. In a recent study, Forrester et al. [67] reported a lower weight and body mass index in Hispanic men with and without human immunodeficiency virus infection who used cocaine alone or with opiates compared with men who used only opiates or men who were human immunodeficiency virus-positive but did not use drugs. The observed differences in body mass index are not attributed to differences in reported dietary energy intake, resting energy expenditure, malabsorption, or infection with human immunodeficiency virus or hepatitis. In sum, the only factor associated with reduced lean and fat mass is heavy illicit drug use among women, a pattern not seen in men, while other factors, such as human immunodeficiency virus or hepatitis C, seem not to be associated with body composition parameters [48].

Amphetamine

No data are available in the literature on the nutritional status and energy expenditure in

amphetamine abuse. However, several studies have shown a marked loss of appetite secondary to 3,4-methylenedioxymethamphetamine and methamphetamine exposure, which persists for a day or more after the drug is taken [184]. Moreover, amphetamines have an indirect fat-mobilizing action, dependent on endogenous catecholamine release [152], and exercise-promoting effects, which increase energy expenditure [53].

Benzodiazepines

Benzodiazepines have the property of enhancing palatability through their central brain action. The effects of this action include the promotion of food consumption [51]. However, further studies are necessary to establish whether benzodiazepine abuse is correlated to changes in nutritional status and metabolic features.

Introduction

The undertreatment of pain is considered a significant public health problem. Over the last two decades, clinicians have been encouraged to actively manage painful conditions, and the concept of using opioids for chronic, non-cancer pain has gained more widespread acceptance. The significant increase in opioid prescribing for analgesia has been mirrored by an increase in prescription opioid abuse, highlighting another pervasive, undertreated, and significant public health problem: substance abuse and addiction [39]. Concerns about initiating addiction and fear of penalties against clinicians who act in good faith threaten to reverse the gains made in pain management to the detriment of both of these patient populations. With proper education and resources, most patients can be treated effectively without undue risk to themselves and society.

Use of opioid analgesics to treat cancer and acute pain is not controversial, and data support its efficacy. Treatment of chronic non-cancer pain with opioids is controversial and will be discussed. The clinical role of cannabinoids as analgesics has not been established and is not discussed. This chapter is intended to provide an understanding of the chronic, neurobiologic diseases of pain and addiction, key clinical

characteristics, and strategies for treating pain and addiction as comorbid diseases.

Definitions

Pain

Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory or emotional experience associated with actual or potential tissue damage or perceived in terms of such damage". It has also been defined as "whatever the experiencing person says it is, existing whenever that person says it does" (Margo McCaffery, 1967). The latter definition has been amended by Fishman to state that pain "is whatever the patient states it is unless proven otherwise by poor adherence to an agreed upon medical regimen" [23]. Pain has also been conceived as primarily a motivational state that has a powerful influence on decision making.

Pain states have been further classified as: physiologic and pathologic; acute and chronic; inflammatory; neuropathic, and malignant bone pain. Physiologic pain exists as an innate protection. It is transient, well-localized, may have an inflammatory component, and exhibits a stimulus-response relationship. Pathologic pain, sometimes known as clinical pain, does not serve a protective function and is indicative of maladaptive changes in the peripheral and central nervous systems. Pathologic pain is either inflammatory, neuropathic, malignant bone pain or a combination of these. Acute pain exists in the presence of an injury or painful disease and resolves with resolution of the injury or disease event. Chronic pain exists in the absence of any injury or discernable tissue damage or in conjunction with chronic diseases that have ongoing inflammatory or neuropathic components. Inflammatory, neuropathic, and malignant bone pains have distinct neurochemical profiles and respond to pharmacologic and physiologic interventions in specific ways.

Addiction

The definitions of addiction, abuse, tolerance, and dependence have evolved over time. One major problem is the inclusion of pharmacological dependence and tolerance in the definition of drug addiction. Both conditions are an expected consequence of long-term opioid therapy, and neither indicates problematic drug use or addiction per se. Lack of consensus has led to confusion among clinicians, patients, regulators, and the general public, resulting in misconceptions regarding the medical use of opioids for analgesia or for addiction. This has caused unnecessary suffering, stigmatization of the disease of addiction, undue economic burdens to society, and inappropriate legal and regulatory actions against clinicians and patients.

In 2003, Savage et al. published "Definitions Related to the Medical Use of Opioids: Evolution Towards Universal Agreement" [63]. This document contains the recommendations of the Liaison Committee on Pain and Addiction, formed jointly by the American Pain Society, the American Academy for Pain Medicine, and the American Society for Addiction Medicine in 1999, to clarify the nomenclature used to define terms that are used to describe addiction and therapeutic opioid use. Its definitions are:

- Addiction is a primary, chronic, neurobiological disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving;
- Physical dependence is a state of adaptation that is manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist, and
- Tolerance is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.

Additionally, an understanding of pseudoaddiction and chemical coping is relevant when considering pain and addiction. Pseudoaddiction is described as drug-seeking behavior in the setting of uncontrolled pain. It disappears when analgesic interventions, including increased doses of an opioid, become effective [78]. Frequently, this drug-seeking behavior is indistinguishable from that of an opioid addict, including the use of illicit opioids. However, unlike in drug addiction, the motivation to use opioids is to achieve analgesia and not for its psychological rewarding effects. When analgesia is achieved, aberrant drug use behaviors resolve.

Chemical coping is described as using medications in non-prescribed ways to cope with stress. It constitutes an avoidance-type coping strategy. Individuals who suffer from depression, anxiety, alexithymia, and somatization, as well as sensation seekers, are frequently identified as chemical copers [37]. It is often extremely difficult for this population to acknowledge and participate in non-pharmacological aspects of their treatment, including learning more adaptive coping skills, and to change from their coping medication of choice. All addicts are chemical copers but not all chemical copers are addicts.

Incidences of Pain and Addiction

Approximately 50–70 million people in the United States are inadequately treated or untreated for a chronic painful condition, resulting in an estimated cost of $61 billion in lost productivity [8].

The 2007 National Household Survey on Drug Use and Health reported that 9.2% of the population aged 12 years and older abuse substances or are substance dependent. The range varies from 3 to 16%. Over 15 million Americans have admitted to abusing prescription drugs, of whom 1.6 million are prescription opioid addicts. This is the second-largest type of illicit drug abuse after marijuana, and exceeds the total number of people abusing heroin (0.3 million), cocaine, hallucinogens, and inhalants. Opioids are the most commonly prescribed medications in the United States [35].

Based on these data, approximately 5–7 million people have addiction and a chronic pain condition. In one study of an addicted population on methadone maintenance treatment the incidence of chronic non-cancer pain was 61.3% [31]. When chronic pain and addiction exist together, they are mutually reinforcing conditions.

Neurobiology of Pain

Pain exists as a physiologic protection. It is innate, except in extremely rare people with anociceptive mutations. Nociceptive afferent pathways are present and functional from 24 weeks post-conceptual age. The development of central inhibitory pathways lags behind and is not mature until 4–6 months of age.

In the classic pain pathway unmyelinated C-fibers and myelinated A-δ fibers transduce noxious stimuli at the periphery and transmit them to laminae I–VI of the dorsal horn in the spinal cord, where they are modulated. Secondary and tertiary neurons in the central nervous system transmit impulses to higher centers where the sensation is perceived and acted upon. Persistent pain that no longer serves a protective role is pathologic and should be considered as a disease of the nervous system. Neuroplasticity in the central nervous system allows pain to become pathologic. Congenital anociception [1, 14] is a rare, fatal condition. Sufferers typically die of sepsis during childhood. In contrast, fibromyalgia appears to represent a constitutional hyperalgesic state [60].

There are two types of specialized peripheral primary sensory nociceptive neurons. Those activated by specific stimuli, e.g., chemical, thermal or mechanical, and those that are more adaptive called wide dynamic range neurons. Wide dynamic range neurons evidence weak activation by innocuous mechanical stimuli and more intense excitation by noxious mechanical or thermal stimuli. The presence of these distinct

receptor types indicates differences in coding of information from the periphery. Stimuli-specific neurons that synapse in laminae I and II provide the basis for differentiating noxious and non-noxious events. The large receptive fields of the wide dynamic range neurons that synapse in laminae V and VI set the responsiveness of higher centers. The axons of spinal neurons arising from dorsal horn laminae I, V, and VI terminate in the midbrain and thalamus. Activated peripheral nociceptive afferent fibers exhibit a notable propensity to increase their responsiveness to subsequent stimuli.

Tissue injury results in inflammation and changes in the extracellular milieu as intracellular contents issue from injured cells. The presence of protons, potassium ions, adenosine triphosphate, serotonin, bradykinin, prostaglandins, growth factors, and cytokines at nociceptive nerve endings sensitize them, and are partially responsible for increased pain (primary hyperalgesia) in injured tissue. Continued peripheral activation leads to central sensitization and "cross-talk" in the dorsal horn laminae. "Cross-talk" occurs when high-intensity firing from acute pain (inflammatory) or low-intensity firing from chronic pain (neuropathic) induces Aα and Aβ fibers to conduct "pain" signals. Inflammation also recruits silent nociceptors. Once activated, these previously silent nociceptors increase afferent transmission of mechanical stimuli, e.g., pain associated with inflammatory arthritides [58].

Persistent noxious stimuli are associated with increased synaptic activation of spinal neurons and up-regulation in the central nervous system, leading to evoked pain in uninjured tissues (secondary hyperalgesia). This phenomenon of "central sensitization" is the postulated mechanism for chronic and neuropathic pain. It is characterized by decreased thresholds for activation, shorter response latencies, spontaneous neural activity, and exaggerated responses to a given stimulus (hyperalgesia and allodynia). Central sensitization is primarily mediated by activation of *N*-methyl-*D*-aspartate glutamate receptors, which leads to the recruitment and increased activity of non-*N*-methyl-*D*-aspartate α-amino-3-hydroxy-5-methyl-4-isoxazole propionate, kainate, and 1-aminocyclopentane-1,3-dicarboxylate spinal glutamate receptors. *N*-methyl-*D*-aspartate receptor activation, in particular, induces a persisting afferent facilitation, leading to the generation of long-term potentiation of synaptic effectiveness. Descending inhibition of spinal pain-related activity is produced by neurons utilizing different chemical mediators from those involved in activation of peripheral nociceptors and afferent secondary neurons. Chemical mediators of descending inhibition include serotonin, catecholamines, and endogenous opioids.

Chronic pain arises from changes in neural functioning leading to persistent nociceptive input. Long lasting aberrant central nervous system-generated activity that triggers the perception of pain also produces plastic alterations in behavior and nervous function. In addition to phenomena such as sensitization of peripheral nociceptors and central neurons, rearrangements of activity and neuronal connections occur through gene induction. Principal factors in clinical circumstances are the emotional and motivational concomitants of persisting pain symptoms.

Brain imaging confirms that the cerebral cortex plays an important role in pain processing. Noxious stimulation evokes prominent signs of localized metabolic increases in several distinct cerebral cortical areas, including the anterior insula, the anterior cingulate cortex, and somatosensory II regions. A robust correlation exists among stimulus intensity, activation of these cortical areas, and patient reports of pain [22]. The lateral thalamic nuclei contribute terminals to several nuclei of the ventral posterior thalamus, a main somatosensory zone with spatial and modality characteristics suggestive of a role in discrimination. In contrast, the medial thalamic ventrolateral projection targets neurons in nuclei usually associated with affective or motivational regions. Less consistent, more context-influenced or smaller activations occur in other cortical regions. The amygdala and hypothalamus participate in affective and homeostatic functions related to nociceptive

mechanisms in addition to other sensory inputs. Mental state, attention, and disposition modify the pattern and details of imaged cortical responses to noxious input distinguishing pain as special from other sensations [4, 29]. For example, the activity in the anterior cingulate cortex evoked by pain-causing stimuli is related to emotion and motivation. Nociceptive signals also reach higher brain centers via multi-synaptic routes by way of connections in subthalamic brainstem nuclei.

The combined evidence supports pain as a discriminative sense and as an emotion [15, 58]. As such, it consists of a sensation and a motivation for action. The affective-motivational component of pain includes perception of the negative hedonic quality of pain, emotional autonomic and motor reactions, a general activation or arousal, and the drive to terminate the stimulus that causes the pain [71]. It is thought to be mediated via the anterior cingulate cortex. The anterior cingulate cortex has a high density of opioid receptors and is one of the brain regions most consistently activated by painful stimuli in human imaging studies. The opioid receptor density in the posterior, motor part of the anterior cingulate cortex, the midcingulate cortex, is lower than in the anterior cingulate cortex proper in the perigenual region. Morphine binding has been shown to modulate affective aspects of pain via receptors in the anterior cingulate cortex proper and motivational aspects of pain via receptors in the midcingulate cortex. This would explain the finding that morphine has a more profound effect on the affective component of pain than the sensory component.

There are many hypotheses describing the neurobiology of pain, but none of them fit all the data available. It is known that the mechanisms of pain include specialized receptive organs, selective and convergent pathways, plasticity of responsiveness, and interactive modulation, and that three neurochemically distinct types of pain have been identified in the central nervous system: inflammatory, neuropathic, and malignant bone pain [12]. Although research into the role of glia in pain physiology and opioid efficacy is in its infancy, early data are promising. This knowledge could allow targeted therapies to correct underlying abnormalities in the central nervous system to relieve pain. For example, anti-inflammatory medications are most appropriately used to treat inflammatory pain. Unfortunately, there are many more ions, neurotransmitters, receptors, and cell types involved in pain and nociception than there are therapies to modulate them. This field is rich with ongoing research and the potential for development of new therapeutics.

Neurochemistry of Addiction

Physiologically, dopaminergic and opioid systems modulate a number of processes including: the regulation of reward and affective states; cardiovascular, immunological, and neuroendocrine functions, and the effects of substances of abuse and the development of addiction [65].

Addiction is a chronic neurobiological disease of the brain's reward and motivation centers. The reward centers exist to preserve the organism and propagate the species. Natural cues that stimulate these centers include eating, sex, social interactions, and unexpected novel stimuli. Opioids, as well as other drugs of abuse, stimulate these centers in a similar fashion to endogenous ligands, but their effects are more intense and prolonged. For drugs that use brain reward centers, craving assumes the strength and characteristics of a primary survival drive. Thus, addictive drugs activate and dysregulate endogenous reward centers. By utilizing these brain circuits, they take over behavior. This leads to progressive loss of control over drug use despite negative consequences to the user. Dopamine, gamma-aminobutyric acid, and glutamate are key to these reward circuits. Serotonin, norepinephrine, enkephalin, endorphin, and cholecystokinin are also functionally important [65]. Interestingly, the central nervous system areas involved in physiologic drug tolerance and dependence are separate from the reward centers, which confirms the clinical observation that physical dependence and

tolerance to drugs are not associated with addiction and craving, although the converse is true.

Addiction involves drug, host (trait variables), and context (state variables) (Fig. 1). Their interrelationship regulates the functional set point for hedonic tone. Manipulating the neural connections can alter drug-taking behavior.

The cortico-mesolimbic reward pathway is a specific limbic circuit generating feelings of pleasure [65]. It is also involved in traditional memory and in mediating addictive behavior. Emotional memories can be very powerful and may be relevant in the etiology and persistence of addiction, e.g., victims of childhood sexual abuse have an increased incidence of subsequent substance abuse and addiction. Notable structures of the cortico-mesolimbic reward pathway are the ventral tegmental area in the brainstem, the nucleus accumbens in the basal ganglia, and the medial prefrontal cortex.

Cortico-mesolimbic dopamine neurons arising from the ventral tegmental area project to the nucleus accumbens and terminate on medium-sized spiny cells that contain gamma-aminobutyric acid (GABA) and endogenous opioid peptides. These cells reportedly fire in anticipation of food and water [17]. Opioids produce their rewarding effects via activation of μ-opioid receptors located on GABAergic midbrain interneurons that negatively regulate dopamine cell firing. Activation of these inhibitory Gαi-coupled μ-opioid receptors reduces the GABAergic inhibition of midbrain dopamine neurons, thereby increasing their firing rate and the amount of dopamine released in the nucleus accumbens [28]. The nucleus accumbens has been termed the universal addiction site because it is a region where drugs as diverse as cocaine, amphetamine, alcohol, opioids, marijuana, and nicotine all increase dopamine levels. Opioid-containing neurons project from the nucleus accumbens to several reward centers, including the lateral hypothalamus (feeding and sex center), medial prefrontal cortex, and other limbic structures.

The ventral tegmental area is an important site of opioid control for goal-directed behaviors. Dynorphin is an endogenous peptide that is κ-opioid receptor selective. Dynorphin terminals synapse onto dopamine dendrites in the ventral tegmental area and inhibit dopamine neuron signaling by a direct post-synaptic action via activation of a G-protein-coupled inwardly rectifying potassium channel.

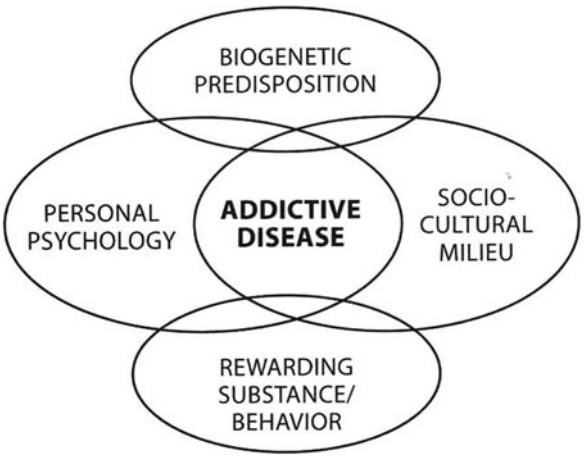

Fig. 1 The relationship between drug, host, and context variables in the etiology of addictive disease—biogenetic predisposition (altered neurochemistry); personal psychology (patients with comorbid bipolar disorder, attention-deficit hyperactivity disorder, schizophrenia, antisocial personality disorder, and psychopathic personality disorder are especially at risk); rewarding substance/behavior (exposure to the drug of choice), and socio-cultural milieu (environmental stressors, especially in those with the following psychological traits: extreme shyness, borderline personality, anxiety proneness, alexithymia, and poor stress coping). Reprinted from Jovey [32] with permission from the International Association for the Study of Pain

Kappa-opioid receptor agonists infused into the ventral tegmental area inhibit dopamine neurons that project to the medial prefrontal cortex but not to the nucleus accumbens. Thus, medial prefrontal cortex dopamine concentrations decrease, with attendant behavioral effects, while nucleus accumbens dopamine concentrations remain unchanged. Midbrain dynorphin levels increase after amphetamine administration. Prolonged administration of drugs of abuse, e.g., alcohol or cocaine, produces long-lasting down-regulation of κ-opioid receptor messenger ribonucleic acid levels in the ventral tegmental area. Alterations in dopamine release in the cortex may also contribute to the psychotomimetic effects of κ-opioid receptor activation in humans [44].

Initial drug use stimulates dopamine release in the reward centers. However, over time, dopamine stores and receptors become depleted, and higher concentrations are needed to overcome this. When dopamine release is maximal but stimulation continues, or increases, other brain areas are recruited, particularly the glutamate rich frontal cortex. Glutamate release enhances second messenger systems, activates nuclear transcription factors, and changes long-term gene expression. These glutamatergic pathways mediate drug "cues". Glutamate is proalgesic and is one of the excitatory amino acids associated with hypersensitivity to pain in the central nervous system manifested as hyperalgesia and allodynia. Reduced dopamine-mediated reward is associated with high rates of depression, irritability, anxiety, and suicide—characteristics common to patients in pain and with addiction.

The effects of excessive dopamine associated with addiction cause a decrease in dopamine type-2 receptor numbers over time. The reward circuitry becomes damped, a state maintained long after drug use stops since it takes a prolonged period for the dopamine type-2 receptor density to return to normal. On magnetic resonance imaging, recovering addicts demonstrate persistent reductions in metabolic activity in the prefrontal cortex, orbitofrontal cortex, and anterior cingulate cortex and reductions in the neuronal density of frontal lobe regions. These changes make these brain areas particularly sensitive to re-exposure to drugs of abuse. Deficits in impulse control and decision making that characterize addictive behavior are mediated by the orbitofrontal cortex and anterior cingulate cortex. Limbic impulses are also suppressed.

In primate studies stress increases vulnerability to cocaine self-administration [50], whilst a less stressful, more privileged environment attenuates the reinforcing effects of drugs and provides a degree of protection from addiction and relapse during recovery. A less stressful, more enriched lifestyle boosts the number of dopamine receptors in the brains of primates and makes them less vulnerable to the reinforcing effects of cocaine and less likely to relapse. The role of environmental enrichment in humans is unknown. However, human studies have suggested that the number of dopamine type-2 receptors an individual has might be related to his or her vulnerability to the rewarding effects of a drug. Relatively, people with subnormal levels of dopamine type-2 receptors might experience euphoria with stimulants while those with normal levels of dopamine type-2 receptors could perceive them as unpleasant. Nevertheless, although treatments that could increase the brain's dopamine type-2 receptors have been suggested as potential treatment for drug abuse [38], the results of clinical studies have been disappointing.

It has been theorized that opioid abusers may have a biologic predisposition to opiate dependence in much the same way that some individuals appear predisposed biologically to developing alcohol dependence. According to this proposal, exogenous opioids might be filling a neurochemical deficiency in the central nervous system, and opioid addicts may be self-medicating to correct the deficit. This proposal has not been proven but is supported by data from patients in opioid maintenance therapy who have a near normal, stable brain chemistry whilst in treatment.

The overlap of addiction and pain pathways in the brain, e.g., at the nucleus accumbens, anterior cingulate cortex, and hippocampus, might

explain, at least partially, the close association between pain states and addiction. Pain circuits and addiction pathways both utilize endogenous opioids. Also, both conditions involve sensitization and synaptic plasticity, which alter the responsiveness of the central nervous system to sensory input.

Neurochemistry of Opioids

Opioid analgesics do not simply inhibit pain transmission pathways. They mimic the actions of endogenous opioids released in response to specific conflict situations. Agonists at each receptor modulate neurons in a circuit that selectively controls nociceptive transmission. Opioid actions contribute to, and are determined by, the state of the circuit. The circuit can operate in both pain-inhibiting and pain-facilitating states. Thus, opioids can produce either analgesia or pain, depending upon the circumstances [20].

Opioid receptors (μ, κ, δ, and opioid receptor-like) belong to a large superfamily of G-protein-coupled receptors. Endogenous opioid peptides are released in the central nervous system in response to stressful stimuli. Mu-opioid receptors couple preferentially to the pertussis toxin-sensitive G proteins, Gi and Go, and inhibit the adenylyl cyclase/cyclic adenosine monophosphate pathway. Mu-opioid analgesia is attributed to the $G_{\beta\gamma}$ dimer (released from Gi/o proteins) that activates G-protein-activated, inwardly rectifying potassium channels and inhibits voltage-dependent calcium channels, thereby suppressing cellular activities through hyperpolarization. In particular, it inhibits signaling between primary afferent terminals and second-order dopamine neurons. The anatomic distribution of δ-, κ-, and opioid receptor-like opioid receptors parallels those of the μ-opioid receptors present in the component nuclei of the pain modulating circuit. Ligands selective for each opioid receptor regulate various motivated behaviors including feeding, alcohol and psychostimulant consumption, and pain [74].

Opioids control the pain-transmission pathway directly through actions in the superficial layers (laminae I, II, and IV–VI) of the dorsal horn. Both primary afferent terminals and second-order dorsal horn neurons bear μ-opioid and δ-opioid receptors [22]. Mu-opioid agonists are powerful analgesics and produce profound appetitive motivational actions. The contribution of δ- and κ-opioid receptors to motivational states is less clear.

In addition to their direct action on the spinal cord, μ-agonists also activate supraspinal structures that project down and control pain transmission at the level of the spinal cord. This "top–down" pain modulatory circuit includes the frontal lobe cortical regions, hypothalamus, and amygdala that project to the para-aqueductal gray, which in turn projects via the rostral ventral medulla and dorsolateral pontine tegmentum to the superficial layers of the dorsal horn. This anatomic arrangement enables the descending system to control nociceptive transmission at the first central synapse where the nociceptive primary afferents terminate. The component nuclei of this pain-modulation pathway contain μ-opioid receptors and a relatively high concentration of the endogenous opioid peptides leucine- and methionine-enkephalin. Activation of the rostral sites leads to release of endogenous opioids in downstream regions. Lesions to, and antagonists applied at, these sites block the analgesic effects of systemic μ-opioid agonists.

There are three distinct types of component neuron in the descending modulating pathway: OFF cells activated by μ-opioid agonists that inhibit responses to noxious stimuli; ON cells that are activated by noxious stimuli, are inhibited by μ-opioid agonists, and facilitate responses to noxious stimuli; and NEUTRAL cells that do not change their activity [48]. ON and OFF cells are found in the para-aqueductal gray, the dorsolateral pontine tegmentum, and the rostral ventral medulla. The rostral ventral medulla ON and OFF cells project directly to the dorsal horn, where they modulate pain transmission. Increased OFF cell activity contributes to the anti-nociceptive effect of μ-opioid receptor

ligands while analgesic doses of μ-opioid receptor agonists silence ON cells. Very simply, OFF cells "switch off" pain whereas ON cells "switch on" pain. OFF cells are activated by decisions to ignore pain, μ- and δ-opioid receptor agonists, cannabinoid agonists, and gamma-aminobutyric acid-A antagonists. ON cells are activated by decisions to respond to pain and conditions associated with hyperalgesia, e.g., tonic noxious stimuli, acute opioid abstinence. The rostral ventral medulla neurons contain primary and secondary cells. Primary cells respond to κ-opioid receptor agonists and represent physiologically characterized ON cells. Secondary cells respond to μ-opioid receptor agonists and represent OFF cells.

Endogenous μ-opioid receptor agonists increase OFF cell activity by pre-synaptic inhibition of GABAergic inputs and directly hyperpolarizing ON cells. These actions tip the balance in favor of OFF cell activity and, hence, analgesia. Activation of OFF cells, rather than the inhibition of ON cells, is critical for the suppression of noxious stimuli.

Kappa-opioid receptor agonists alter OFF and ON cell function via glutamate release. Kappa-opioid receptor agonists attenuate μ-opioid receptor agonist-mediated analgesia by hyperpolarization of OFF cells, a direct post-synaptic inhibition, and by pre-synaptic inhibition of glutamate release. They also inhibit glutamatergic transmission at ON cells, reducing ON cell stimulation. Glutamate antagonists applied directly to the rostral ventral medulla have the same effect, i.e., OFF cell activation and anti-nociception by systemic μ-opioid receptor agonists (e.g., morphine) are prevented. The selective inhibition of OFF cells explains the anti-analgesic effect of κ-opioid receptor agonists while the selective inhibition of ON cell firing explains their anti-hyperalgesic effects. These effects are demonstrated in studies where κ-opioid receptor agonists applied directly to the rostral ventral medulla reduce the analgesic behaviors observed in response to systemic μ-opioid agonists but also produce analgesia themselves. It also predicts that other conditions that result from activation of rostral ventral medulla pain-facilitating neurons (presumably ON cells) such as hypersensitivity produced by nerve injury will also be relieved by κ-opioid receptor agonists. Endogenous κ-opioid agonist actions in the rostral ventral medulla regulate behavioral responses to noxious stimuli in a state-dependent manner [48].

Pain has been conceptualized as primarily a motivational state that has a powerful influence on decision making. Stress-induced analgesia represents a "do not respond to pain" decision as occurs with OFF cell activation in the endogenous opioid-mediated, pain-modulatory descending pathway described above. It can be blocked by lesions of the central nucleus of the amygdala and by opioid antagonists (e.g., naloxone). A "do not respond" decision occurs under conditions of threat and anticipated reward. The specific brain circuitry of the analgesic effect of reward expectancy is not known. It is hypothesized to involve the mesostriatal dopamine neurons implicated in drug and food reward. Mu-opioid agonists placed directly on the nucleus accumbens promote analgesia and increased food consumption. Opioids directly affect the decision process through an action in the mesostriatal dopamine pathway, where they concomitantly promote reward seeking and raise the threshold for responding to noxious stimulation.

In the rostral ventral medulla, δ-opioid receptors are present on axon terminals. Selective antagonists block analgesia produced by para-aqueductal gray activation. Delta-opioid receptor agonists produce changes in rostral ventral medulla ON and OFF cells that are similar to, but weaker than, those produced by μ-opioid receptor agonists and produce weak-to-moderate analgesia. Prolonged inflammation is associated with an enhanced anti-nociceptive effect for deltorphin (a δ-opioid receptor selective ligand) in the rostral ventral medulla. Delta-opioid receptor function might be more robust if the receptor is studied under appropriate conditions.

Nociceptin, a ligand selective for the opioid receptor-like opioid receptor, strongly hyperpolarizes all classes of neurons in the rostral ventral medulla and para-aqueductal gray through

activation of an inwardly rectifying potassium channel. Nociceptin inhibits gamma-aminobutyric acid release by a pre-synaptic action. In vivo, the opioid receptor-like ligand acts post- synaptically to strongly inhibit all ON and OFF cells in the rostral ventral medulla. The behavioral effect of an opioid depends on whether the circuit is in the ON cell or OFF cell state. When morphine is given, ON cells become silent and OFF cells fire continuously. In the OFF cell-activated state, dorsal horn neurons and withdrawal reflexes are inhibited. Serotonergic neurons in the rostral ventral medulla that project to the dorsal horn provide a third, state-dependent element that controls nociceptive transmission.

Placebo and nocebo (development of adverse effects or worsening of a condition after administration of a placebo) effects are mediated via central dopamine and opioid systems [65]. Placebo analgesia is mediated through activation of μ-opioid receptors in the midcingulate cortex, insular cortex, and nucleus accumbens. It is thought to represent a form of reward expectation processing; a process mediated by cortico-mesolimbic dopamine neurons. Molecular imaging studies have examined the response of nucleus accumbens dopamine transmission in the presence of a placebo with expected analgesic properties, and the relationship between nucleus accumbens dopamine and endogenous opioid systems. Placebo analgesia is most strongly predicted by activation of dopamine neurotransmission in the nucleus accumbens (25% variance). Dopamine activation in this region is correlated with μ-opioid activation in the rostral and subgenual anterior cingulate cortex, orbitofrontal cortex, anterior and posterior insulae, medial thalamus, nucleus accumbens, amygdala, and para-aqueductal gray. The magnitude of the placebo response correlates directly with the degree of neurotransmitter activation. Conditioned analgesia is blocked by application of μ-opioid receptor antagonists into the basolateral amygdala, para-aqueductal gray, and rostral ventral medulla, but not by δ- or κ-opioid receptor selective antagonists. The analgesia that accompanies conditioned fear is inhibited by κ-opioid receptor agonists in the rostral ventral medulla.

Opioid-mediated pain modulatory circuits can be engaged during appetitive as well as aversive motivational states. The rostral ventral medulla ON cell burst and OFF cell pause are reduced during food and water consumption. In animal studies, eating and food cues activate an opioid-mediated pain modulatory circuit, increasing the probability that the food will be consumed despite conflicting drives. Mu- and δ-opioid receptor agonists in the nucleus accumbens (the region of the basal ganglia crucial for linking motivation to action) induce both anti-nociception and consumption of sweet and rich food and ethanol. Instinctive as well as learned motivational states with either appetitive or aversive valence are associated with activation of opioid-mediate anti-nociceptive mechanisms. Dopaminergic activity in the nucleus accumbens is activated during both rewarding and aversive environmental events. It increases with anticipation of a positive outcome and reduces when the desired outcome becomes less likely. In rodents, a robust morphine locomotor response is dependent upon, and specific to, dopamine release. Dopamine-deficient mice display morphine analgesia, but the dose-response curve is shifted rightwards, suggesting that dopamine may mediate some of the analgesic effects of morphine. Data support the hypothesis that dopamine projections to the spinal cord provide tonic pain suppression mediated through dopamine-type 2 receptors.

Role of Glia in Analgesia, Pain, and Nociception

The role of glia in maintaining pain syndromes and in the efficacy and adverse effects of opioid drugs has only recently been identified and studied. It may be the key to understanding chronic pain and analgesia. Glia are microglia, astrocytes, and oligodendrocytes. They were originally considered to have a passive, supportive role in the central nervous system. Now it is known that they actively participate in

brain functioning and information processing [2]. Microglia are part of the immune system and enter the brain from the bloodstream during development. Microglia have primarily a surveillance role, rapidly extending and retracting processes to sample constantly the extracellular environment. The remaining glial cells arise from the neuroectoderm. Astrocytes are primarily involved in providing energy sources and neurotransmitter precursors to neurons, cleaning up debris, regulating extracellular levels of ions and neurotransmitters, and actively modulating synaptic transmission [76]. Under basal conditions, glia are not important regulators of pain transmission. However, when activated by damage to peripheral tissues, peripheral nerves, spinal nerves, or the spinal cord, microglia and then astrocytes in the spinal cord become activated. Activated glia release numerous neuroexcitatory substances including pro-inflammatory cytokines and chemokines, nitric oxide, reactive oxygen species, adenosine triphosphate, prostaglandins, and excitatory amino acids, all of which are pro-algesic and contribute to the maintenance of pain syndromes. Microglia and astrocytes also produce D-serine, an endogenous ligand for the glycine modulatory site on *N*-methyl-*D*-aspartate receptors, that enhances C-fiber-mediated excitation of pain-responsive neurons. Glia also decrease reuptake of glutamate in the spinal cord, thereby increasing synaptic glutamate and potentiating nociceptive signaling.

Astrocytes communicate with each other in a bidirectional manner through waves of calcium ions, propagating information over large distances. They possess many of the same neurotransmitter receptors as neurons, and neurotransmitter release by neurons activates calcium-based signaling cascades in astrocytes. Astrocytes then release neuroactive substances, signaling back to neurons in a feedback loop. Different types of molecules secreted by astrocytes can either inhibit or enhance overall levels of neuronal activity, and this is implicated in the etiology and maintenance of pathological pain, specifically neuropathic pain. These effects occur throughout the pain pathways including peripheral nerves, dorsal root ganglia, and spinal cord. Additionally, activated glial cells are known to reduce the analgesic effects of opioid drugs and may have a role in the evolution of opioid tolerance, physical dependence, and withdrawal [76].

Neuropathic pain arises from trauma, inflammation, and/or infection of peripheral nerves. It is characterized by allodynia, hyperalgesia, paresthesias, dysesthesias, and spontaneous pain. Damaged nerves alter their axon receptor expression to become increasingly responsive to substances that cause pain and to substances that normally do not. Neurons that do not normally signal pain can alter their gene expression and produce "pain" neurotransmitters (e.g., substance P, adenosine triphosphate, excitatory amino acids). Immune cells in and around peripheral nerves, and immune-like glial cells in the spinal cord, are key to both the creation and maintenance of pathological pain states. These same glial cells compromise the efficacy of opioids for pain control.

Peripheral nerve injury is associated with the local release of chemokines, bradykinin, serotonin, prostaglandin E2, histamine, substance P, and calcium gene reactive peptide. This "inflammatory soup" leads to enhanced afferent excitability that is exacerbated by neutrophils, macrophages, and pro-inflammatory cytokines, along with nitric oxide and reactive oxygen species, activated to kill invading microorganisms. Unfortunately, these substances also directly increase nerve excitability, damage myelin, disrupt the blood-nerve barrier, and expose the nerve to immune cells, thus creating a vicious cycle of nerve damage. Nerve damage is further exacerbated by the release of calpain, a calcium-activated protease in Schwann cells and associated myelin that destroys myelin. Destruction of myelin releases pro-inflammatory cytokines (primarily tissue necrosis factor, interleukin-1, and interleukin-6) and chemokines. In animal models, thalidomide and clonidine (an α-2 adrenoceptor agonist) both prevent neuropathic pain [76]—the former by concomitantly decreasing tissue necrosis factor while increasing the anti-inflammatory

cytokine interleukin-10, and the latter by reducing tissue necrosis factor and interleukin-1 while increasing the anti-inflammatory cytokine trophic growth factor β1. Tumor necrosis factor is thought to increase excitability in spared sensory neurons as a result of nearby neuroinflammation by stimulating retrograde transport leading to changes in gene expression and exerting autocrine and paracrine actions within the dorsal root ganglion. Additionally, tissue necrosis factor can trimerize and insert itself into lipid membranes, forming cation-permeable pores and cause demyelination of peripheral nerves. This increases membrane conductance by altering sodium and calcium channel functioning and leads to nerve damage with consequent insertion of ectopic sodium channels in the exposed membrane. This is associated with ectopic nerve firing and neuropathic pain. Tumor necrosis factor also increases the conductivity of glutamatergic α-amino-3-hydroxy-5-methyl-4-isoxazole propionate receptors (pronociceptive), and stimulates the overproduction and release of glutamate from microglia by upregulation of microglial glutaminase. Similar changes occur in the dorsal root ganglion, where satellite glial cells, along with resident and recruited immune cells, are well-positioned to alter the excitability of both damaged and healthy dorsal root ganglion neurons [76].

Activation of spinal cord glia amplifies peripheral and dorsal root ganglion-associated pain states. Release of substance P, adenosine triphosphate, and excitatory amino acids in response to afferent nociception leads to activation of microglia and then astrocytes with the consequent release of neuroexcitatory substances, including prostaglandins, interleukin-1, interleukin-6, and nitric oxide. Microglia are exquisitely responsive to extracellular adenosine triphosphate [76]. They release plasminogen, a protein that enhances *N*-methyl-*D*-aspartate receptor function and brain-derived neurotrophic factor. Both cause neuroexcitation by decreasing GABAergic and glycinergic inhibition.

The effects of glial products, such as pro-inflammatory cytokines, on spinal cord dorsal horn neurons depend on the presence or absence of ongoing neuropathic pain [76]. Glial activation in one central nervous system region can lead to glial activation in projection regions. Glia in the brain regulate many important functions, including responses to opioids such as morphine. The mechanisms underlying neuropathic pain and morphine tolerance are surprisingly similar.

Glial activation dysregulates the action of opioids at both spinal and supraspinal sites [76]. Recent data show that chronic morphine dosing activates microglial p38 mitogen-activated protein kinase and stimulates the production of spinal pro-inflammatory cytokines, both of which are associated with morphine tolerance. Blocking the pro-inflammatory cytokines reverses morphine tolerance. Morphine tolerance is associated with down-regulation of glial GLAST (excitatory amino acid transporter (1)) and GLT-1 (glial glutamate transporter-1, also known as excitatory amino acid transporter (2)) glutamate transporters (major transporters responsible for regulating extracellular levels of excitatory amino acids) in spinal cord dorsal horn which concomitantly leads to an increase in extracellular excitatory amino acids. Tolerance may occur through an opposing increase in neuronal excitability due to glial-induced elevations in glutamate and pro-inflammatory cytokines. Spinal inhibition of pro-inflammatory cytokines abolishes morphine resistance in neuropathic animals [76].

Glia may also play a role in opioid withdrawal symptoms. Rodents given a glia inhibitor during morphine administration did not manifest withdrawal when given a μ-opioid antagonist. Glia may also contribute to morphine reward. Injection of activated astrocyte cultures onto the nucleus accumbens or anterior cingulate cortex increased morphine conditioned place preference. Glia, in addition to regulating pathological pain, opioid analgesia, and opioid tolerance, should be considered as contributing to the phenomena of morphine reward and morphine dependence/withdrawal.

Endogenous μ-opioids (met- and leu-enkephalin) stimulate the release of interleukin-1 from microglial cultures. Spinal pro-inflammatory cytokine blockade increases the

magnitude and duration of action of acute analgesia to morphine and methadone. Different receptors mediate the pain-suppressive effects of morphine than its pain enhancing effects. Hence, it should be possible to separate the neuronally mediated, pain-suppressive effects of opioids from their glial-activating, pain-enhancing effects, either by structurally modifying opioids to prevent their binding to the glial non-stereotactic opioid receptor or by co-administration of a [+]-opioid antagonist that would block glial activation while allowing opioid action on neurons to remain unaltered, e.g., [+]-naloxone (inactive at neuronal opioid receptors).

Although pro-inflammatory substances may cause chronic neuropathic pain, anti-inflammatories, e.g., prostaglandin inhibitors and steroids, are not effective in its treatment. This may be explained by differences in chemical effects at different sites. What is anti-inflammatory in the periphery is not so in the central nervous system. Prostaglandin E2 (inflammatory and damaging in the periphery) is anti-inflammatory and neuroprotective in the central nervous system. Intrathecal steroids may decrease the expression of glial glutamate transporters and increase spinal neuronal expression of *N*-methyl-*D*-aspartate receptors, effects predicted to increase the excitability of neurons. Adrenal steroids increase microglial activation, including the induction of pro-inflammatory cytokines, and exert multiple pro-inflammatory effects in the central nervous system.

Lastly, clinical depression is associated with a profound loss of oligodendrocytes and myelin. The myelin loss that accompanies glial activation in the presence of persistent neuronal excitation may explain the strong association between depression and chronic pain.

Opioid Receptors: Pharmacologic Tolerance and Hyperalgesia

During chronic opioid exposure, opioid receptors desensitize via phosphorylation by G-protein-coupled kinases. Subsequent binding by the regulatory protein β-arrestin in turn reduces the efficiency of intrinsic Gi/o protein coupling leading to uncoupling of μ-opioid receptors and endocytosis or "internalization" [47, 74]. This receptor decrease and subdued Gi/o coupling contributes to opioid analgesic tolerance.

Other mechanisms of opioid analgesic tolerance include increased cyclic adenosine monophosphate production through activation of adenylyl cyclase by $G_{\beta\gamma}$. The $G_{\beta\gamma}$ dimer that signals to adenylyl cyclase after chronic morphine administration originates from the Gs heterotrimer and not the Gi/o proteins that have reduced their coupling to μ-opioid receptors. The excitatory effect on the cell that occurs during opioid tolerance appears to be additive or synergistic reflecting loss of adenylyl cyclase inhibition by Gi/o proteins and stimulation of adenylyl cyclase by both Gs proteins and their associated $G_{\beta\gamma}$ dimers [74]. The increase in cyclic adenosine monophosphate mediates an increase in cation conductance, causing increased excitability in the para-aqueductal gray and dorsal raphe areas with increases in glutamate and gamma-aminobutyric acid transmission. Dependence and withdrawal occur primarily due to this opioid receptor counter-adaptation [47]. Alternatively, continued signaling and recycling of opioid receptors and G proteins during prolonged μ-opioid exposure may result in regrouping of μ-opioid receptors, G proteins, effectors, and regulatory molecules that facilitate novel interactions merely by variations in proximities among these membrane constituents [74]. Prior subanalgesic doses of morphine reduce subsequent analgesia produced by an analgesic dose of morphine. This phenomenon is mediated by glial activation and p38 mitogen-activated protein kinase.

The presence of an ongoing painful neuropathic condition does not prevent the rapid and profound development of opioid tolerance. However, the central actions of morphine are modified in the presence of inflammatory pain, compared with when it is used in the absence of pain. Animal models of inflammatory pain have shown that the presence of inflammation inhibits the development of anti-nociceptive tolerance to morphine and suppression of morphine-induced

rewarding effects [69]. These effects are mediated via the activation of endogenous κ-opioid receptors in response to inflammatory nociception, which in turn blocks morphine activation of the mesolimbic dopamine system—a process that is reversed by administration of a κ-receptor antagonist.

Opioid-induced hypersensitivity [43, 66] is an opioid-activated, pro-nociceptive mechanism resulting in heightened pain sensitivity. This phenomenon is distinct from opioid tolerance and is mediated through distinct cellular mechanisms involving glia [76], increased endogenous dynorphin (a pro-algesic κ-receptor agonist), nitric oxide, glutamatergic *N*-methyl-*D*-aspartate receptors, and descending facilitation (ON cell activation). The cellular mechanisms of opioid-induced hyperalgesia have commonalities with those in neuropathic pain and opioid tolerance and include a diverse array of structures and peptides including substance P, glial cells, *N*-methyl-*D*-aspartate, cyclic adenosine monophosphate, alpha-calcitonin gene-related peptide, orphanin FQ/nociceptin, serotonin, cholecystokinin, and others. *N*-methyl-*D*-aspartate receptor antagonists, e.g., ketamine, can reverse the glutamatergic component of pain sensitivity. Opioid-induced hypersensitivity should be considered when previous opioid dose escalation has failed to achieve the expected analgesic effect, if pain diminishes as opioid doses are decreased, and if there is an otherwise inexplicable exacerbation in pain after an initial period of effective opioid analgesia. Opioid-induced hypersensitivity-induced pain is generalized and not confined to specific dermatomes.

Opioid-induced hyperalgesia is thought to be the cause of increased pain sensitivity noted in opioid addicts and patients on methadone maintenance treatment. In a study of 53 patients with chronic painful diseases, also diagnosed with prescription opioid dependence as determined by *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition [3] criteria, admitted to an inpatient psychiatric unit for voluntary detoxification from opioid analgesics, the most significant finding was that self-reported pain scores improved during the detoxification period in hospital [49]. An analysis of variance of all assessed variables revealed that only the admission prescription opioid medications per day predicted a decrease in pain scores from admission to discharge, confirming that opioid medications can worsen pain syndromes.

Different opioids have varying abilities to induce hyperalgesia. Morphine is more likely to produce opioid-induced hyperalgesia than methadone. If opioid-induced hyperalgesia is suspected, treatment includes tapering the opioid dose, adding an *N*-methyl-*D*-aspartate receptor antagonist to the existing regimen, opioid rotation to a less "inducing" drug, and use of adjunctive, non-opioid analgesics.

The risks of unwarranted chronic opioid treatment include unnecessary invasive procedures and tests (for increased pain sensitivity), accident proneness, adverse health consequences, impaired judgment and cognitive function, a decline in occupational and social functioning, and strained family relationships. The adverse health consequences of long-term opioid use include pharmacologic tolerance, physical dependence, addiction, abnormal pain sensitivity, hormonal changes (primarily androgen deficiency and osteoporosis), and immune modulation [30].

The excitatory effects of chronic exposure to μ-opioid agonists are prevented by ultra-low-dose opioid antagonists [76]. Ultra-low-dose naloxone suppresses Gs coupling while enhancing Gi/o coupling, maintaining analgesia by continued inhibition of adenylyl cyclase or by the interaction of Gi/o-associated $G_{\beta\gamma}$ with ion channels. Naloxone's attenuation of the μ-opioid receptor-Gs coupling, concurrent with a restoration of μ-opioid receptor-Gi/o coupling, may explain its attenuation of both tolerance and dependence. A phase III trial of oxycodone with ultra-low-dose naltrexone showed significantly greater pain relief than the same doses of oxycodone given alone. Equivalent analgesia with less oxycodone was achieved in the combination preparation. Additionally, there was less

physical dependence, and the aversive effects of opioid withdrawal and the acute rewarding (euphoric) effects of opioids were reduced [76].

Physical Dependence and Withdrawal

Physical dependence occurs within days to weeks of opioid administration. It is a neuropharmacological phenomenon resulting from neuroadaptation and neuroplasticity [27]. Physiologic changes associated with physical dependence include increased respiratory rate, blood pressure, temperature, basal metabolic rate, glucose, inorganic phosphate, blood lactic acid, and erythrocyte sedimentation rate. Body weight, caloric intake, and sleep quality decrease. After discontinuation of opioids, blood levels of glucose, lactic acid, and inorganic phosphate return to baseline within a month. Body temperature, caloric intake, sleep quality, and respiratory rate regain their normal values within 2–3 months. Physiological equilibrium returns within 4–6 months.

Symptoms of opioid withdrawal include dysphoria, depression, nausea, vomiting, diarrhea, abdominal cramping, deep bone pain, joint pain, back pain, muscle aches, rhinorrhea, piloerection, lacrimation, diaphoresis, mydriasis, anxiety, irritability, fatigue, yawning, fever, insomnia, and an intense drive or desire to use more drugs. Acute withdrawal symptoms last 2–3 days and reach maximal intensity within 2 days. Conversely, intoxication includes euphoria followed by apathy, dysphoria, depressed mood and affect, impaired social and occupational functioning, drowsiness, impaired attention and concentration, faulty memory, and poor insight and judgment. Physiologic responses include papillary constriction, hypotension, constipation, slurred speech, psychomotor agitation or retardation, anxiety, depression, respiratory depression, and cardiovascular collapse. Drug tolerance is often insufficient to overcome the intoxicating effects of larger doses of opioid medications.

Individuals with chronic pain who use frequent doses of short-acting opioids on a regular basis become physically dependent and develop intermittent withdrawal phenomena including arousal, increased muscular tension, and receptor "hunger" between medication doses. This results in a low-grade protracted abstinence syndrome characterized by general discomfort, anhedonia, and drug craving, which serves to increase pain by mechanisms discussed previously. Withdrawal pain can be confused with breakthrough pain. It is usually severe and often indistinguishable from the original pain symptom. As opioids themselves, in larger doses, can produce pain, this situation is best remedied by reducing or ceasing opioid dosage, or by using long-acting rather than short-acting opioid drugs and formulations.

Opioid withdrawal is largely mediated by excessive norepinephrine release in the locus coeruleus, a mechanism separate from the dopaminergic pathways and limbic sites associated with reward. Alpha-2 agonists, e.g., clonidine, ameliorate withdrawal symptoms by suppressing pre-synaptic release of norepinephrine by inducing inhibition at the α-receptor on the pre-synaptic norepinephrine neurons. Diazepam may act similarly at the benzodiazepine site on the gamma-aminobutyric acid chloride channel by diffusely reducing sympathetic nervous system discharge of catecholamines in general by acting to suppress central nervous system excitability during opioid withdrawal. In addition, general anesthesia has been used to treat withdrawal since it activates gamma-aminobutyric acid receptors and will inhibit glutamate release.

Psychiatric Disorders and Opioid Use

Prospective studies of primary care populations suggest that chronic pain promotes depression and vice versa, equally strongly [67]. This is supported by research on glial function showing that biologic mechanisms important in the etiologies of depression and chronic pain are

linked [76]. Pain has also been shown to induce an anxiogenic effect in animals 4 weeks after induction of an inflammatory or neuropathic pain state [52]. Anxiety decreases pain thresholds and pain tolerance, and increases endorsement of medical symptoms and catastrophizing misinterpretations of arousal associated with pain [25]. Attitudes toward pain and fear of harm in humans significantly alter clinical functioning [73].

Chronic pain, depression, and anxiety are linked through changes in opioidergic function in the amygdala. The amygdala is rich in endogenous opioid peptides and plays a key role in fear and anxiety. Dysfunction of μ- and δ-receptors and possible enhancement of κ-opioid receptor function in the amygdala mediate the mood-altering effects of chronic pain. Sustained pain, via regionally selective release of endogenous opioids, induces a reduction in μ-opioid receptor availability in the amygdala as measured by positron emission tomography. Mu-opioid receptors are internalized and recycled.

Inflammatory, but not nerve injury, pain models cause marked activation of the endogenous κ-opioidergic system in the amygdala and nucleus accumbens. Kappa agonism produces a dysphoria similar to that seen in depression and chronic stress. Concomitantly the central stimulatory effects of selective μ- and δ-opioid receptor agonists are diminished. Delta-opioid receptor activation is associated with anxiety and depression. Delta-opioid receptor knockout mice exhibit less anxiety behavior than wild type mice [52]. Neuropathic pain-like states are associated with a reduction in μ-opioid receptor function in the ventral tegmental area. Together these data confirm that the mechanisms of neuropathic and inflammatory pain-like states are distinct, and that physiologic changes in supraspinal opioid transmission can alter mood and analgesic efficacy. Specifically, μ-opioid receptors are less responsive to endogenous opioids in pain-free patients with a high negative affective state (e.g., anxiety and depression). Thus, if chronic pain and negative affect both diminish the analgesic effects of endogenous opioids in the central nervous system, it is not surprising that patients with severe mood disorder have greater pain intensity and experience less analgesia from opioid therapy than patients with low psychiatric morbidity. In one study, opioid analgesic efficacy was reduced by 40% in patients with high psychiatric morbidity [75].

Approximately 50% of patients with chronic pain have clinical depression. These individuals also are at higher risk for opioid abuse. Treating a comorbid affective disorder can decrease current substance-abuse behaviors or the risk of relapse. Patients with high psychiatric morbidity have higher self-reported symptoms of anxiety, depression, history of sexual or physical abuse, and history of psychologic adjustment. Patients with a mood disorder and aberrant drug behaviors show a reduction in risky behavior when their mood disorder is treated, indicating that chemical coping rather than addiction is motivating their behavior.

Although chronic pain and negative emotions including anxiety and depression share certain neurophysiological pathways, and while negative emotions can be increased by chronic pain, chronic pain is rarely suppressed by treatment with anxiolytic medications. However, pain intensity and pain interference are improved when depression is treated.

Clinical Correlates of Opioids, Pain, and Mood

Much of the attention in managing chronic, non-cancer pain has focused on the minority of patients who engage in drug misuse and addiction. Consequently, many studies seek to characterize patient factors and opioid-use patterns in an attempt to identify and avoid prescription opioid therapy in patients lacking a clear indication and who do not evidence a subsequent reduction in pain intensity or improvement in functional abilities.

Population-based observation surveys have identified that the prescription of opioid drugs is as closely related to mental health as it is to

pain states [67, 68]. Endogenous opioids modulate basal emotional state. Opioids are frequently used to treat poorly differentiated states of mental and physical pain—a situation that has persisted for centuries. Exogenous opioids elevate mood at least temporarily. Opioid analgesics are much more likely to be prescribed to individuals with psychological distress arising from depression, anxiety, and other psychiatric disorders than to those with comparable physical discomfort without mental health disorders. Pain arising from chronic medical disorders is perceived by patients as more severe in the presence of major depression.

Illustrative of this is a longitudinal study of 6,439 patients in a primary care setting from 1998 to 2001 [68]. Respondents with a mental health disorder in 1998 were twice as likely to use prescribed opioids in 2001 compared with patients without mental health or substance use disorders. Patients with a mental health disorder who were not using opioids in 1998 were more likely to initiate prescription opioid use during the 3-year study period. Patients with problem drug use in 1998 were 3 times more likely to use prescription opioids in 2001. However, as a proportion of patients surveyed, the number of patients with common mental health disorders (major depression, dysthymia, generalized anxiety disorder, and panic disorder) far exceeded the number with problem drug use. Individuals receiving long-term opioids reported a greater perceived need for mental health care, but not substance abuse care, compared with non-opioid-prescribed patients (30% vs. 10%) [67, 68]. While respondents with problem alcohol use only were only somewhat more likely to receive opioid therapy than non-problem drinkers, antidepressant use was significantly related to opioid use [67]. The more psychological distress patients manifested, the more likely they were to be prescribed opioids. When one or two mental health disorders were present, there was a 5 times higher likelihood, and with three or four disorders, a 9 times higher likelihood of prescription of opioids.

In another population sample of 9,279 patients surveyed for regular prescribed opioid use, substance use problems, mental health disorders, physical health, pain, and sociodemographics, those individuals prescribed opioids for chronic non-cancer pain had higher rates of substance misuse compared with non-users of prescribed opioids (14.5% vs. 3%) [19]. Patients using prescribed opioids had higher rates of non-opioid illicit drug use, non-opioid problem drug use, and problem alcohol use compared with non-users of prescribed opioids. However, these data appear to be partially mediated by depressive and anxiety disorders, indicating that mental health disorders strongly contribute to substance abuse among prescription opioid users, rather than prescription opioids themselves prompting abuse.

It is not known whether improved recognition and treatment of mental health disorders will decrease the need for chronic opioid therapy [67]. However, it is clear that the unmet need for mental health care is associated with higher rates of substance use [19, 67, 68] and that depressive and anxiety disorders are significantly undertreated in patients receiving opioids [51]. Of the common mental health and addictive disorders, comorbid depression is the strongest indicator for drug misuse [19]. This poses a significant clinical problem given the high prevalence of depression in the general population, one that overshadows drug misuse by patients with an existing drug abuse history.

Pain beliefs play an important role in patients' adjustment to their illness and influence their physical as well as psychosocial functioning. Beliefs about medications are central to patients' adherence to medication regimens. Patients also appear to engage in a cost-benefit analysis prior to taking medications.

In a study of 288 opioid-prescribed patients with chronic non-cancer pain, the role of opioid medication beliefs was compared with therapeutic response [64]. Patients without a history of substance abuse, or with a history of alcohol abuse alone, did not believe they needed higher prescription drug doses and had similar low levels of medication misuse behaviors. In contrast, patients with a history of substance abuse believed they required significantly higher doses

of prescribed opioid analgesics. They reported higher symptoms of anxiety and that pain more frequently stopped them from completing activities. They were also more likely to endorse beliefs that narcotics are effective for pain control, that medication use will improve mood, that they would be more able to function with free access to medications, and that they need higher amounts of narcotics to experience pain relief than other patients. They also had a greater belief in the addiction potential of narcotic medications. These attitudes were magnified in patients with a dual diagnosis of a psychiatric disorder and substance abuse. Overall, the belief in a better quality of life associated with freer medication access and higher doses exceeded the belief in the potential for addiction, and this may lead to medication abuse in patients with psychiatric morbidity.

A history of substance abuse was related to higher rates of mediation misuse behaviors unrelated to medication effectiveness or the amount of medication prescribed. A prior psychiatric disorder was also associated with increased medication misuse regardless of substance abuse status. Rates of medication use increased the most in patients with both a psychiatric diagnosis and previous substance abuse. There were no significant differences in the overall amount of narcotic prescribed to patients with and without a substance abuse history; nor did pain relief, medication effectiveness, or level of disability differ between patients based upon their pain beliefs.

Anxiety was the only mood variable independently related to medication abuse behaviors and was a significant, although partial, mediator of the relationship between substance abuse history and medication beliefs. State anxiety accounted for 30% of the effect of addiction history on beliefs. The effects of addiction history on the prescription drug use questionnaire (see Section "Screening Tools") results were completely mediated by medication beliefs and state anxiety. After accounting for beliefs and state anxiety, addiction history had no direct influence on prescription drug use questionnaire scores.

Misattribution of anxiety-related physical symptoms leads patients to control these symptoms with pain medications and to alter beliefs about their medication needs. Clinicians have to identify not only physical sources of pain but also psychological contributors. These must be addressed as part of the regular treatment plan. Specific cognitive-behavior interventions may help patients differentiate and cope with symptoms associated with anxiety versus symptoms associated with chronic pain.

Diagnosis of Addiction

Addiction is a disease of the brain that is diagnosed by assessing the patient's behavior and ability to function in society and within a therapeutic framework. The typical profile of an addicted patient who has chronic pain is remarkably similar to that of a non-addicted patient with severe untreated pain and has the following characteristics: chaotic social situation, concurrent mental health problems that exacerbate their pain experience, limited coping mechanisms with a bias toward chemical coping, and resistance to utilizing non-pharmacological analgesic treatments.

Seemingly non-addicted patients who present for pain management and go on to abuse opioid medications tend to be younger (18–30 years old), have a greater severity of lifetime psychiatric disorders, are more likely to have a positive toxicology screen (usually cocaine or marijuana), and demonstrate four or more aberrant drug use behaviors [25]. This mirrors the epidemiologic profile of extramedical analgesic users in the general population who, in addition, tend to be female, have less than a college education, and have lower incomes [18]. Twenty percent of non-addicted patients with pain engage in drug-seeking behavior [64].

The commonest cause of "iatrogenic" opioid addiction is a previous history of substance abuse. Thus, a psychological assessment and attention to existing psychiatric disorders are essential in treatment planning and risk stratification in patients with chronic pain. In patients who are opioid naïve, with no previous substance

abuse, therapeutic prescription of opioids very rarely induces addiction, and the rate of opioid abuse is approximately 2% in such individuals [21]. Should abuse behavior occur, the challenge is to determine whether it represents recreational use, addiction, intentional criminal diversion, or an attempt to treat depression or anxiety associated with undertreated pain. Risk factors for addictive disease include a genetic predisposition, a risk-taking personal psychological profile, and the socio-cultural context in which the drug exposure occurred. The differential diagnosis for dependence and addiction includes "therapeutic dependence" (chronic pain patients receiving adequate doses of opioids but who hoard opioid medications to ensure an adequate reserve), pseudoaddiction, chemical coping, and recurrent subtle withdrawal [30].

Prerequisites in Providing Pain Management

One of the root causes of undertreated pain is the apparent belief on the part of clinicians that the treatment of pain should be based upon a different set of principles and practices than any other type of patient care. Pain complaints in the setting of cancer, or acute illness or injury, are accepted and treated, while people suffering from chronic, non-cancer pain are met with skepticism and do not receive the same therapeutic approach to care. There is also a failure on the part of health care professionals to acquire and maintain up-to-date knowledge and skills, thus preventing their ability to provide adequate, appropriate care and counseling, resulting in the persistence of so much myth and misinformation [61]. Patients with addictive disorders can suffer the same fate. One of the biggest obstacles to caring for patients with chronic pain, addiction or both is ignorance in the medical community and general population. In one survey, only 39.6% of physicians noted receiving any training in diagnosing medication abuse and addiction [42]. A revised, comprehensive educational input into health care teaching programs is essential if the next generation of clinicians is to diagnose and manage these diseases effectively.

Approaches to Treatment

"Ethically, what is worse? To give 16 people medications they do not need or to withhold from 84 people medications they do need?" [59]. These questions address the fact that the majority of patients with painful medical conditions treated with opioid analgesics do not develop substance misuse. De novo addiction is very rare when opioids are used for acute pain relief [49]. However, if every sixth patient with chronic pain can be expected to misuse prescribed opioid therapy in some way, and at some time, are opioids worth the risk? Some clinicians consider a 3.8% rate of opioid addiction [25] a small risk compared with the alternative of continuous pain and suffering. Yet, are opioid analgesics necessary in the treatment of chronic pain? Drugs acting at the μ-opioid receptor are the most powerful analgesics available that permit a reasonable level of function. They are the first line in the treatment of acute severe pain. However, in the treatment of chronic non-cancer pain, efficacy has not been demonstrated beyond the first 3 months of therapy [21]. Consequently, opioids should not be first-line treatment for non-cancer pain expected to last longer than 1 month.

Chronic pain, like other long-term diseases, is multifaceted and complicated by substantial psychological and functional impairment, including depression, disability, and loss of livelihood. The traditional treatment model of diagnosis and acute management of medical problems in a single provider-patient relationship does not serve this patient population well. The strong interaction between pain and psychiatric morbidity, especially depression and substance misuse, mandates that pain management encompass more than pharmacological management directed at pain scores and include a variety of behavioral and psychosocial therapies. To this end, psychological and rehabilitation

programs emphasizing patient self-management skills were endorsed to improve function, mood, and pain relief, and the biopsychosocial or "disease management" model of pain became the preferred therapeutic model. It integrates the physical, psychological, emotional, social, and spiritual elements of pain and suffering and attends to aspects of quality of life and life meaning that foster enrichment and relevance of the individual. It forms the basis of the multidisciplinary, multimodal approach to pain management. The focus of a multimodal, multidisciplinary treatment strategy is to free the patient of dependence on the medical community by lifestyle adaptation, rational use of medications including opioids, and treatment of pain symptoms with various therapies [57].

The goal of any pain treatment is to maximize the efficacy of alleviating discomfort and limit unwanted side effects. Multidisciplinary models for chronic pain management include a structured psychological investigation and psychological therapy. This approach identifies those with a mental health or substance abuse history earlier, thereby permitting appropriate changes in psychiatric and analgesic management [57]. Mental health professionals play a significant role in facilitating care, especially during initial patient assessment, ongoing assessments for substance use and mental health, and psychological treatments such as developing effective coping strategies for managing chronic pain (e.g., cognitive behavioral therapy, relaxation techniques, biofeedback) and better resource utilization, including medications [51].

The impact of a multidisciplinary team providing integrated care and utilizing evidence-based algorithms, interval visits to monitor responses to therapy, and information systems that permit tracking of outcomes and adjustment of therapy was evaluated in an academic general medical practice over a 3-month period [8]. In that study, the multidisciplinary team comprised the patient's primary care physician, a clinical pharmacist, a program assistant with training in health behavior, a psychiatrist with subspecialization in pain management, and a study nurse.

The management principles algorithm utilized: longer-acting opioids when short-acting preparations were only partially effective; short-acting opioids for breakthrough pain; longer-acting opioids were titrated at interval visits; less costly, generic medications were favored, and tricyclic antidepressants, gabapentin, and other non-opioid medications were used adjunctively, especially for neuropathic pain. All patients underwent a psychiatric evaluation and urine drug screen and signed medication contracts. Substance misuse was monitored through clinical history, review of medications, communication with pharmacies and providers, and urine drug screening. Serious drug misuse violations meant termination of opioid therapy (but not discharge from the clinic per se) and referral for substance abuse treatment.

Long-acting opioids were favored because continuous occupation of the endogenous ligand μ-opioid receptor system allows interacting physiological and behavior systems to return to normal. Their use avoids rapid increases in opioid concentrations in the brain, reducing euphoria and addictive potential [30]. Around-the-clock dosing reduces pain, increases function, minimizes the development of tolerance, abolishes anticipation of the medication produced by frequent medication peaks and troughs throughout the day, and provides a better quality of life [27, 51]. In cases where short-acting opioids are warranted, e.g., incident pain, they should be given on a time-contingent basis and throughout around-the-clock dosing. The maximal daily dosage should also be clearly established with the patient [51].

Overall, this multidisciplinary pain management approach improved pain, depression, and disability scores in opioid-treated patients with chronic non-malignant pain and improved their quality of life. These results were attributed to the combined effects of systematizing pain management and treating depression. Clinical improvements were independent of opioid dose. Intensifying pain management may have a beneficial effect on depression by enhancing antidepressant efficacy. Severe pain impairs the response to antidepressant therapy. The

prevalence of substance misuse was 32%. Opioid therapy was to be reconsidered after 6 months if the patient continued in recovery. Substance-abusing patients who did not complete the study tended to be non-white, have a history of illicit drug or alcohol use, worse depression, and higher pain scores at baseline. Meticulous documentation in an electronic medical record and centralized monitoring for opioids and other controlled substances allowed patient tracking within the program and prevented migration within their practice. Despite the inclusion of mental health professionals in the team, difficulty accessing mental health and substance abuse treatment services remained. Not surprisingly, higher rates of aberrant drug use have been reported in multidisciplinary pain management programs [49]. These programs screen for mental health and addictive disorders, and "challenging" patients are referred to them.

Chronic back pain is one of the most common long-term non-cancer pain syndromes. The prevalence of opioid treatment, its efficacy, and the prevalence of substance use disorders among patients receiving opioid medications for chronic back pain was assessed by meta-analysis and systematic review [45]. Opioids are commonly prescribed for chronic back pain, and short-term efficacy (less than 16 weeks of treatment) was confirmed. Opioid analgesic efficacy lasting longer than 16 weeks is unclear as no longer-term studies were evaluated. Substance use disorders were common with a prevalence of aberrant medication-taking behaviors of up to 24%. Opioid prescribing for chronic back pain varied by treatment setting (range, 3–66%) and was more common in patients with impaired functional status. Pain relief was not significantly different in patients managed with opioids compared with those taking non-opioid analgesics or placebo. These data suffer from a paucity of high-quality studies of opioid analgesia and chronic back pain. The studies reviewed were very heterogeneous, with small sample sizes and too short an evaluation period, and used various diagnostic criteria and functional conditions. However, patients who fail to respond to opioid analgesia should be weaned and other classes of analgesics and additional non-pharmacological treatments utilized. The American Pain Society has endorsed guidelines for the management of chronic back pain [9, 11].

Multidisciplinary, multimodal pain management approaches are especially useful in patients with psychiatric illness, substance misuse, or both. Patients with primary opioid dependence report high levels of chronic pain and have lower pain thresholds to experimental pain than controls [49]. This pattern of lower thresholds and shorter tolerance to pain than non-addicts continues into recovery. Thus, active and recovering opioid addicts have increased opioid requirements, reflecting inherent differences in underlying neurophysiology, perception, and experience of pain compared with non-addicts [25]. Additionally, the long-term administration of opioids modifies pain perception [41, 76].

The initial assessment of all chronic pain patients should include a mental health and opioid abuse risk assessment and triage into one of three risk categories [36] (Table 1). Attempts should be made to identify patients who seek opioid drugs in the absence of pain. The diagnosis and treatment of psychiatric disorders are important steps when considering patients for opioid therapy. Opioid abuse risk is highest in patients who have binge use, use opioids for their psychoactive effects, obtain opioids from other sources, and experience withdrawal symptoms and other features of dependence. Inquiry should be made as to mood, occupational and family functioning, sleep disorders, and physical functioning. Urine should be tested for drugs (licit and illicit) and records from previous

Table 1 Opioid abuse risk stratification

Category 1	No standard risk factors for abuse or diversion
Category 2	Family history of substance abuse or other evidence of increased risk of opioid abuse, e.g., previous substance abuse, history of physical or sexual abuse, history of or current psychiatric disorder
Category 3	Active drug abusers

care providers obtained. Spouses and significant others should be interviewed to obtain information regarding early signs of dependence and aberrant drug use behaviors [34].

Assumptions by clinicians that a positive drug screen (e.g., cocaine or marijuana) or aberrant drug use behaviors automatically mean opioid use disorder have veracity. When 801 patients with chronic non-cancer pain, treated in a primary care setting, were studied for all types of chemical substance abuse over a 30-day period, 24% had positive toxicology tests for illicit drugs, significant underreporting of drug use, and a strong association between illicit drug use and substance use disorders. Forty-six percent of patients with a positive toxicology screen denied illicit drug use even when anonymity was guaranteed [25]. The presence of other mental illness was not specifically examined.

This patient sample was assessed for 12 aberrant drug behaviors [54] (Table 2) and the Addiction Severity Index [46] (see Section "Screening Tools"). Four specific aberrant behaviors were identified with substance abuse and opioid addiction: sedating oneself, using opioids for non-pain reasons, increasing dose without authorization, and having felt intoxicated when using opioids [25]. The causes of aberrant drug behaviors were considered to be pseudoaddiction, untreated psychiatric syndromes, organic mental syndromes, chemical coping, situational stressors, and criminal intent. Co-occurring medical disorders, higher lifetime rates of substance use disorders, and younger age were associated with, and increased the frequency of, three aberrant behaviors: lost or stolen medication, documented use of multiple physicians, and requests for two or more early refills. Patients with a family or personal history of substance abuse were more likely to exhibit aberrant behaviors. In that study [25], opioid use disorders were 4 times higher in the chronic non-malignant pain population than in general population samples (3.9% vs. 0.9%, or 1 in 25 patients on opioid therapy).

Table 2 Aberrant drug behaviors

1.	Purposely oversedating oneself
2.	Frequency of drug intoxication
3.	Involvement in motor vehicle accidents
4.	Requesting early renewals
5.	Self-directed changes in dosing
6.	Lost or stolen prescriptions
7.	Obtaining opioids from more than one doctor
8.	Non-pain-related use of medication
9.	Using alcohol for analgesia
10.	Success in obtaining additional medication
11.	Missed doctor's appointment
12.	Hoarding of medication

Opioid misuse is associated with untreated, or inadequately treated, psychiatric disorders, most notably depression, anxiety, panic disorder, post-traumatic stress disorder, borderline personality disorder, somatization, and other dissociative disorders [68]. These conditions must be diagnosed and treated adequately before initiating opioid analgesic therapy. Close follow-up is essential to prevent negative outcomes such as declining functional status or opioid misuse. Clinicians treating patients with chronic pain should be proficient in treating common psychiatric disorders or refer to a mental health specialist. A high index of suspicion for mental health disorders should be maintained in patients prescribed opioids.

Addiction patients can have pain treated effectively with opioids if they are properly monitored and supervised. They should be referred to a center that can provide the necessary analgesic therapy while simultaneously managing the comorbid substance abuse. Unfortunately, the number of centers nationally that can provide this type of care is extremely limited.

When chronic pain exists in an opioid-dependent patient, or in one with significant risk factors for substance misuse, it is even more important to attend to confounding psychiatric morbidity and to ensure the therapeutic efficacy of pharmacotherapy and behavioral interventions. The treatment model for opioid-dependent pain patients includes education as to why chronic opioids are likely to maintain pain, to correct chemical coping, detoxification, treatment of pain with non-opioid analgesics, psychological support, coordination of care, and

promotion of healthful behaviors. Prescription of opioids with a high addiction potential (e.g., oxycodone, hydromorphone) should be avoided. Psychological and physical needs must be treated simultaneously.

Many non-controlled drugs or their metabolites have central effects that can interact with opioids to increase their harmful adverse effects, e.g., sedation and respiratory depression. Examples include muscle relaxants, antiemetics, and sleep aids. Tramadol, an analgesic that works primarily by inhibition of norepinephrine and serotonin reuptake and is not classified as an opioid analgesic, does have weak μ-opioid agonist effects. It has been identified in addiction relapse and in de novo addiction in susceptible individuals. In addition, over-the-counter and herbal (natural) remedies should be monitored to prevent unfavorable drug interactions and relapse.

Individuals in recovery should be asked about cravings. A positive response provides an early warning sign of relapse and allows renewed efforts to maintain recovery [51]. Family involvement with the rehabilitative process is essential and may include the family in therapy, e.g., family cognitive behavioral therapy. Relapse is more likely during stressful life events, including exacerbation of pain. The psychosocial state of patients should be re-evaluated at regular intervals in addition to pain intensity and function and whenever changes in compliance patterns occur. Several of the non-opioid treatments for chronic pain overlap with those used to treat substance abuse, e.g., family involvement, group support, and "contingency contracting". Cognitive behavioral therapy is particularly useful in treating cravings. Addiction as a disease leaves memory traces laid down in circuits in the brain. These circuits become overlearned during addiction. As no single treatment works for everyone, therapists must be flexible and tailor treatment to the individual.

Case reports of patients with chronic non-cancer pain and concurrent opioid abuse can be helpful in illustrating the treatment models recommended [16, 66].

The Role of Opioids in Pain Medicine

Although it is beyond the scope of this chapter, it is essential that clinicians are knowledgeable about drug pharmacology, especially the medications they prescribe. Key factors in the selection of drugs include their physicochemical properties, absorption and transportation characteristics, metabolism, excretion, and drug interactions. Pharmacogenetics is extremely important in determining whether a patient will experience analgesia from an opioid prodrug, e.g., codeine and hydrocodone. Morphine has analgesic and sedative metabolites that are renally excreted. Thus, morphine is relatively contraindicated in the presence of renal failure. Methadone is a racemate of l- and d-methadone. L-methadone is a μ-agonist similar to morphine. D-methadone is an *N*-methyl-*D*-aspartate receptor antagonist. Thus, methadone is unique in being composed of two analgesic racemates. This combination may explain its utility in neuropathic pain. Selection of analgesics in general is also determined by efficacy, adverse effects, and cost. Of the non-opioid analgesics used to treat neuropathic pain, tricyclic antidepressants are more efficacious than serotonin-norepinephrine reuptake inhibitors, which are more efficacious than selective serotonin reuptake inhibitors. However, the tricyclic antidepressants have a higher incidence of treatment limiting adverse effects. Although all anticonvulsants have efficacy in relieving neuropathic pain, currently gabapentin and pregabalin are most commonly used because of unwanted effects with other drugs in this class.

Opioids are analgesic in that they reduce the sensitivity of the central nervous system to noxious stimuli, i.e., raise the pain threshold. However, they do not treat the biologic etiology of pain. Inflammatory, neuropathic, and bone cancer pain have distinct neurochemical profiles in the central nervous system [12]. Treating pain by addressing its etiology with pharmaceuticals targeted to correct the unique neurochemical changes associated with pain makes more sense. Additionally, the neurochemical changes associated with the affective components of pain

can be relieved by non-pharmacological therapies such as distraction, e.g., virtual reality analgesia [29]. Thus, the mainstay of chronic pain treatment should include psychological, physical, social, emotional, and pharmacologic therapies—the latter focusing on disease modification, and anti-inflammatory, anticonvulsant, and antidepressant analgesia with opioid analgesics as adjuncts (Table 3).

Table 3 Analgesic therapies used in multimodal pain management

Pharmacological	Acetaminophen
	Non-steroidal anti-inflammatory drugs
	Cyclo-oxygenase type 2 inhibitors
	Opioids
	Pro-drugs
	Mu-receptor agonists

Disease modifying	Chemotherapy
	Radiation therapy
	Radioisotopes
	Bisphosphonates
	Immunotherapy
	Hormone therapies

Any opioid is effective for relieving any type of pain in the short term, but the efficacy of long-term opioid analgesia for chronic non-cancer pain remains unproven. Data suggest that only 30–40% of patients with chronic non-cancer pain accrue sustained benefit (i.e., stable function without significant tolerance or side effects worth reporting) from long-term opioid therapy over months and years [35]. Equally, 30–40% of patients do not report an analgesic response to opioid therapy either initially or with increased doses [81]. When an initial response is not seen, management strategies include up-titration of the opioid dose, addition of another analgesic, introduction of a non-pharmacological therapy, e.g., physical therapy, obtaining a psychological consult, or trying a different opioid or route of administration. If these measures fail, non-opioid analgesics and non-pharmacological therapies including rehabilitation therapies, physical modalities (e.g., ice or heat), psychological therapies (e.g., cognitive behavioral therapy), and complementary alternative medicine should form the basis of the pain management plan. Opioids should be weaned whenever their efficacy is in question or other therapies have become effective. In the context of chronic non-cancer pain, opioids for analgesia have been likened to a "bridging therapy", used to achieve analgesia in the face

of severe pain but not to be considered the primary analgesic therapy. Their use for 1 to 3 months is intended to provide sufficient comfort and function to allow other analgesic therapies to work. When these other long-term therapies are in place the opioids are withdrawn in a controlled fashion. The use of etiology-specific analgesic therapies (e.g., anti-inflammatory medications to treat inflammatory pain) in the context of multimodal therapy offers better analgesia with fewer adverse effects. Clinical guidelines for the use of chronic opioid therapy in chronic non-cancer pain are available [10, 72].

Medication tapering is indicated if the opioid dose is well above 300 mg/day of morphine or its equivalent [34]. Tapering can improve patients' mood and pain because the cycle of intoxication and withdrawal is less extreme once they have been stabilized at a lower dose. It also reduces the incidence of drug tolerance, physical dependence, withdrawal hyperalgesia, and opioid-induced hyperalgesia. The endpoint of successful tapering is either abstinence or a moderate scheduled dose that provides effective analgesia with minimal withdrawal symptoms.

Screening Tools

Fears of being sued for both the undertreatment of pain and iatrogenic opioid addiction have created huge dilemmas for many practitioners. Attempts to predict who is at risk for medication misuse and addiction have led to the creation of risk assessment tools [33]. These vary between those intended for use prior to the initiation of opioid therapy and others designed to assess patterns of opioid use during therapy. Self-report measures dominate, but physician-rated observation scales are available. Screening for risk of addiction should be performed before initiating long-term opioid treatment in chronic non-cancer pain patients and at intervals throughout their therapy. The most comprehensive review of assessment tools to date is provided by Passik et al. [56]. Examples of several scales follow.

The Chemical Coping Index Tool Evaluation [37] is intended to identify chemical copers a priori. This tool evaluates 38 items over 6 categories: self-treatment, overly drug focused, not making progress, alexithymia/somatization, sensation seeking, and tendency toward accidental overmedication. Psychotherapy and rehabilitative approaches are particularly important in these patients as symptom and functional improvement are unlikely to occur until their coping abilities improve.

The Screener and Opioid Assessment for Patients with Pain [6] includes 24 patient administered items over several domains including substance abuse history, doctor-patient relationships, and psychosocial problems. It is intended to predict aberrant drug-taking behavior prior to the initiation of opioid therapy. The score generated is based on the sum of 14 of the 24 items. A score of 8 or above suggests a high risk for problematic opioid use. The most predictive items for high-risk patients are a positive urine drug screen and the need for a cigarette within the first hour of the day. Although this tool has the best psychometrics of all the screening tools, it utilizes few medical and demographic data and may lack sensitivity in some patient subpopulations.

The Opioid Risk Tool [77] is one of the briefest measures available, utilizing 5 yes-or-no self-report items to predict the probability of a patient displaying aberrant behavior when prescribed opioids for chronic pain. It has excellent discriminatory ability in both men and women. It has been validated in pain patients and is specifically designed to predict problematic behavior in patients prescribed opioids for pain. Its brevity and ease of scoring make it very useful clinically. It suffers from being susceptible to deception. A score of 3 or more out of 5 indicates opioid abuse.

The Addiction Severity Index [46, 62] is intended for use by primary care physicians. It utilizes information regarding medical illnesses, legal events, employment status, family/social problems, psychiatric treatment and severity, and current and lifetime substance use problems and treatment. Collateral information from family,

friends, and previous providers is very helpful, especially in patients who are in denial or unwilling to disclose sensitive clinical information. By focusing on problems and their previous treatments, the Addiction Severity Index can assist in formulating a more comprehensive pain treatment plan. It particularly addresses the impact of the high rate of psychiatric disorders in chronic pain patients, their tendency to misuse alcohol and other substances, and their higher risk for suicide.

The Drug Abuse Screening Test [80] is a 28-item yes-or-no self-report questionnaire. A cutoff score of 6 indicates drug abuse or dependence. The Drug Abuse Screening Test has face validity, high test-retest reliability, and good sensitivity and specificity. It is susceptible to deception and has yet to undergo a validation trial in pain patients. It predicts substance abuse but not the risk of aberrant drug behaviors during treatment.

The Diagnosis, Intractability, Risk, Efficacy score [5] is designed to predict which chronic, non-malignant pain-suffering patients will experience effective analgesia and be able to comply with long-term opioid maintenance therapy. It shows high sensitivity and specificity for predicting both compliance and efficacy. To be effective, the clinician needs to obtain a thorough history and maintain a good relationship with the patient as this tool works best when used over time, rather than as an initial screening instrument. It can be useful in identifying deception by patients and has the advantages of ease of use and rapid administration.

The Addiction Behaviors Checklist [79] utilizes a 20-item longitudinal tool to track behaviors characteristic of opioid addiction in chronic pain patients. The majority of items are scored on observed behavior or objective information. The minority are self-reported. A cut-off score of 3 correlates well with clinical decisions to terminate opioid therapy for problematic drug use. It also has good correlation with the Prescription Drug Use Questionnaire. The Addiction Behaviors Checklist score bears no relationship to the pain intensity score.

The Prescription Drug Use Questionnaire [13], for use in opioid-treated chronic pain patients, consists of 39 items over 5 domains: the characteristics of the pain condition, opioid use patterns, social/family factors, familial/personal history of substance abuse/addiction, and psychiatric history. Scores > 15 correlate with substance use disorder. The 3 items most predictive of addictive disease are: patient believes he or she is addicted, increases analgesic dose/frequency, and has preference for a specific drug or route of administration. This tool assesses risk at a single time point. It can be used to complement other risk tools.

The Chronic Opioid Misuse Measure [7] is designed for use in patients already receiving chronic opioid therapy. Seventeen of the original 40 items in the alpha version were found to measure aberrant behavior adequately. This tool continues to undergo study to refine it and assure its validity.

Most prescription controlled drugs abused by young adults (18–25 years old) are obtained from friends and relatives with and without their permission (67.4%) [34, 53], stolen from pharmacies, or obtained from one physician. Thus, in addition to screening for high-risk patients, high-risk families and social situations should also be identified.

The most studied predictor of opiate misuse in chronic non-malignant pain is a history of substance abuse. The presence of two or more risk factors is positively associated with clinical evidence of opiate misuse. Risk factors included patients' report of substance abuse history, family history of substance abuse, and a history of legal problems related to substance abuse. Behaviors most closely associated with risk variables are a urine drug screen positive for illegal substances or non-prescribed opioid drugs, a high dose of opioid medication, and the need for a cigarette within the first hour of the day. Recent polysubstance abusers and oxycodone abusers are poor candidates for opioid therapy [64]. Alcoholics in recovery with no other psychiatric morbidity are generally good candidates for opioid therapy.

Universal Precautions in Pain Medicine

A strategy of "Universal Precautions" has been advocated when treating patients with chronic opioid therapy. Just as one takes precautions not to contract and spread communicable diseases by performing the "Universal Precautions" of hand washing, wearing gloves, etc. when handling body fluids because it is not always apparent who has an infection, so it is not possible to tell immediately which patient is at risk for substance abuse or addiction. This forms the basis of the "Universal Precautions" recommended by Gourlay et al. [26]. They propose adopting ten steps that constitute best medical practice to reduce abuse risk while optimizing therapeutic outcome:

1. *Make a diagnosis with an appropriate differential*: The pain experience is multifaceted. Treatment should be directed at the cause of the pain whenever possible rather than to the symptom alone. Comorbid conditions, e.g., depression and other psychiatric disorders, must be treated.
2. *Psychological assessment including risk of addictive disorders*: Risk factors for addictive disorders, including a history of personal and family drug misuse, past and present, should be sought. This should be done non-judgmentally and with a reassurance that the pain will be treated seriously regardless of risk. Urine drug testing should be considered in high-risk patients regardless of treatment regimen and periodically in all patients on chronic opioid therapy. A finding of illicit or non-prescribed licit drug use should lead to further assessment and treatment for substance use disorders. Patients who refuse treatment, or whose psychiatrist considers the risk of opioid therapy too great, are not suitable candidates for treatment with controlled substances. Absence of the prescribed substance warrants re-evaluation of the patient [51].
3. *Informed consent*: The treating physician must explain and discuss the treatment plan with the patient, including the anticipated benefits and potential risks. When opioid therapy is prescribed, the issues of addiction, abuse, physical dependence, withdrawal, tolerance, and lack of efficacy should be explained.
4. *Treatment agreement*: This can be written or verbal. The expectations and obligations of the patient and the clinician should be stated explicitly and understood. Clearly defined boundaries help in identifying aberrant drug behavior. The treatment agreement with informed consent forms the basis for a treatment trial. Sample treatment agreements can be found at www.oqp.med.va.gov under "Opioid Therapy for Chronic Pain" and www.guidelines.gov [51].
5. *Pre- and post-intervention assessment of pain level and function*: This is essential before embarking on a therapeutic trial. Continuing a particular treatment modality relies upon evidence that the therapy is effective in meeting the stated clinical goals. Failure to meet the treatment goals requires reassessment of the diagnosis and treatment plan.
6. *Appropriate trial of opioid therapy with or without adjunctive medication*: Opioids are analgesic but non-specific in regard to targeting the etiology of painful conditions. Thus, they should be used as part of a multimodal treatment plan in doses appropriate to the individual patient and be weaned when benefit no longer accrues.
7. *Reassessment of pain score and functional level*: This is essential to establish ongoing efficacy. It may be helpful to have the patient's reports of comfort and function corroborated by a relative or close friend.
8. *Regularly assess the "Four A's" for pain medicine*: Assessment of analgesia, activity, adverse effects, and aberrant behavior helps direct therapy and provides appropriate documentation for justification of therapeutic interventions or withdrawal. The Pain Assessment and Documentation Tool

originally proposed documenting outcomes using these domains [55]. "Affect" is often added as the fifth "A".

9. *Periodically review the pain diagnosis and comorbid conditions including addictive disorders*: Underlying disorders change over time. Pain and psychiatric morbidity may change in dominance, dictating that the focus of treatment should change over time. Untreated psychiatric disorders will likely prevent successful pain management.
10. *Documentation*: Thorough documentation of all patient contacts is necessary for appropriate treatment tracking and management planning in addition to being a medicolegal requirement. This combined with a positive doctor-patient relationship improves the quality of the treatment regimen and protects against regulatory sanction.

These recommendations complement the United States Federation of State Medical Boards' Guidelines that call for a patient evaluation, treatment plan, informed consent, periodic review, consultation, that medical records be maintained accurately and completely and ready for review, and be in regulatory compliance [36].

How well do these precautions work? One multi-disciplinary, comprehensive, interventional pain management center found that adherence monitoring reduced controlled substance abuse in their patient population by 50% [42]. Their strategy included a controlled substance agreement, periodic monitoring, pill counts, periodic drug testing, and education to reduce abuse.

Systems that support safer prescribing are being advocated [36, 40]. Tamper-proof prescription pads and use of state prescription-monitoring data for each patient are recommended [24] in addition to urinalysis and addiction screening in all patients on long-term opioid therapy. However, very few prescription-monitoring programs have been adequately evaluated to determine their impact on the availability of controlled substances for legitimate medical purposes or the subsequent incidence of drug abuse and diversion. It is known that when physicians are faced with barriers to prescribing a certain type of medication, they will often prescribe around that barrier by selecting medications that are perceived as less scrutinized even if they are less efficacious and/or potentially more harmful, e.g., hydrocodone instead of morphine. Barriers to benzodiazepine prescribing in New York led to an increase in alcohol use by patients to compensate. The maximum value from electronic prescription-monitoring programs will be realized in states that design them as health care programs with significant law enforcement benefits. The combination of an electronic data transmission system that monitors prescribing practices with a forgery-resistant security paper prescription program for all prescription medication schedules appears able to balance the frequently disparate needs of physicians and law enforcement officials.

In the meantime, all controlled medications should be prescribed by one physician and all prescriptions filled at one pharmacy [81]. Initially, weekly prescriptions without refills will help to demonstrate the patient's ability to adhere to the treatment program. No deviation from the prescribing plan is allowed, e.g., no telephoned prescriptions or early refills. Short-acting opioids, should they be required for break through pain treatment, should be held by a participating friend or relative who understands how they are meant to be taken to reduce the possibility of misuse. Patient-controlled analgesia is generally not recommended in persons recovering from addictive disorders.

The creation of opioids with less abuse potential is being sought. Specifically, opioids that are naturally long-acting with 100% bioavailability are much less susceptible to abuse than short-acting opioids formulated as long-acting preparations. The addition of ultra-low-dose opioid antagonists to a μ-opioid agonist has also been shown to enhance analgesic efficacy while decreasing tolerance and physical dependence [74].

Non-opioid pharmacological treatments (e.g., non-steroidal anti-inflammatory drugs, anticonvulsants, antidepressants), physical therapies,

and psychosocial, emotional, and spiritual support should form the mainstay of chronic pain treatment, especially in addicted persons, whenever possible. More intensive social and emotional support will be needed at times of increased environmental and physiologic stress to guard against relapse and aberrant drug behaviors.

Substance Use Disorders and Pain: Clinical Considerations

Programs that treat psychiatric disorders and substance use disorders simultaneously produce better substance use treatment outcomes. The need for pain treatment in substance use programs has been generally overlooked. Pain is associated with a unique and more severe pattern of substance use, and should be an essential part of the treatment of addictive disorders.

Co-occurring pain in patients with substance abuse disorders complicates their substance abuse treatment in several ways. Pain drives drug-seeking behavior in animals and humans. Patients with substance use disorders and chronic pain have increased drug-seeking behavior and craving. Pain may increase the drive to use substances that produce euphoria. Therefore, effective pain treatment would be expected to improve outcomes in substance abusers. Further, pain is often associated with mental health problems that worsen substance abuse outcomes. This is especially true after traumatic injuries, where the occurrence of post-traumatic stress disorder is associated with greater drug abuse severity and worse treatment outcomes. The functional and social disabilities associated with pain make it more difficult for substance-abusing patients to remain in substance abuse treatment programs, as does the requirement to be "drug free" when benefit is accruing from opioid therapy. Thus, this patient group has unique treatment requirements that differ from patients with substance abuse without pain and those with pseudoaddiction [70].

Particular differences between substance abusers with chronic pain and those without pain include more relief-seeking behaviors (e.g., illicitly obtained analgesics, increased health care visits to primary care and substance treatment providers), pain avoidance behaviors (e.g., depression and anxiety), and reduced physical and social functioning. Attempts made to minimize their pain frequently exacerbate their substance abuse, which exaggerates their emotional, physical, and functional impairments. All of these behaviors and conditions worsen with increasing pain intensity, indicating that pain is responsible for these behaviors. The ability to improve the pain experience in these patients, even without complete pain relief, has been shown to improve incrementally patients' well-being.

The pattern of substance abuse engaged in by abusers with chronic pain shows a greater use of non-prescribed analgesics, the selective administration of substances known to provide pain relief, and higher doses of alcohol. Patients in chronic pain drink more in one sitting than abusers without pain [70]. This increases the toxicity of opioid therapy by augmenting its central depressant effects. Opioid abstinence syndromes, and opioid therapy in some individuals, are associated with hyperalgesia, which further complicates pain management [21].

One other consideration is the use of buprenorphine rather than methadone for opioid substitution therapy. Buprenorphine is a partial μ-agonist with an analgesic ceiling. When it is added to therapy utilizing a full agonist it can precipitate withdrawal. Thus, patients maintained on buprenorphine for addiction may need to change to methadone maintenance therapy in order to benefit from acute opioid analgesic therapy.

Analgesic Management of Opioid Substitution Patients: Acute Pain

All too frequently, patients on chronic opioid therapy for pain and/or addiction treatment fail to receive their baseline drug doses upon admission to the hospital for acute care and undergo drug withdrawal [47]. This is especially

problematic in the surgical population where increased pain postoperatively is inevitable. Clearly, at the very least, patients should continue to receive their pre-admission drugs in their pre-admission doses with additional analgesia as needed. The fear of relapsing into drug abuse behaviors drives some recovering addicts, and those in opioid substitution programs, to refuse analgesia in the belief that exposure to another opioid will cause craving, etc. Physicians' fears that opioid analgesia will make an addict worse lead to failure to provide analgesia and undertreatment. In actuality, the cellular and molecular changes that accompany long-term opioid use make the endogenous opioid system less responsive. This manifests itself in higher pain scores and lower pain tolerance. Cross-tolerance to morphine and other opioids requires higher doses than in opioid-naïve subjects to obtain pain relief. In the author's experience, in methadone maintenance patients, greater analgesia is experienced when the daily maintenance dose is divided into thirds and given at 8 hourly intervals. The problem of buprenorphine in μ-opioid agonist therapy is problematic as described previously.

Fortunately, opioid analgesia is not the only effective therapy available for acute pain management. In the majority of patients, local anesthetic-mediated techniques (e.g., epidurals, peripheral nerve blocks, intravenous lidocaine), non-opioid analgesics (e.g., non-steroidal anti-inflammatory drugs, cyclo-oxygenase type 2 antagonists, anticonvulsants, antidepressants), low-dose ketamine and dextrometorphan (*N*-methyl-*D*-aspartate receptor antagonists, which enhance opioid analgesia), and physical therapies (e.g., thermal modalities, massage, exercise, transcutaneous electrical nerve stimulation) are extremely effective and will suffice in combination or singly, with or without supportive psychotherapy.

Conclusions

Pain and addiction are complex, chronic neurobiologic disorders that are poorly understood, inadequately treated, and underresourced in health care settings and society. Physical and affective components of these diseases should be treated simultaneously in multimodal, multidisciplinary disease management programs for best outcomes.

Expansion of health care resources and collaboration between pain medicine and addiction medicine specialists to allow patients with comorbid conditions to be treated effectively are necessary. Pain physicians need support and resources to effectively implement care programs and "Universal Precautions". Addiction physicians need support and resources to effectively provide rehabilitation programs with the flexibility for patients requiring therapeutic opioids for pain, i.e., non-drug free.

Opioid prescribing is, directly or indirectly, a major driver of prescription opioid abuse. Depression, generalized anxiety disorder, panic disorder, and somatization associated with painful conditions may be a large and heterogeneous patient group mistreated with opioid analgesics. Education is paramount in achieving the balance and cooperation needed to provide dual care to addicted individuals who also require opioid analgesia and for pain patients at risk of developing abusive or addictive disease. Health care providers, law enforcement agencies, and the general population alike should be educated in the nature of these diseases if they are to be diagnosed, assessed, and treated appropriately. Law enforcement should complement the efforts of clinicians in providing needed medical care while clinicians fastidiously assess, treat, and document therapies.

New areas of research, such as glial function in nociception and mood disorder, have the potential to provide unique therapeutics with strong analgesic potential, and possible antidepressant effects, without the risk of addiction and other serious adverse effects associated with current analgesic medications.

Introduction

Concurrent substance abuse and psychiatric disorders in individuals who are infected with the human immunodeficiency virus (HIV) are common. Prevalence rates vary significantly across reported studies and range from 10% to nearly 70% depending on the study [64, 67]. In a large cross-sectional study, as many as half of the clients in an HIV clinic had at least one psychiatric disorder, with nearly 40% abusing drugs (other than marijuana) and up to 12% with drug dependence during the previous 12 months. There are high rates of bipolar II disorder and cyclothymic and hyperthymic temperaments that have been linked with up to 70% of the HIV population [64]. All have been associated with higher rates of increased impulsivity along with greater novelty-seeking and risk-taking behavior in this population. Thus, we can infer that unsafe sexual practices and needle-sharing are very common.

Similarly, psychiatrically ill individuals often go on to develop substance abuse disorders. Independently, substance abuse disorders may contribute to psychopathology and the emergence of psychiatric illness. Both will impair judgment and contribute to high-risk behaviors such as sharing needles and injection paraphernalia or trading sex for money.

Given the high comorbidity between the dually diagnosed (mentally ill and substance abuse) and HIV, the purpose of this review is to examine recent data regarding the interactions

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_58,

between dual diagnosis and HIV as well as associated comorbidities—especially hepatitis C infection.

Scope of the Problem

The highest rates of HIV infection are in individuals with dual diagnosis of severe mental illness and substance use disorder. In one study of HIV-positive participants with comorbid substance use and psychiatric problems ($n = 1{,}848$), HIV prevalence was 4.7% in those having a diagnosis of both substance abuse and mental illness, whereas HIV prevalence was only 2.4% in those diagnosed with a substance abuse disorder alone. Psychiatric illness appeared to almost double the risk of HIV—especially in those with concurrent poor psychosocial support [10]. These findings were confirmed by a cross-sectional survey of 3,806 adults living with HIV across four major metropolitan areas in the United States, which showed that 72% of respondents reported at least occasional use of various drugs, and 40% of respondents reported frequent use of various drugs—only 28% declared abstinence from all drugs [50]. In the group reporting frequent use of drugs, more were likely to be identified as heterosexual, had public health insurance, and endorsed increased symptoms of depression [10, 50], which illustrates the complexities of the relationship between the triple diagnoses of mental health-substance abuse and HIV infection.

Drug Abuse Disorders

Alcohol use alone has been linked to multiple risk factors associated with HIV including sexually transmitted disease histories, condom non-use, multiple sex partners, and lower HIV-related knowledge. These risks appear to increase substantially with increasing amounts of alcohol use and those demonstrating abstinence from alcohol appear to have the lowest risk profile. The impact of alcohol upon these risk factors remains present even in the absence of other drug abuse [61].

Intravenous drug use has long been associated with an increased prevalence of comorbid psychiatric diagnosis—especially dysthymia and depression [1]. Depressive syndromes in intravenous drug use populations have also been repeatedly linked to increased willingness to share needles, syringes, and other paraphernalia, which further increases the risk of HIV transmission [1, 12, 75]. Stein and colleagues examined the association of depression severity and drug injection HIV risk behavior among injection drug users. Even after controlling for multiple confounding variables, including age, race, gender, number of days on which injection drugs were used, and the average number of injections per injection day, a diagnosis of depression was significantly associated with injection risk behavior [75].

Similarly, other data illustrate that depressed individuals are more likely to engage in sex with intravenous drug use populations, heightening an already substantial risk of transmission [38]. This same population also demonstrates increased rates of sexual abuse. This again predicts depressive features, increased suicidality, and increased non-adherence to antiviral therapy, making the risk of disease progress and viral resistance greater in this group [11, 51, 65]. Poorer outcomes in HIV-infected intravenous drug users have been related to a variety of factors, including increased rates of hepatitis C, delayed access to treatment, diminished adherence to highly active antiretroviral therapy regimens, depression, psychosocial stressors, and death [49].

Among individuals who inject drugs, studies have shown that up to one-third are at risk for severe depression with women appearing to experience increased depressive symptoms as compared with men. Correlates of depression in both men and women include perceived functional limitation, greater negative feelings regarding condom use, lower social support, and a lower sense of empowerment/external locus of control. Similarly, being physically abused

as an adult and Latino race also appeared to be significant predictors of depression among HIV-seropositive intravenous drug users of both genders [79].

Methamphetamine-dependent men who have sex with men also demonstrate high lifetime rates of psychiatric disorders including major depression and anxiety disorders. Generalized anxiety disorder, specific phobia, bipolar disorder, and major depressive disorder have all been linked to higher rates of sexually transmitted infections including gonorrhea and HIV [72]. Crystal methamphetamine use has evolved to be a major risk factor for the development of depression and other mental illness as well as increased transmission rates of HIV. Naturalistic interview studies have demonstrated the wide prevalence of a cycle of severe depression and anxiety in the context of methamphetamine use as well as persistent anhedonia. Almost all respondents in such studies reported that crystal methamphetamine was severely damaging to social relationships with a resultant increase in self-isolation. In addition, methamphetamine use has been closely tied to random sexual encounters and increased numbers of sexual partners with a decreased likelihood of condom use [59]. A better understanding of these patterns and risks are essential in developing effective prevention strategies.

Psychiatric Disorders

Common mental disorders among individuals with HIV and substance abuse include adjustment disorders, sleep disorders, depressive disorders, mania, dementia, delirium, psychosis, and personality disorders [8]. A careful psychiatric assessment is necessary in order to engage in differential diagnostic considerations and differential therapeutics. There are three categories of mental disorders of concern in HIV-infected substance abusers: substance-induced mental disorders, HIV-related mental disorders, and medication-related mental disorders [8].

Psychiatric Disorders in Human Immunodeficiency Virus Infection

Mania and Bipolar Disease

Bipolar disease in the context of HIV is especially problematic in that it involves cyclical moods that not only predispose its sufferers to the risk factors of depression, but also heightened risks of contracting HIV due to features of mania that include impulsivity, hypersexuality, and increased goal-directed behavior. Individuals with comorbid hepatitis C/HIV are more likely to have comorbid psychiatric disorders including bipolar type [5]. Bipolar illness frequently co-occurs with substance abuse and has been linked to heightened risk taking and impulsivity. One study examining the link between mania and HIV risk found that most study participants had been sexually active in the past 6 months (75%), and they reported high rates of sexual risk behaviors such as unprotected intercourse (69%), multiple partners (39%), sex with prostitutes (24%, men only), and sex trading (10%). Severity of bipolar illness was also associated with HIV risk profile [58].

Schizophrenia

Individuals with serious and persistent mental illness (schizophrenia, bipolar, major depressive disorder) have been noted to have approximately twice the incidence of HIV as compared with those without serious and persistent mental illness, and there is also a greater incidence of infection with hepatitis C [22]. However, the source of this increased risk has been debated, and some data suggest that in the absence of comorbid substance abuse, these individuals do not share an elevated risk for acquiring HIV compared with other non-serious and persistent mental illness populations [36]. Poor HIV knowledge and increased risk-taking behavior is also significant in this cohort [46, 47].

Identification of comorbid serious and persistent mental illness is important in this population in that comorbidity incurs a worse prognosis for both the schizophrenia and the HIV due to factors such as psychosocial instability and adherence [22].

Depression

Depression is a common co-occurring condition with HIV and is the most common mood disorder found in people living with HIV. While depression may decline in non-HIV-seropositive populations with advancing age, this does not appear true of HIV-seropositive individuals, which places them at continued risk of depression even during older age [69]. Depression has also been closely linked to apathy in HIV-seropositive populations, and both apathy and depression are linked to highly active antiretroviral therapy non-adherence [68]. Similarly, fatigue has also been linked to depressed mood and a diagnosis of major depressive disorder [29]. Depression severity has also been linked to a greater frequency of injection drug risk behavior among depressed injection drug users [75].

Women have been reported to be a special risk group in regard to depression and intravenous drug use. Depression rates and severity appear to be more present in women who are both infected with HIV and injection drug users [60]. Women also report the poorest quality of life scores in the context of HIV infection, in spite of showing some protection against cognitive decline with respect to male counterparts [84]. Drug use, violence, and depression have been deemed a "tripartite HIV risk" among African-American women and are underexplored areas of research. Women with a history of sexually transmitted diseases have been noted to be more likely to experience violence and depression—both alone and comorbidly. This described tripartite risk group is also reflective of those women having two or more sexual partners in the last 30 days as well as those having an early onset of alcohol abuse [42]. Similarly, antiviral adherence has been noted to be worse in drug-abusing women as compared with men. However, mental health care has been shown to be significantly associated with adherence in this population as opposed to men [77]—again highlighting the need for effective psychiatric services in this at-risk group.

Psychosocial Issues

Childhood sexual experiences have been linked as a strong predictor to psychological distress as well as risk of substance abuse and HIV transmission risk [3, 43]. Among men who have sex with men, those with a history of childhood sexual abuse were more likely to engage in high-risk sexual behavior including unprotected receptive anal intercourse, to engage in trading sex for money or drugs, to report being HIV seropositive, and to experience non-sexual relationship violence [43]. Additionally, when confronting this group of at-risk individuals, it is useful in distinguishing forced childhood sexual abuse versus consensual childhood sexual experiences. Individuals who experienced forced sexual contact have the highest risk of these three factors as compared with the consensual group who only demonstrated increased rates of substance abuse and HIV transmission risk as compared with a no-exposure group [3]. Thus, an assessment of these groups should include a discussion of patterns of risk exposure and childhood sexual exposure to better tailor interventions to the specific individual.

The role of past trauma in placing individuals at risk of HIV has also been found in large populations of HIV-seropositive women [39, 62]. Hutton identified that among women prisoners, HIV risk behaviors in the 5 years preceding incarcerations included unprotected sex (56%), injection drug use (42%), sexual intercourse with a partner who injected drugs (42%), prostitution (30%), needle sharing (30%), receptive anal sex (19%), and having more than 100 sex partners (7%). After adjusted for age, education, race, HIV status, and addictive disorders, post-traumatic stress disorder was associated

with the practice of receptive anal sex and prostitution and appeared to contribute to these high-risk activities.

In addition, Myers identified that greater drug dependence has been associated with increasing rates of HIV, depression, and higher chronic disease burden among women. Similarly, alcohol dependence and trauma have been associated with increased depression and social instability in this group as well [62, 74]. Importantly, both childhood trauma and depression severity appear to predispose to ineffective and avoidant coping strategies, which may predispose this group to additional burdens of depression and disease throughout life [74]. Likewise, among non-adherent women prescribed highly active antiretroviral therapy, the use of cocaine and heroin and a history of abuse decreased the likelihood of acceptable adherence to highly active antiretroviral therapy [18]. These items taken alone or together illustrate not only the need for substance abuse programs but also the important role of sexual abuse prevention efforts and abuse treatment strategies in at-risk groups.

Other data support a high prevalence of depression and substance abuse among HIV-seropositive individuals enrolled in methadone maintenance treatment programs or needle exchange. Depression is extremely common in these programs, and one study has estimated rates as high as 54%. Women, persons with a comorbid alcohol abuse diagnosis, and those with diminished social support were more likely to be depressed even after controlling for age, race, education, and HIV status. Those enrolled in methadone programs showed significantly less depression than similar participants in a needle exchange program [13].

Comorbid Medical Disorders

Hepatitis C

Another complicating factor that commonly exists in dually diagnosed individuals with HIV disease is the concurrent diagnosis of hepatitis C infection. Large observational retrospective cohort studies in high-risk populations have demonstrated that over one-third of people living with HIV are also hepatitis C seropositive, and the group with combined infectivity is characterized by being older minority men who were more likely to acquire HIV by intravenous drug use. In addition, individuals with both HIV and hepatitis C were more likely to have a diagnosis of mental health illness, depression, alcohol abuse, substance abuse, and hard drug abuse compared with those infected with HIV alone. Individuals with both HIV and hepatitis C were also less likely to have received highly active antiretroviral therapy during the previous year [4].

Cognitive Disorders and Dementia

One of the common complications of HIV infection is neurocognitive impairment. This alteration of brain-behavior functioning may range from a subjective sense that one has slowing of thinking and difficulty with memory retrieval to a severe dementia with confusion, mutism, and gross neurologic signs. Numerous studies indicate the percentage of HIV-infected individuals having any cognitive impairment during the course of their illness to be 38.8–54.4% overall and meeting the full criteria for dementia to be 10.4–25.2% [23, 63, 78], despite more and more effective antiretroviral therapy [63]. With this percentage of people with potential cognitive loss, it follows that clinicians working with HIV-infected individuals must be sensitive to any signs that cognition is declining, be prepared to refer for a formal neurocognitive evaluation to fully delineate the problems, and, if results show that there are deficits, have a treatment plan available to improve functioning [28, 37]. There may also be cognitive complications from substance-induced psychiatric disorders including effects from both illicit and prescribed drugs as well as antiretroviral and cancer-related chemotherapy [16, 35, 48].

Individuals with both HIV and hepatitis C may also experience significant impairment in the realm of cognitive functioning given that both HIV and concurrent disease such as hepatitis C impact central nervous system processes. In addition, hepatitis C has been linked to fatigue, increased depression rates, and impairments in health-related quality of life that are independent of the severity of the liver disease [30]. Multiple explanations for these symptoms have been offered, but central nervous system effects of substance abuse, personality types, and hepatitis C viral load have all been prominent reasons to explain these effects. In particular, the central nervous system impact of hepatitis C has been noted most in the domains of attention, concentration, and processing speed [17]—all of which can mimic deficits secondary to HIV illness as well as major depression [81, 84].

The impact of major depression upon cognitive performance in HIV-seropositive populations cannot be neglected, and data support the link with depression as a risk factor for neuropsychological disturbances in seropositive drug abusers. Cognitive performances across multiple domains appeared impaired secondary to depression in an HIV-positive, drug-abusing population including attention, cognitive flexibility, and motor speed [80].

Similarly, previous alcohol abuse has been demonstrated to be linked with additive levels of cognitive dysfunction in HIV-seropositive populations. Significant and synergistic interactions in the realms of verbal reasoning, auditory processing, and reaction time have been noted in HIV-seropositive populations with a history of alcohol abuse. These interactions did not exist in a HIV-seronegative control group with a history of alcohol abuse [34]. This illustrates the potential synergistic and combined cognitive effects that triply diagnosed individuals may experience, along with the need for a high level of clinical suspicion for cognitive disorders in this group. This is especially important in that cognitive disorders in HIV are also important predictors of highly active antiretroviral therapy nonadherence. Addressing hepatitis C and cognitive deficits will continue to be of high importance in a dually diagnosed population with concurrent HIV disease.

Role of Mental Illness and Substances of Abuse in the Treatment with and Adherence to Highly Active Antiretroviral Therapy

Previous studies examining the relationship between depression and HIV transmission have shown mixed results, but the role of depression upon adherence to highly active antiretroviral therapy has been confirmed in multiple studies on the subject. A recent longitudinal study on adherence rates from 2001 to 2004 of HIV-seropositive individuals with concurrent mental illness and substance abuse demonstrated several concerning patterns. Almost 73% of participants met criteria for major depressive disorder and depression was linked to non-adherence [9]. Importantly, this group was reflective of the growing HIV epidemic in that 75% were people of color, 66% described their sexual orientation as heterosexual, and most were unemployed [9].

Given that mental health diagnosis and substance abuse problems are common among individuals infected with HIV, a great deal of attention has been devoted to the study of these factors and their impact upon adherence. Large cross-sectional studies demonstrated that mental health diagnoses including depression, generalized anxiety disorder, or panic disorder were more likely to be non-adherent to highly active antiretroviral therapy over the previous week than non-psychiatrically ill counterparts. Non-adherence was also associated with cocaine, amphetamines, or sedative use in the previous month, but cocaine demonstrated the strongest predictor of non-adherence in the drug abuse group, while generalized anxiety disorder demonstrated the largest odds of non-adherence among the mental health diagnoses. However, frequent heavy alcohol abuse showed the largest odds ratio of non-adherence among all diagnoses combined, illustrating the need for effective interventions among this population [76].

The role of mental illness and substance abuse upon HIV populations is significant in that multiple studies have linked diminished adherence rates to these risk factors. Even active cigarette smoking is an independent predictor of non-adherence in HIV-infected individuals receiving highly active antiretroviral therapy, and, importantly, this risk of non-adherence diminishes with cessation of smoking [73]. Based upon available data, a history of substance abuse without current abuse does not predict non-adherence, which again illustrates the importance of active interventions designed to curb substance abuse and dependence.

Further, the presence of depression has also been linked as an independent risk factor in not only non-adherence but also HIV disease progression, viral load, and CD8 activation [27]. This pattern has most recently been documented in a study of highly active antiretroviral therapy-treated HIV-infected drug users of which intravenous drug users comprised 17% of the study group. Depression was encountered in 46% of the study group during the follow-up period, and non-adherence reached 31%. Clinical predictors of disease progression included both non-adherence to highly active antiretroviral therapy as well as a higher score of depressive symptoms following highly active antiretroviral therapy initiation, which remained significant even after controlling for non-adherence behavior [11]. Similar studies focusing upon HIV-seropositive women also found that chronic depression was a predictor of AIDS-related deaths with symptoms being more severe among women in the terminal phase of their illness [21]. Interestingly, mental health care has been associated with reduced mortality [21]. Other affective syndromes including bereavement and chronic grief have also been linked to disease progression in HIV-infected populations [32].

However, encouragingly, depressed individuals living with HIV who receive psychiatric treatment with antidepressants are more likely than untreated individuals to receive appropriate care for their HIV disease and increase adherence to HIV interventions. Antidepressant therapy for treatment of depression in this population has also been demonstrated to be associated with a lower monthly cost of medical care services based upon at least one study examining merged Medicaid and surveillance data. Encouragingly, women and drug users engaged in treatment were most likely to receive an antidepressant response, and those receiving antidepressants achieved a 24% reduction in monthly total health care costs as compared with a depressed but untreated cohort [71].

Risk-Taking Behavior

Previous cross-sectional data has illustrated a close relationship between substance abuse, depression, and at-risk behavior, but limitations of cross-sectional data include the idea that it difficult to infer causal relationships, whereas longitudinal data can better support causal associations. One longitudinal study examining the relationship between depression and sexual risk behaviors in a community sample of 332 inner-city drug abusers found that increasing severity of depression predicted sexual encounters with multiple partners as well as sexual encounters with known injection drug users [83]. Similarly, depression has been linked to greater frequency of injection risk behavior among depressed intravenous drug users [75].

Other studies have confirmed a link between mental health and risk-taking behavior, even when controlling for substance abuse patterns, across a variety of populations. One study examining a subset analysis of clinic clients with sexually transmitted diseases who met the criteria for major depressive disorder [38] found that depressed individuals were more likely to have sex for money or drugs, a greater number of lifetime sexual partners, and a higher likelihood of abusing alcohol or other substances. The HIV risk behaviors associated with depression persisted even when controlled for substance abuse, which again illustrates the importance of depression screening in at-risk populations.

Similarly, another longitudinal study examining the HIV risk behaviors and drug use among 557 Latino heroin and cocaine injectors not in treatment demonstrated a close association between both mental health and substance abuse variables [53]. Intravenous drug users in this study reported high rates of both depression (52%) and severe anxiety (37%), with concurrent alcohol intoxication in the last 30 days by 18% of participants. Those showing polysubstance abuse (alcohol and injecting behavior) were more likely to inject three or greater times daily, share needles, and share cotton. Polysubstance abusers were also more likely to engage in casual sex or prostitution as well as unprotected sex [53]. These studies illustrate that prevention efforts designed to reduce HIV risk behaviors cannot neglect addressing both mental illness and substance abuse in this triply diagnosed population.

Another impact of the presence of comorbid mental health disorders and substance abuse has been its role in promoting increased sexual risk-taking behavior in young age populations. One study examining a cohort of newly homeless youth who were followed longitudinally for up to 24 months demonstrated that drug use was a significant predictor of having multiple sexual partners as well as decreased condom use. Similarly, living in a non-family setting also was a significant predictor of sexual risk-taking behavior and condom use [66].

However, the impact of depression and substance abuse upon adherence and HIV transmission is heightened by consideration that available data do not only support a link between decreased adherence to highly active antiretroviral therapy and dually diagnosed individuals, but also support a link that dual diagnosis increases the risk of unsafe sexual encounters among those with a known resistant virus. Data from the Study of the Consequences of the Protease Inhibitor Era [15] showed that among participants taking highly active antiretroviral therapy, 60% had genotypic resistance to at least one drug. In those with documented drug resistance, 27% of men who have sex with men and 11% of heterosexual men and women reported at least one episode of unprotected penile-anal or penile-vaginal intercourse in the previous 4 months. Importantly, up to 17% of men who have sex with men reported unprotected intercourse with an HIV-uninfected or status-unknown partner. Significant predictors of these behaviors included younger age, depression, and the use of sildenafil and alcohol. As with other studies of this population, these risk factors were identifiable and allow a targeted intervention with limited resources [15].

As noted previously, the role of psychostimulant abuse—especially cocaine and methamphetamine—is a major risk factor in HIV behavior, and rates of methamphetamine abuse appear to be increasing in at-risk populations (e.g., men who have sex with men). Medical complications from methamphetamine abuse are myriad and include hypertension, hyperthermia, rhabdomyolysis, and stroke [15]. In addition, comorbid methamphetamine abuse and HIV infection has been linked to increased likelihood of severe cognitive and movement disorders [45].

A large analysis of 736 enrolled participants in the EXPLORE study, who were men who have sex with men, described patterns of use with methamphetamines, poppers, and cocaine as well as sexual risk behavior. Younger participants were more likely to increase their use of drugs over time, and high-risk sexual behavior was more common during periods characterized by increased methamphetamine, popper, or sniffed cocaine use. Importantly, a within-person analysis found that both light drug use (less than weekly use) and heavy drug use periods were significantly associated with engaging in unprotected anal sex with HIV-seropositive or unknown status partners as compared with periods of no drug use [19]. Importantly, these data suggest that a risk-reduction model of addressing substance abuse in this population is likely to be ineffective in reducing HIV transmission, while engagement in an abstinence model appears safer and more effective. Similar data regarding the risk of moderate alcohol use upon non-adherence also support an abstinence model over a risk-reduction one [76].

Assessment of the Triply Diagnosed

The assessment of the triply diagnosed poses special difficulties, as they are more likely to manifest complex disease in all aspects of care, including increased numbers of viral mutations and resistance, complex psychiatric needs including treatment-resistant depression and post-traumatic stress disorder, as well as either ongoing substance abuse or being at high rates of relapse for substance abuse. Ideally, psychiatric consultation liaison services and substance abuse services are available within the infectious disease clinic, so the client can be approached and evaluated simultaneously by multiple practitioners to gain a more three-dimensional understanding of his or her needs and risk factors so as to allow optimization of the individual treatment plan.

The comprehensive assessment of these individuals should include an extensive and detailed psychosocial history designed in part to elicit sources of stress, sources of support, past psychiatric history, and any history of abuse, given that these all appear significant in predicting non-adherence and disease progression. Additionally, a detailed substance abuse history including types of substances, age at first use, frequency and route of use, triggers, and any available protective factors is an essential step toward providing support and guiding individuals toward appropriate treatment that will both allow and run concurrently with their HIV treatment [7, 25, 26].

Substance Use/Abuse Treatment of the Triply Diagnosed

Many factors contribute to the delayed entry of the triply diagnosed. These can include dropping out of care, living in unstable housing, lack of food, lack of transportation, the complexities of the healthcare system, health maintenance organization-required payment authorizations, and idiosyncratic referral practices of the medical team for either psychiatric care or drug abuse/dependence consultations, or both. Injection drug users are less likely to receive antiretroviral therapy than any other population. Factors associated with poor access to treatment include active drug use, younger age, female gender, sub-optimal health care, not being in a drug treatment program, recent incarceration and lack of health care provider expertise [31]. Yet these individuals should be considered and can be treated effectively. Department of Health and Human Services guidelines state that antiretroviral therapy can be successful in intravenous drug users [31]. Antiretroviral therapy requires that providers and clinical care sites become more supportive, having increased awareness of interactions with methadone as well as risk of side effects and toxicities, and use of simple tenchniques to enhance adherence can be successful. One study of triply diagnosed women lost to follow-up in an HIV clinic [2] received nursing outreach intervention over 3 months to assist in treatment entry. Follow-up included home visits to assist in making and keeping appointments, accompanying the women on their initial clinic visits, integration of care among HIV, substance abuse, and mental health providers—all were found to assist in access, adherence, and retention.

Longitudinal data demonstrate that both HIV-seropositive status and baseline depression independently predicted recurrent or persistent episodes of major depression in intravenous drug users. HIV-seropositive drug abusers with baseline major depression showed a 90% rate of at least one subsequent episode of major depression over a 3-year period and 47% experienced at least three subsequent episodes [41]. However, less than 40% of this population received psychiatric treatment during this time [41], making them at high risk for not only engaging in behavior that perpetuates HIV transmission but also being undertreated for risk factors contributing to this same behavior.

One study examining the effects of an intensive outpatient cocaine treatment program over 9 months found that risky behavior among participants was correlated with high intake

problem severity and psychological symptomatology. Over the course of treatment, the amount of risky behavior was found to decrease significantly among those participating actively in the treatment program. The decrease in risky behavior was linked to decreased substance abuse, but did not appear affected by demographic variables, type, or duration of treatment in this study [33].

Other potential data-driven intervention models include brief peer-delivered educational interventions. This model has been shown to be effective as compared with a standard National Institute on Drug Abuse HIV testing and counseling protocol for cocaine abusers [20]. Both models, however, have demonstrated effectiveness in reducing crack cocaine use, injection drug use, and the number of intravenous drug-using sex partners. Subjects diagnosed with an antisocial personality disorder demonstrate less improvement than non-antisocial controls. However, neither intervention model was shown to be effective in improving condom use [20], which illustrates the complex nature of these risk factors and the need to have multiple interventions to target at-risk behaviors.

Methadone maintenance treatment programs are also an essential part of the treatment of triply diagnosed individuals. Increased numbers of clients in methadone maintenance treatment show intravenous drug use abstinence [24]. Methadone maintenance treatment has been demonstrated to dramatically reduce illicit opiate use as well as criminal activity. More recent data support that methadone maintenance treatment also reduces incarceration rates, which would likely diminish the risk factor of sharing needles while incarcerated and lower exposure to high-risk practices [82]. In addition, opiate treatment-resistant dually diagnosed individuals show better long-term survivability in methadone maintenance treatment programs than their non-dually diagnosed counterparts [52].

Non-methadone maintenance treatment programs centering on group activity and support also demonstrate significant roles for the treatment of this complex population, and involvement in either methadone maintenance treatment or non-methadone maintenance treatment programs is associated with improved antiretroviral therapy adherence [44]. Buprenorphine programs are likewise associated with improved highly active antiretroviral therapy adherence [70], although they are widely underused in HIV-seropositive populations in the United States. France appears to have the most experience with buprenorphine programs in HIV-positive populations, and data support their effectiveness in this population [14] even though both methadone and buprenorphine have significant drug-drug interactions with highly active antiretroviral therapy medications.

Methadone is primarily metabolized via cytochrome P450 3A4, and this cytochrome also is responsible for the metabolism of multiple highly active antiretroviral therapy medications—most notably, the protease inhibitors. Consequently, drug-drug interactions and potential complications involving methadone/buprenorphine prescribed concurrently with highly active antiretroviral therapy include changes in pharmacokinetics as well other effects such as a prolonged QTc interval [6, 54]. Ritonavir produces strong 3A4 inhibition initially, but has also been documented to induce 3A4 when administered chronically. Therefore, it is clear that drug-drug interactions are difficult to predict over time and require careful monitoring. For instance, initiation of a ritonavir- or other protease-containing antiretroviral therapy regimen in an individual on stable methadone maintenance treatment may result in opiate toxicity and overdose due to early cytochrome inhibition [40]. Conversely, lopinavir is a potent inducer of methadone metabolism, with one study finding that the combined effects of lopinavir/ritonavir administered to methadone maintenance treatment recipients included significant reductions in the methadone area under the concentration-time curve and reductions in the maximum serum concentration in the setting of increased methadone oral clearance [57]. Consequently, the authors also noted increased rates of opiate withdrawal in this population, highlighting the need for careful monitoring of clients during either methadone

maintenance treatment initiation or highly active antiretroviral therapy initiation.

Buprenorphine is also metabolized by 3A4, and concurrent ritonavir acutely inhibits its metabolism, producing higher levels as with methadone [40]. However, conflicting data also demonstrate relative safety in using buprenorphine in the setting of protease inhibitors as well as non-nucleoside reverse transcriptase inhibitors [56]. However, one case series of three buprenorphine/naloxone-maintained participants did report increased sedation with buprenorphine when the atazanavir/ritonavir combination was initiated, which raises the possibility that atazanavir or atazanavir/ritonavir may increase buprenorphine concentrations that require a subsequent dose reduction [55].

Summary and Conclusions

In summary, the triply diagnosed individual presents with significant disadvantages with regard to health potential. The highest HIV rates are seen in individuals with dual diagnoses, and multiple factors contribute to delayed entry or premature cessation of antiviral treatment. All those who enter an HIV treatment program should also be assessed systematically for mental disorders and substance abuse. Individuals with dual diagnoses who are also diagnosed with HIV should be referred both to substance abuse treatment programs and to programs offering psychopharmacological interventions coupled with individual, group, or family therapy as appropriate. Drug interactions between antiretroviral therapies and street drugs or psychotropics can increase or decrease action of either drug, so special attention must be given to potential drug-drug interactions. Cognitive remediation strategies can be used to address cognitive impairment, while a harm reduction approach can minimize the impact from concurrent drug or alcohol use.

Substance Use Stigma as a Barrier to Treatment and Recovery

Jason B. Luoma

Contents

Introduction

Stereotypes and judgments about people with substance misuse problems are extremely prevalent and negative [15, 18, 22, 73]. The content of these stereotypes varies, with examples including "people who use drugs are immoral," "alcoholics are unreliable," or "addicts are dangerous." These negative evaluations are held not only by those who abstain from substance use, but also by those who themselves use and abuse substances. As the criminalization of drug use has increased over recent decades in the United States, the level of negative attitudes toward drug use has also increased [10].

While the exact form of these stereotypes and judgments may vary across different substances and social groups, substance misuse appears to be at least as stigmatized as psychological disorders such as depression, schizophrenia, or borderline personality disorder, if not more so [15, 18, 22, 73]. While the data are quite clear about the prevalence and negativity of stigmatizing attitudes, research to date on the links between these attitudes and subsequent negative outcomes for those with substance addiction is relatively sparse. As the body of data on stigma toward the mentally ill is much broader and deeper, especially for psychotic disorders, this chapter depends somewhat on extrapolation from mental illness stigma, to substance abuse stigma.

A review of sociological and historical analyses of factors that have contributed to the stigma

of substance abuse is beyond the scope of this chapter. Other authors (e.g., [105]) have provided excellent narratives on such topics as the history of legal policy toward substance use and how larger values systems such as Puritanism contribute to stigmatization. Instead, this chapter will focus on the nature of stigma and its impact on those with substance abuse problems through review of scientific research and theory. We also will discuss implications for interventions regarding stigma, particularly in the context of the substance abuse treatment system. The chapter begins with a short review on the nature of stigma in general, followed by a focus on stigma as directed toward those using or abusing substances.

What Is Stigma?

As with most other common language terms that have been adopted by the social sciences, the concept of stigma has been difficult to narrow to a single definition. As used conventionally, stigma refers to an attribute or characteristic of an individual that identifies him or her as different in some manner from a normative standard and marks that individual to be socially sanctioned and devalued. One of the most widely cited definitions of stigma comes from Goffman [38], who saw stigma as an "attribute that is deeply discrediting". This attribute impacts the perceiver's global evaluation of the person, reducing him or her "from a whole and usual person to a tainted, discounted one" (p. 3). Another influential definition comes from Jones et al. [56] who suggested that a stigmatized person is "marked" as having a condition considered deviant by a society. Through an attributional process, this mark is linked to undesirable characteristics that discredit the person in the minds of others. Perhaps one of the most comprehensive definitions of stigma comes from the work of Link and Phelan [72], who define stigma as occurring when the following processes converge: (1) people distinguish and label human differences; (2) dominant cultural beliefs link labeled persons to undesirable characteristics that form a stereotype; (3) labeled persons are seen as an outgroup, as "them" and not "us"; (4) labeled persons experience status loss and discrimination that lead to unequal outcomes; and (5) this process occurs in a context of unequal power distribution, where one group has access to resources that the other group desires.

Stigma Depends on Basic Verbal/Cognitive Processes

Stigma is always in the eye of the beholder. At a psychological level of analysis, all the above definitions hinge on the role of the cognitive and emotional responses of the perceiver in determining who is stigmatized. Stigma emerges from some of the most basic functions of language and cognition, such as categorical, evaluative, and attributive processes [41]. As verbally able humans, a common cognitive activity is evaluating and classifying the people in our social world. This is particularly common when a lack of extensive personal experience with someone leads us to rely on cues for assigning that person to a social category, whether accurately or inaccurately. Our ability to classify according to socially defined categories is universal among language-able humans and also unique to us as a species. Just try it out for yourself. Read the following sentences and fill in the blank:

Men are _____.
Women are _____.
Alcoholics are _____.
Gays are _____.
Addicts are _____.

Were you able to fill in those blanks? Even if doing so felt uncomfortable, most people are able to provide responses that *seem* to describe the group in question. Answers may readily appear even when they are unwanted or disagreeable. Anyone who participates in a cultural/verbal system learns common stereotypes for the groups that have been defined in that culture [26] whether they agree with them or not.

Throughout a typical day we classify people into groups based on some identifying characteristic or behavior, make judgments about what this means about them, and respond based on this judgment. Much of this process of stereotyping and responding occurs outside of our normal awareness and is harmless, even adaptive. For example, we identify the person at the checkout counter in the grocery store as a clerk and proceed to have them scan our groceries. Research has shown that stereotypes help to reduce the burden of problem solving in complex social environments (e.g., [80]). We are able to quickly develop evaluations and expectations of individuals based on their perceived membership in a group about which we have some social knowledge (i.e., stereotypes [40]). These stereotypes allow us to predict that person's behavior and act accordingly. Sometimes this is quite useful, such as when purchasing items in a grocery store. Sometimes it is less so, for example, when seeing a bumper sticker on a person's car endorsing a disliked political candidate, we may make unsavory assumptions about the driver and may be more inclined to engage in discourteous behavior on the road. Sometimes this process is clearly harmful, for example where culturally sanctioned stereotypes devalue certain individuals and this same process results in stigmatizing, rejecting, and even discriminatory interactions. Through this process of objectification and dehumanization, we fail to appreciate the complex, historical human being and respond to the person solely in terms of their participation in verbal categories [43, 77].

Stigmatizing Thoughts are Resistant to Change

Stigmatizing thoughts and attributions have been shown to be difficult to change through direct intervention [43]. One reason for this may be that judgment and stereotyping are massively useful for the individual in many social situations and thus are highly prevalent and automatic, often happening without awareness. Additionally, verbal/cognitive networks, once formed, tend to maintain themselves [43]. Stereotype disconfirming information that occurs during social interactions tends to be forgotten if the new material conflicts with older stereotypes [49]. People tend to infer stereotype-congruent behaviors to dispositional causes, while stereotype-incongruent behaviors are inferred to situational causes [46], thus further supporting their already existing stereotypes. Even people who exhibit low levels of prejudice know the common stereotypes of stigmatized groups, and once learned, these stereotypes do not go away [26]. If a person learns new ways of thinking, the old ways of thinking do not disappear, but rather are available to re-emerge if the new ways of thinking are frustrated or punished (e.g., [144]). Thus, if new stereotypes are learned about a group, these generally do not replace the old stereotypes; rather, the new learning is metaphorically "layered over" the old learning. The old stereotypes are still available to reemerge under situations in which the newer learning is put under strain.

Stigma Is Sustained Through Cultural Practices

While stigmatization is a universal human phenomenon, *what* is stigmatized has been shown to vary over time and across cultures [66]. This suggests that stigma results from cultural practices that exist on the basis of their past ability to facilitate the survival of that culture [5, 143], much in the same way that genes are selected based on their contribution to the survival of a species. Cultural practices which support categorization and stereotyping facilitate membership in and favoritism toward a perceived in-group (e.g., [47, 127]), as well as the resulting mistreatment of those in a perceived out-group [131]. These distinctions preserve and sustain a variety of cultural practices when they generate advantages for the in-group, even when the groups are based on arbitrary characteristics bearing no direct adaptive value. Though stigmatization is defined as the behavior of an individual, it is

always generated and sustained by cultural practices which reinforce and support stigmatizing attitudes, stereotypes, and actions. Thus, in order to change stigma, it is important to change both the behavior of individuals and the cultural practices which support stigma among individuals of that culture.

Types and Levels of Stigma Toward Substance Abuse

The above section was only a brief overview of the vast literatures on stigma, stereotyping, and prejudice. In contrast, the rest of this chapter focuses specifically on stigma toward addiction and begins with a review of types and levels of stigma in relation to substance abuse. Stigma can be subdivided into various types and levels. One distinction can be made between structural and individual stigma. Structural or institutional stigma refers to macroscopic patterns of discrimination toward those with substance misuse that cannot be explained at the individual psychological level alone. This kind of stigma can be either intentional or unintentional [16]. Intentional stigma refers to the rules, policies, and procedures of private and public organizations and structures with power that consciously and purposely restrict rights and opportunities of the stigmatized group. Intentional structural stigma toward addiction would include laws and tax codes that provide inadequate levels of funding for addictions treatment compared to other health conditions or harsher sentencing laws for crack cocaine versus powder cocaine. In contrast, unintentional stigma refers to instances where rules, policies, or procedures result in discrimination, seemingly without the conscious prejudicial efforts of a powerful few [48]. Examples of unintentional structural stigma might include the lower wages and poorer benefits paid to substance abuse treatment professionals compared to other health care or mental health care workers, thus potentially resulting in poorer quality care. Another potential example of unintentional structural stigma would be the exclusion of substance abuse treatment benefits from the Mental Health Parity Act of 1997, resulting in less accessibility of addiction treatment services. This exclusion continued until 2008, when the Mental Health Parity Act of 2008 included substance use disorders.

It is conceivable that prevalent negative attitudes toward substance abuse might contribute to institutional practices that typify structural stigma. For example, prevalent attitudes that people who are addicted to substances are blameworthy and not likely to recover from addiction might make it less likely that the public would be supportive of spending a portion of their tax dollars on treatment. This phenomenon has been witnessed in a German sample who reported that during periods of economic difficulty, they would be prefer to cut funding for mental illness and addiction treatment before cutting funding for physical problems [119].

At the individual level, stigma can be broken down into two types [21, 78], public stigma and self-stigma. The most obvious form of stigma is public stigma, which refers to the reaction the general public has toward the stigmatized group. This includes stereotypes and attitudes toward the stigmatized group, as well as acts of discrimination, termed enacted stigma. For example, rejection by a friend following discovery of a person's substance abuse history, denial of a job opportunity because an employer suspects an applicant is in recovery, or disparaging remarks about people with addictive disorders would all be examples of enacted stigma. People abusing substances and those in recovery frequently encounter enacted stigma [1, 78]. Enacted stigma has been clearly associated with a number of adverse outcomes in mentally ill populations [68, 94, 97, 98, 100]. Though data demonstrating direct links between encounters with enacted stigma and negative outcomes are less available in substance-misusing populations, data showing more negative social attitudes toward substance abusers than those diagnosed with schizophrenia [15, 18, 22, 73] suggest that enacted stigma is even more severe toward those abusing substances.

The second type of individual level stigma is that of self-stigma, which refers to difficult thoughts and feelings (e.g., shame, negative self-evaluative thoughts, fear of enacted stigma) that emerge from identification with a stigmatized group and their resulting behavioral impact [78]. For example, a person with substance abuse problems or a person in recovery might avoid treatment, not apply for jobs, or avoid intimate social relationships because, as a result of self-stigma, they no longer trust themselves to fulfill these roles or fear rejection based on their substance-using identity. Among populations with serious mental illness and dual diagnoses, self-stigma has been associated with delays in treatment seeking [64, 117, 129], diminished self-esteem and self-efficacy [20, 74, 145], and lower quality of life [112].

Perceived stigma is a component of self-stigma and refers to beliefs among members of a stigmatized group about the level of public stigma in society (cf. [68]). A result of perceived stigma may be that people may limit their actions (e.g., seeking treatment or acknowledging their own struggles with recovery) in an attempt to avoid stigmatization. Some data are available showing that perceived stigma may serve as a barrier to treatment adherence, at least in some groups [126]. At least one cross-sectional study of stigma in addiction [78] has generated empirical support for the conceptual distinctions between public, perceived, and self-stigma.

The Need to Study Stigma in Context

Despite the volume of available research on stereotyping, prejudice, discrimination, scapegoating, social categorization, and social deviance, the amount of stigma literature relating these processes specifically to substance abuse is quite sparse. Ahern [1] has suggested that this hole in the literature may result from the common perception that stigma and discrimination against drug users serves to deter drug use and that the possible negative effects of stigma are relatively minor compared to the deterrent value of stigmatization. A substantial body of literature from a law enforcement and criminal justice perspective views stigma as a positive form of social control which discourages illegal activity [11]. This literature largely ignores the potential negative effects of stigma. In contrast, most of the professional literature from mental health and recovery perspectives views stigma as negative and in need of reduction [111]. This literature seems largely to ignore the possibility that stigma might have beneficial effects in some contexts. Each of these perspectives seems to minimize the importance of context and neither seems to acknowledge the possibility that stigma may have both beneficial and harmful effects depending upon the context in which it is found.

A comprehensive scientific approach to stigma would involve examination of the phenomenon across the myriad of situations in which it occurs. Stigma is a complex phenomenon with many forms and widely varying impacts on the individual. Prior to initial drug use and throughout the developmental trajectory for addition and recovery, stigma may have various possible functions. For example, stigma may affect some who are currently not using drugs by dissuading them from initial use. On the other hand, those who identify with marginalized populations may actually be attracted to drug use because of its marginalized status. Once a person has bypassed barriers to initial drug use, stigma could serve to further reinforce and isolate drug-using subcultures, further supporting consumption. For many, stigma serves as a barrier to entering treatment because of fear of being labeled and stigmatized by others. For others, experiences of being stigmatized and judged by others once drug use is discovered or labeled as problematic might serve as a motivator for treatment entry. The effects of stigma might change again after a person enters treatment. Those experiencing more self-stigma or who are more fearful of enacted stigma may stay in treatment for longer periods of time, perhaps benefiting more from treatment. On the other hand,

the impact of self-stigma may impede recovery by reducing substance abusers' motivation and creating negative beliefs about their ability to recover, resulting in earlier relapse. Some people may be relatively unaffected by stigma, perhaps because of personal conditions which help guard against its impact (e.g., financial resources), or because they do not identify with a stigmatized group. Finally, ongoing experiences of stigma-related rejection may serve as a barrier to reengagement with healthy, non-drug-using social relationships, returning to work, or obtaining a reasonable living arrangement. This array of possibilities suggests that simple judgments about the goodness or badness of stigma may be insufficient in understanding the role of stigma in initial drug use, the development of addiction, and recovery from substance abuse. Given the potential complexities, we need a contextually situated approach to examining the effects of stigma on drug use and related outcomes in order to maximally benefit all involved.

Straying from the hypothetical scenarios described in the above paragraph, a study by Farrimond [32] nicely demonstrates the contextual nature of stigma's impact. Qualitative analyses of reports from tobacco smokers in the United Kingdom showed that smokers from lower socio-economic status groups were more likely to internalize smoking related stigma and feel badly about themselves for smoking, rather than change their behavior to avoid it. In contrast, smokers from higher socio-economic status groups were less likely to internalize smoking related stigma and were more likely to have the resources to change their behavior to avoid being stigmatized. The authors suggested that this finding was a partial explanation for the much higher rates of smoking found in lower socio-economic status groups. They hypothesized that broad-scale campaigns to stigmatize smokers might reduce smoking in higher socio-economic status brackets who would work to avoid it, whereas those in lower socio-economic status may not be responsive, and furthermore, that such campaigns may even impede efforts to stop smoking because of increased internalized stigma. They argued that intervention efforts promoting stigma could actually exacerbate disparities already present between higher and lower status groups.

Thus far, this chapter has outlined the nature of stigma in general, including its types and levels. It has outlined how stigma is a complex phenomenon, the effects of which vary by context. The remainder of this text is more focused specifically on what is known about the stigma of substance abuse specifically, describing its importance for those individuals with substance abuse problems, information about stigma in families and social networks of those with addiction, stigma in the treatment system, and interventions to change stigma.

The Impact of Stigma on Individuals with Substance Abuse Problems

Self-Stigma

The psychological impact of stigma on the individual can be described under the term self-stigma. Self-stigma can be defined as shame, evaluative thoughts, and fear of enacted stigma that results from an individual's identification with a stigmatized group and serves as a barrier to the pursuit of valued life goals [77]. The dominant stereotypes about stigmatized groups are widely known in a given culture. Self-stigma comes about when a person first sees himself or herself as a member of a stigmatized group; now the negative stereotypes and biases of society that used to be about someone else apply to the self. For example, at the point when the person who misuses substances identifies himself or herself with the category "addict," relevant stereotypes (e.g., "addicts are irresponsible") that once applied to another now apply to himself or herself. To the extent that people believe this stereotype, they are likely to impede their own chances for success, for example, by not applying to jobs that would require them to be responsible. As the dominant stereotypes of marginalized groups are largely negative and

devaluing, self-stigma may further increase the shame that often comes with addictive behavior that violates important societal and personal values and norms.

A second component of self-stigma is the fear of enacted stigma. Out of this fear of being the target of stigma a person might avoid treatment in the first place or might not get needed social support that could come from disclosing their concerns to trustworthy others. People with substance abuse widely report fear of stigma as a reason for avoiding treatment [23, 50, 62, 136, 137]. Less evidence is available for other effects of self-stigma in addiction, but self-stigma in mental illness has been associated with delays in treatment seeking [64, 117, 129], diminished self-esteem/self-efficacy [20, 75, 145], lower quality of life [112], early dropout from treatment [126], poorer social functioning over time [99], and increased depression at follow-up [109].

Coping and Self-Stigma

Much of the harm of self-stigma comes not only from the presence of shame, painful self-evaluations, or fear of stigmatization, but also from understandable yet costly attempts to cope with these difficult thoughts and feelings. For example, when people who identify with a stigmatized group enter situations where they perceive the potential for devaluation based on this identity [130], they often expend energy searching for and defending against this perceived threat. The effort is taxing and distracts the individual in ways which might hinder social or intellectual performance. In a recent test of this idea, Quinn et al. [104] found that individuals with a history of mental illness who revealed this history prior to taking an intelligence test had poorer performance compared to a control group who did not relate their history of mental illness. These results are in line with more general findings on stereotype threat, that is, that people perform more poorly in situations where a specific stereotype about the group of which they are a member applies [130]. Specifically in relation to substance abuse stigma, these findings suggest that when people with a history of substance abuse problems are in a situation in which addiction-related stereotypes might apply, they may perform more poorly than they would in situations unrelated to addiction-related stigma.

People also cope with stigma by withdrawing their efforts from or disengaging their self-esteem from domains in which one's in-group is negatively stereotyped or in which they fear being a target of discrimination. In an attempt to cope with the potential judgment, failure, or shame that might result from "confirming" a stereotype, a person may exert less effort in domains of living that relate to relevant stereotypes [81]. For example, a person who identifies with the stereotype that alcoholics are immoral might not engage with spiritual or religious groups out of fear that he or she might be judged by others for their "moral weakness." Unfortunately, when a domain is one that might be part of living well (e.g., a steady job) and is likely to elicit thoughts of common stereotypes (e.g., "they won't hire an addict"), then disengagement from that domain (e.g., not looking for work) is likely to interfere with recovery.

Whether a stigmatizing mark can be concealed is also a relevant variable to how people cope. For example, some stigmas may be relatively concealable, such as a past felony conviction or a history of depression, while others may be quite difficult to conceal, such as obesity or diseases with obvious physical characteristics. For many people with substance abuse problems, their condition is concealable, while for others it is less so. Another way to think about concealable stigma is the distinction between "discredited" versus "discreditable" individuals [38]. For individuals with a concealable stigma, a common occurrence is deciding with whom, where, and when to disclose the stigmatizing identity. Whether disclosing a stigmatizing identity is helpful or harmful is likely to be highly dependent on context [29]. In some cases, through disclosing a stigma a person may be able to obtain social support or direct assistance from treatment agencies or health care professionals. Revealing a secret to a trusted confidant has

also been shown to be related to a number of psychological benefits, including improved psychological and physical health [59, 110]. On the other hand, disclosure of a stigma could result in social rejection and isolation, the loss of a job, rejection by family members, judgment from treatment professionals, or disappointment that others were not more helpful. Research on secrecy as a method for coping with the stigma of addiction is relatively scarce and what exists is somewhat crude, typically examining secrecy as a generalized tendency in response to the fear of stigma, rather than examining the patterns of disclosure and how they might interact with social context. As a general rule, the use of secrecy and withdrawal from others as a coping mechanism has been associated with negative psychosocial outcomes [1, 71, 78, 114]. However, this general pattern should not be overgeneralized as a recent large study of mostly minority drug users [1] found that talking with friends and family about being stigmatized and judged was associated with poorer health outcomes. One difference between the Ahern study and other studies of stigma was that Ahern specifically focused on discussions of being stigmatized, whereas most other studies examined the tendency to keep substance use a secret. This suggests that the content of what is disclosed may also affect the likelihood of a positive outcome from disclosure.

All of the coping processes described above (i.e., searching for potential threats, withdrawing efforts from valued domains, and secrecy) could be seen as forms of a broader process termed experiential avoidance. Experiential avoidance refers to the attempt to avoid, control, or reduce the frequency of difficult or painful emotions, thoughts, memories, or other private experiences [44]. Experiential avoidance overlaps with several closely related concepts, including lack of distress tolerance [9], cognitive and emotional suppression [140], and emotion/avoidance-focused coping [12]. As a broader pattern, experiential avoidance has been shown to contribute to a wide range of psychological and behavioral problems, including substance abuse, depression, anxiety, psychosis, and burnout among others [44]. Since experiential avoidance has been shown to be modifiable through mindfulness and acceptance based interventions [35, 45, 138], this suggests that teaching mindfulness and acceptance may be helpful in coping with stigma.

Multiple Stigmatized Identities

For a person with substance abuse problems, the stigma of substance abuse is often only one of several stigmatized identities. Each stigmatized identity is layered on top of the other, creating a dense web of ideas about the self that must be managed and responded to depending upon the social and personal context. For example, substance abuse disorders are highly comorbid with other psychiatric disorders, meaning that the majority of people in treatment for drug abuse also have to contend with the stigma of mental illness [30, 60]. Many people in addiction treatment are also sexual or racial minorities. They may have a stigmatized medical condition such as hepatitis or HIV. They are frequently poor or homeless, both situations which carry their own stigma. Women who abuse substances are often assumed to be promiscuous [118]. Many people with substance abuse histories also have had problems with the legal system or have been incarcerated. In addition to the stigmatization that people may experience directly from the legal system, they now have the added stigma of a prior conviction. Each additional stigmatized identity increases the chance of stigmatization. Each layer of stigmatized identity carries its own challenges that make it even harder to cope with the stigma of drug addiction.

In addition to the problem of multiple stigmas, the impact of substance abuse stigma can also compound existing social inequalities. For example, the stigma of substance abuse has disproportionately impacted the African–American community in the United States, whose drug-related incarceration rate far outstrips their comparative prevalence as drug users [141]. As many in treatment for addiction are relatively poorer, the stigma of drug abuse that tends to fall on those in treatment will also tend to further reduce

the life chances available to those who are experiencing poverty [32]. Again, in addition to the direct effects of the stigma of addiction, stigma also tends to exacerbate the effects of already existing prejudice, marginalization, and disadvantage based on other identities.

Stigmatizing Attitudes and Behavior of Friends and Family

Supportive, cohesive, and non-critical social networks predict good outcomes in addictions treatment [31, 89, 93], while conflict with several members of a social support network, interpersonal conflict, and isolation predict poor treatment outcomes [89, 90]. People entering treatment for addictive disorders are often marginalized, with few connections to family, friends, or coworkers. Entering treatment may be a marker for having exhausted their "moral credit" with employers and families [111]. Stigma may contribute to poorer outcomes by further contributing to the disruption of social ties and increasing isolation beyond the problems created through the direct impact of addictive behavior. Some data are available that bear directly on this point. A recent study of primarily minority drug users [1] found that discrimination and stigmatizing interactions from family and friends was common and independently associated with poorer mental and physical health.

Stigma appears to degrade social networks over time. In one longitudinal study of people with mental illness, many of whom also abused substances [70], perceptions of stigma were associated with reduction in support from non-household relatives over time. Stigmatizing attitudes and behavior of friends and family may also reduce treatment adherence. A recent study of individuals taking antidepressants for depression [121] found that stigmatizing caregiver attitudes predicted premature discontinuation of treatment.

Family members of substance abusers may also suffer from "courtesy stigma." Courtesy stigma refers to the tendency to devalue and stigmatize people who maintain or enter relationships with those in the stigmatized group [38]. For example, in a study by Barton [3], parents of adolescents who abused drugs reported that neighborhood children were told to stay away from their child, resulting not only in isolation for the child but also feelings of shame for the parents. Parents of substance-abusing adolescents also experienced shaming interactions when dealing with institutions such as schools, police, and the legal system. Courtesy stigma may disrupt social cohesion through contributing to struggles inside families that have a member who abuses substances. Family members may attempt to distance themselves from a substance-abusing family member in order to distance themselves from courtesy stigma and the shame that can accompany it. It may be the case that much of the behavior described in the literature as "enabling" or "co-dependent" may result from the family's attempt to avoid the shame of stigma [34] and maintain its identity as a "normal" family.

Stigma in Treatment Settings

Stigma as a Barrier to Initial Treatment Engagement

The public health implications of untreated substance abuse and dependence are enormous. Despite the proven benefits of substance abuse treatment, only a small fraction of those who could benefit ever enter treatment. In 2005, only about 2.3 million of an estimated 23.2 million Americans with substance abuse problems received some form of treatment [115]. Barriers to treatment entry are structural (e.g., location of facilities, lack of qualified personnel, lack of funding), and social (e.g., fear of stigma among those with substance misuse). Stigma contributes to structural barriers when people resist having substance abuse treatment facilities placed in their neighborhoods [6], thus limiting access to treatment. This is important since a having to travel a longer distance to obtain addictions treatment has been associated with poorer

retention [4]. The public is less interested in funding substance abuse treatment compared to other health or mental health problems [119], contributing to long waiting lists and prohibitive cost for treatment. Stressful job conditions result in high rates of burnout and job turnover in addictions professionals [61], resulting in less experienced counselors and less integrated, cohesive treatment centers.

Among the social barriers to treatment entry for addiction, probably the most common barrier cited in the literature is stigma [2, 23, 50, 62, 118, 136]. Across numerous studies, substance-abusing individuals report fear of stigma as a reason for not seeking treatment [23, 50, 62, 136, 137]. For example, Cunningham et al. [23] examined reasons for delaying or not seeking treatment among people with alcohol abuse problems who either self-changed and were in sustained recovery, were still actively abusing, or were currently in treatment. They found that people who were either actively using or self-changed saw treatment as stigmatizing, wanted to avoid the stigma of the label "alcoholic," and reported that embarrassment and pride were barriers to seeking treatment. All three groups reported relatively similar reasons for avoiding treatment, leaving the authors to conclude that "current treatment is stigmatizing and that some alcohol abusers believe that seeking treatment would reflect negatively on them" (p. 352). A study of depressed individuals in Australia found it common to fear that others would think less of them for seeking help and that professionals would respond to them in a condescending manner [2].

Stigma and Treatment Retention and Outcome

For those who are able to overcome barriers and enter treatment, the most stable predictor of positive outcome is length of time in treatment, with studies commonly finding rates of dropout in the first month of outpatient and residential treatment exceeding 50% [53, 54, 124, 125]. Early treatment retention is critical, as data show that early dropouts have equivalent outcomes to those who are untreated [128], and that more time in treatment is related to better outcomes [24, 55, 123]. Unfortunately, stigma doesn't only serve as a barrier to treatment entry; stigma also appears to increase when individuals enter treatment, possibly contributing to poorer retention and thus poorer outcomes [53, 122, 128]. Link and colleagues' [70] modified labeling theory of stigma in mental illness holds that stigma begins to impact people once they have officially received a label from the treatment establishment. A relatively large body of data on seriously mentally ill and dually diagnosed populations supports the hypothesis that entering treatment for a stigmatized condition can result in a labeling process that negatively impacts people's engagement with treatment, psychosocial functioning, and self-concept [20, 74, 145].

The data on such a stigma-labeling process are less developed in the area of addiction, but some direct data are available to support this view. For example, Semple et al. [120] found that methamphetamine abusers who had previously been in treatment reported higher levels of stigma-related rejection than those who had never been in treatment. Another survey of people in treatment for substance abuse [78] found that people with higher levels of current stigma-related rejection had more previous episodes of treatment and that this relationship remained stable even after controlling for other explanatory variables, such as current severity of addiction, demographics, secrecy coping, and current mental health. While this evidence suggests that the impact of stigma and the rate of contact with stigmatizing experiences may increase with treatment entry, we know little about how this happens. For example, we know little about whether stigmatizing messages and rejecting experiences primarily come from non-family social relationships, close family, employers, media, or treatment staff. Moreover, we do not know if certain sources have greater impacts than others, or whether the impact is different for those new to treatment versus those returning to treatment.

Stigmatizing Attitudes and Behavior of Professional Staff

The therapeutic alliance early in counseling has been shown to be a predictor of engagement and retention in substance abuse treatment [88]. Other data show that negative therapeutic alliances predict deterioration in substance abuse treatment [43]. Thus, any actions on the part of substance abuse treatment practitioners that harm the therapeutic alliance are likely to negatively impact retention and treatment outcome among their clients. Health professionals, including addiction counselors, nurses, physicians, and support staff, have been exposed to the same cultural environment that instills stereotyped beliefs in other people. Thus, whether they are aware of it or not, providers likely have internalized many of the same stigmatizing beliefs about substance abuse as others in society. Research shows that health professionals often have moralistic, negative, and stigmatizing attitudes toward substance misuse and believe that substance-abusing individuals are unlikely to recover [86, 89, 108]. For example, one study of mental health support workers in the UK found that alcohol and drug addiction produced more negative responses to an attitude questionnaire than did other problems or mental illness and that those with alcohol and drug problems were mostly likely to be seen as unable to improve if treated [134].

To the extent that stigmatizing attitudes are expressed by providers, they could negatively impact the alliance, thereby reducing retention and creating poorer outcomes. Similarly, support and non-treatment staff could potentially create a hostile atmosphere for clients, further contributing to reduced retention. Because stigmatizing attitudes tend to have a greater impact in situations in which one group has power over another [72], stigmatizing beliefs among healthcare providers may be particularly likely to negatively affect the recovery of those they are trying to help [8]. Some evidence suggests that stigmatizing interactions with providers may be more frequent than expected: one study of methamphetamine abusers found clients' inability to get along with treatment staff was a major reason for dropout [120], while two surveys of consumers of mental health services found that 19% [27] and 25% [139] of consumers had experienced stigmatizing provider behavior. Data from a qualitative study of alcohol and drug abuse counselors found that counselors largely saw illicit drug use as a failing of the individual that needed to be "fixed" with drug treatment rather than seeing the larger context which includes such factors as stigma. In this study, while counselors were generally aware that stigma serves as a barrier to drug treatment, they "did not perceive they as individuals and as treatment workers could perpetuate the same barriers and prejudices" [135] (p. 378).

Interventions to Reduce Stigma

While a large literature on the nature of stigma exists, research on how to change stigma or how to help people with stigma is much more limited [11]. Interventions can target either public or self-stigma and can vary from large-scale interventions targeting the general public to focused interventions targeting high risk or identified target populations.

Reducing Public Stigma

A number of kinds of interventions for reducing stigma in the general public have been proposed and researched. Corrigan et al. [17] proposed three strategies derived from social psychology theory for changing public mental illness stigma that could also be applied to substance abuse stigma: education, contact, and protest. Each of these approaches is reviewed below.

Educational approaches aim to provide new information about a stigmatized group and dispel negative stereotypes. Nearly all the research on education as a stigma reduction method involves mental illness rather than substance abuse

stigma. Cross-sectional research has shown that those who are more knowledgeable about mental illness are less likely to exhibit stigmatizing attitudes [68, 69]. Whether this indicates that people who are less stigmatizing are more open to learning about mental illness, or whether education reduced stigma is unclear. A number of studies have shown short-term improvements in attitudes toward stigmatized groups as a result of educational interventions [17, 19, 58, 92, 96], though results are sometimes inconsistent [52], and studies have generally lacked follow-up assessments. One study that did have a follow-up showed that initial positive results were not maintained [19]. Haghighat [39] has suggested that these positive results might be a product of social desirability rather than true attitude changes. Other data suggest that education may serve to increase positive attitudes among those who already exhibit positive attitudes but may not impact those with negative attitudes or may even reinforce preexisting negative biases [7].

Recently, researchers have also begun to pay attention to the content of educational interventions for stigma reduction, especially the effects of characterizing psychiatric symptoms as caused by psychosocial events versus a disease of the brain with biological, genetic, or structural abnormalities. In general, data are not very supportive for the effectiveness of a biological/genetic message as a method for reducing stigma, and some data suggest that it may actually increase stigma. The one exception is that a biological/genetic message has sometimes been shown to reduce blame toward those with mental illness for causing their own problems, which was found in two studies [67, 87] but not in a third [102]. One of these same studies showed that while a disease explanation reduced blame, it actually provoked *harsher* behavior toward a person described as mentally ill versus a psychosocial explanation [87]. Another experimental study showed that a biological explanation resulted in a less hopeful expectation of improvement [67]. Extensive correlational research shows that genetic or biological explanations for mental illness and diagnostic labeling are related to greater perceptions of dangerousness, desire for distance, and prediction of poor prognosis [102, 106, 107]. For example, surveys in the United States from 1950 and 1996 showed both an increased likelihood to view mental illness as having a biological cause and also to believe that those with mental illness are dangerous [103]. In contrast, data are more reliably supportive of interventions presenting psychiatric symptoms as understandable reactions to life events (i.e., psychosocial explanations). Psychosocial explanations of mental illness have also been related to more positive attitudes toward mental illness in correlational studies [107]. Interventions promoting a psychosocial explanation have resulted in a reduction in fear of dangerousness, desire for social distance, and other negative attitudes [67, 82, 91, 92], though the impact has sometimes been found to vary by target group [67], and these results have not been assessed for their long-term effects. In sum, while a small sample of data suggests that a brain disease message may reduce blame, the preponderance of existing data supports the idea that describing mental illness as a brain disease is not likely to improve stigma on a broad scale and may even lead to increased stigma of some kinds. At the current time, promoting a brain disease message as a stigma reduction method could not be considered an evidence-based practice, while promoting psychosocial explanations for mental illness appears to be promising, at least in these preliminary studies.

While the data indicate that educational interventions based on efforts to characterize mental illness as a brain disease are not likely to reduce stigma, these results do not mean that more complex and nuanced approaches to stigma education that emphasize both biological and psychosocial causes, such as diathesis-stress models, might not be effective. In addition, it remains unknown whether current findings will reliably generalize to the stigma of addiction. It may also be the case that there has been an overemphasis on educational approaches predicated on the idea of information provision as a primary method for stigma reduction and that information provision is simply not a very effective way to change

entrenched attitudes. Other types of interventions based on models other than information provision may be more effective in reducing stigma. Some of these models are explored in more detail below.

The second category of interventions, protest, involves attempting to suppress negative attitudes and representations of a stigmatized group through disputing the morality of holding and expressing such views or through threatening a boycott of a company's products. Research on thought suppression suggests that attempting to suppress or avoid unwanted thoughts can result in paradoxical increases in those very thoughts [140]. People who are asked to suppress thoughts about stereotyped groups can actually become more sensitized to them, resulting in unwanted intrusions of thoughts about that group and more behavioral avoidance of the stigmatized group [79]. Creating conditions that demand correct behaviors (e.g., "do not stare at the physically disabled") can also increase the physical avoidance of stigmatized persons [65]. As suggested by this basic research, most studies of protest strategies targeting attitude and behavior change in individuals have shown it to be inert [17]. In contrast, some anecdotal reports of the use of protest strategies, such as letter writing campaigns or product boycotts to get companies to remove or correct stigmatizing portrayals of mentally ill individuals in the media, have reported some success [13]. In sum, systematic confrontation and protest targeting the stigmatizing behavior of individual persons seems to be largely ineffective and may even exacerbate stigma. On the other hand, the effects of targeting corporations or organizations with organized protest campaigns have not been systematically evaluated.

Finally, contact strategies attempt to change attitudes toward stigmatized groups by creating positive social contact between members of the stigmatized group and the public. Research has shown that people who have more contact with mentally ill individuals endorse less stigma [69, 95, 96], though it is unclear whether contact with mentally ill individuals decreases stigma or whether those with lower levels of stigma are more likely to seek contact. Contact as a strategy for reducing prejudice has long been known to be successful in research on racial prejudice [101]. Interventions based on contact have been the most consistently successful at reducing negative attitudes toward the mentally ill [17, 19], generating at least some maintenance of attitude change over time and impact on related overt behavior. The limits and exportability of this approach are still somewhat unknown as past research has shown that there are a number of situational constraints that can make this approach difficult to implement in real world settings [14]. Specifically, as this approach does not appear to have been tested in stigma reduction with those with substance abuse or in recovery, its putative efficacy in that area remains hypothetical.

The lack of research on stigma reduction strategies in addiction may have to do with conflicting societal views about the usefulness and moral correctness of stigma toward substance use and substance users. In contrast with mental illness where few would argue in support of stigma, there are vocal proponents of actively stigmatizing drug use and drug users [116]. Some large-scale drug prevention programs, such as the Montana Meth Project, which uses advertisements featuring dramatic and often violent depictions of problem drug use, appear actively designed to stigmatize drug users. The Montana program appears to be focused largely on preventing initial drug use and some evidence suggests that this program may be effective in that aim [57]. However, as is common in the criminal justice literature, the potential impact of this campaign on those who are currently using illicit drugs or attempting to recover appears unexamined. Thus, while these types of approaches may reduce initial drug use through increasing stigma, they may have the unintended effect of compounding stigma toward and among those who do become addicted, though further research is needed to examine this question. Thus, the overall public health impact of campaigns such as the Montana Meth Project may be negative, despite the possible reduction in rates of initial drug use that may result from these stigmatization-focused programs.

Reducing Stigma in the Health Care System

Since stigma appears to increase after the person has entered the treatment system and has been labeled as a substance abuser, then it would make sense that interventions targeting the health care system and the process of entry into treatment might be particularly important in reducing the impact of stigma on those attempting to recover from drug addiction. Thus, interventions targeting the prevalent stigmatizing attitudes and behaviors of health care providers and professional staff or focusing on changing organizational structures or admissions procedures might have promise in improving treatment engagement or retention. In targeting stigma in addictions specialty providers, programs designed to provide direct education about stigmatized groups or to promote contact with those in the stigmatized group do not seem very relevant since addictions professionals already know vastly more about these topics than do average persons and have also had a great deal of contact. As protest has not shown much promise, other interventions are needed.

One alternative intervention that has been studied is the use of mindfulness, acceptance, and values processes derived from Acceptance and Commitment Therapy [42]. Acceptance and Commitment Therapy as applied to stigma in addictions professionals focuses on promoting psychological acceptance of difficult thoughts and feelings that come with working with difficult clients (i.e., those most likely to be stigmatized), reducing the behavior regulating impact of the literal content of stigmatizing and evaluative thoughts (e.g., "This client is hopeless"), and helping clinicians to contact the values they bring to their work so that these values can better guide their behavior. In one pilot study of this approach [42], 90 licensed or certified alcohol and drug abuse counselors were randomly assigned to 1-day workshops based on Acceptance and Commitment Training ($N = 30$), Multicultural Training ($N = 30$), or a control lecture about methamphetamine and MDA interventions. Stigmatizing attitudes were reduced post-training in both active treatment groups, but only the Acceptance and Commitment Therapy condition generated lower stigmatizing attitudes at the 3-month follow-up. An additional benefit of the Acceptance and Commitment Therapy intervention is that it decreased burnout at the 3-month follow-up, suggesting that interventions targeting stigma in providers may also have the effect of reducing burnout.

Organizational interventions might also be useful in identifying and remediating stigmatizing policies and procedures. For example, an admission process walk-through [33] might be used to examine whether stigmatizing messages or behaviors occur during initial treatment engagement. These stigmatizing messages might range from the more overt (e.g., telling a client they are hopeless) to more subtle (e.g., therapists telling jokes about "addicts"). Admission walk-throughs could identify stigmatizing interactions that happen during potential client's first contacts with the treatment system and options for remediating these problematic interactions. The overall goal of a walk-through exercise is to identify problematic processes and improve service delivery by allowing providers and those in charge of the system of care to understand what it is like to enter the treatment system [33]. Other organizational and quality improvement interventions might also be adapted to target organizational change relating to stigma.

Empowering Those in Recovery

Another way to help participants in the addictions treatment system is to empower them to overcome the negative evaluative thoughts, shame, and fear of enacted stigma that are part of self-stigma. For substance abuse related stigma, an uncontrolled pilot study targeting self-stigma with Acceptance and Commitment Therapy [78] showed promising outcomes with medium to large effects across a number of variables at

post-treatment. However, the intervention was delivered along with concurrent treatment, making it difficult to rule out the possibility the observed effects were not simply the result of concurrent treatment. Other studies that have examined interventions for self-stigma in mental illness might provide some guidance for developing interventions for self-stigma in addiction.

One aspect of self-stigma is the way that fear of enacted stigma can impede recovery. One study tested an intervention that consisted of education about stigma, discussion of methods to combat and cope with stigma, and discussion about personal experiences of stigma that focused more on coping with enacted stigma than on other aspects of self-stigma. In this study, rehabilitation clubhouse members ($N = 88$) were randomly assigned to either 16 group sessions of the stigma intervention or no treatment. At a 6-month follow-up the intervention group was not significantly different from controls on any measure.

Knight et al. [63] compared a six-session group intervention based on cognitive behavioral therapy to a waitlist. The cognitive behavioral therapy intervention was developed primarily from existing manuals on the group treatment of auditory hallucinations and the group treatment of poor self-esteem. At post-treatment, effects were seen for measures of psychopathology and self-esteem, with these effects mostly maintained through follow-up. However, no effects were seen on stigma coping or empowerment measures, making it less clear whether the effects were more general therapeutic effects or had any specific impact on self-stigma.

Another group intervention for mental illness examined the impact of a 12-session group intervention (1.5 h per group) that focused on helping individuals with first-episode psychosis to maintain an identity distinct from mental illness, promote hopefulness, minimize the impact of stigma, and help them to embrace a healthy sense of self [84]. Results of this randomized trial, comparing treatment as usual to treatment as usual plus the stigma intervention, showed that at post-treatment, the group that received the experimental intervention had improved scores on a measure of self-stigma, hopefulness, and quality of life, but not on several other scales [85]. A previous pilot study of the same intervention also showed an impact on a measure of self-stigma that the investigators termed engulfment, which refers to the tendency to allow illness and its associated stigma to entirely define the self-concept [84].

In summary, there exist a number of promising interventions for self-stigma, with some mixed findings regarding the specificity of their effects. Now that some interventions have begun to show promising effects on stigma and related variables, future research needs to focus more on testing of specific models of change.

Stigma and the Emotion of Shame

Both of the definitions of stigma and most of the research on stigma ignore the emotional responses that are entailed in this phenomenon [76] such as guilt, disgust, anger, and, most prominently, shame. Recently, several prominent stigma researchers called for more research into the relationship between stigma and shame [113]. Much of what has been described as characteristic of the personal experience of being stigmatized has also been described in the literature on the emotion of shame. For example, shame has been defined as an experience of "self as flawed and undesirable in the eyes of others" [37, 133], which is similar to Goffman's [38], idea of stigma as an "attribute that is deeply discrediting" that reduces a person "from a whole and usual person to a tainted, discounted one" (p. 3). Shame is often elicited in social contexts and is associated with thoughts that one is seen as inferior or that others are condemning the self [37]. Similarly, in self-stigma people are fearful of being condemned, stigmatized, or judged by others because of their member in the stigmatized group. Shame is also associated with cultural values, meaning that what is shameful varies according to the standards and ideals of a particular culture [66] as is what is stigmatized varies across cultures.

Shame has been called a "moral emotion" [132], in that it is seen as relating to transgressions of the norms and values of a society. While most authors agree that shame is a highly socially based emotion, substantial disagreement exists as to the usefulness of shame in regulating human behavior. Some authors see shame as a largely maladaptive, negative emotion, with little useful function [133]. Following similar reasoning, some therapy developers have suggested that shame should be directly targeted using shame reduction strategies [25, 142]. Other authors have suggested that shame may serve a valuable function in regulating people's behavior through limiting deviations from accepted norms [28]. As shame can also arise when people violate their own standards and values, shame may have a role in alerting people to important deviations from their own values or self-standards [83] so that they can self-correct their behavior. Seen through this lens, attempts to directly reduce shame during treatment may actually feed the addictive cycle [77] by allowing people to continue deviant behavior or violate self-standards and values [36] without feeling the shame that would ordinarily attend those actions. At least one study [78] specifically targeted the experience of shame in addiction and showed that it could be reduced through treatment. However, in this study, while shame was reduced at post-treatment, the target of the intervention was not the reduction of shame, but rather increasing acceptance of the feeling of shame and mindfulness of stigmatizing thoughts and evaluations. Thus, it may not be as helpful to try to reduce shame directly, but rather to help people change their psychological relationship to shame, so that they are more mindful and accepting of the experience.

As discussed above in reference to stigma, the context in which shame is experienced is probably extremely important in understanding its function and usefulness. In some contexts, shame may be an adaptive, though painful, emotion that highlights deviations from important values or self-standards, whereas in other contexts, shame may simply be excessive and serve no useful function. The debate over whether shame is a maladaptive or adaptive emotion will likely be resolved when more attention is paid to the specific social and psychological contexts in which shame is experienced and how people cope with and respond to shame.

Conclusions

Stigma operates at many levels. Self-stigma works within the individual to impede recovery. Structural stigma operates through the formal and informal policies and procedures of the health care and legal systems. Enacted stigma is expressed in the negative attitudes and behavior of the public. Courtesy stigma extends the impact of stigma to families and to addictions treatment professionals who are paid more poorly than those in other health care fields [51]. Furthermore, the stigma of substance abuse falls disproportionately on those who already experience greater societal injustice, such as racial and sexual minorities and those living in poverty, and who, as a result, have been denied many life opportunities. Stigma is such a broad, pervasive process that it is difficult to characterize its full impact, with any one study only able to document a small portion of its effects. Only by taking an expansive view and appreciating the effects of stigma across many contexts can we begin to see the tremendous cost of this process to the people struggling with drug and alcohol addiction and to society in general.

A broad and pervasive problem like stigma merits a comprehensive and systematic solution. Currently, research and theorizing about the impact of stigma in addiction is in its infancy. We know even less about how to reduce the burden of stigma on those who are attempting to recover from a life damaged by addiction. Anyone who has ever worked with addiction has seen its devastating effects on the lives of individuals and the immense struggle involved in living even a single day clean and sober. People attempting to climb the mountain of recovery do not need the additional burden of stigma, as their road is hard enough.

Religiousness, Spirituality, and Addiction: An Evidence-Based Review

J. Scott Tonigan and Alyssa A. Forcehimes

Contents

Introduction

The 12-step model to the treatment of addiction is the most popular therapeutic model in the United States, and most adherents of the 12-step approach consider spiritual growth singular with recovery. This chapter offers a critical review and discussion of spirituality and religiousness as it has been investigated in the empirical literature on addiction. Curiously, while the 12-step model has been reported to produce relatively equivalent outcomes as more research-based therapies, e.g., cognitive behavioral and motivational enhancement therapies [43, 51], and actually a superior outcome when the treatment goal is total abstinence, the underlying *stated* mechanism of this approach, spirituality, has only begun to be systematically investigated using rigorous methodologies including randomized clinical trials. It is important to acknowledge that non-12 step spiritual and religious approaches also intended to mobilize and sustain addictive behavior change have proliferated in the United States, *regardless* of the presence or absence of empirical support. A cursory Internet search using "alcoholism" and "spirituality" as key words, for example, yielded 944,000 hits. It seems the absence of empirical support for the efficacy of spirituality in reducing substance abuse has hardly impeded its application. Further, referral to Alcoholics Anonymous during and after treatment is the norm in the United States, also regardless of therapeutic orientation of the treatment provider. In this light, the practical issue is not if treatment seeking alcoholics ought to be introduced to spiritual models of recovery. Rather, it is vital that researchers and clinicians have a working knowledge of spiritual approaches to addiction in order to better understand the psychological and

social forces and resources facing prospective clients.

This chapter is organized into three sections. Historical reticence to investigate spirituality and religiosity by addiction researchers stems, in part, from the constructs poorly understood dimensions [20]. The first section of this chapter will therefore offer several working definitions of religiosity and spirituality. These definitions are intimately tied to distinct conceptual models pertaining to the role of spirituality in addiction. These models will be presented and discussed and some attention will then be given to four psychometrically validated measures that are available to clinicians and researchers. The second section of the chapter will advance the orientation that spirituality can be viewed as an outcome, a catalyst or intervention, a moderator, and as a mediational variable; in fact, the construct has been treated in each of these capacities in the empirical literature. A keen awareness of these distinctions is paramount to grasping the implications and avoiding the many pitfalls surrounding the study of alcoholism and spirituality. Third, this chapter will focus on what is currently known about Alcoholics Anonymous-related benefit, the largest and most studied of spiritual interventions. Here, special attention will be given to what is known about the importance of prescribed Alcoholics Anonymous spiritual practices in accounting for reduced drinking. The chapter will conclude with a brief summary.

Several caveats need to be voiced at the beginning of this chapter**.** First, the accelerating nature of empirical research in this area necessarily will result in a somewhat incomplete review. Studies now underway may offer findings that elaborate upon, clarify, or even contradict positions and interpretations offered in this chapter. Related, studies reviewed in this chapter were purposively selected based upon their scientific rigor, not because of the claims and interpretations made by study investigators. In essence, cross-sectional studies purporting to investigate causal temporal relationships were rarely selected for review. Third, it is important to stress the plasticity of spiritual and religious practices and beliefs. An individual rarely is "spiritual" in all situations with all people, nor does evidence indicate that the nature and expression of spirituality remains fixed over time. While this plasticity is obvious and volumes have been written about it, there is a tendency nevertheless to reify spirituality as a trait construct. It is wise to remember that even prophets question, at one time or another, the depth and value of their spiritual and religious beliefs. It is also instructive to remember throughout this chapter that the measurement of this fluid and evolving construct occurred, in general, in research settings. The extent that this context influenced that measurement of spiritual beliefs and practices is unclear but certainly raises concern. Related, the very subjective nature of spiritual and religious beliefs and practices and experiences requires, at this juncture in time and technology, self-report. Legions of studies have investigated the unintended and undetected biases that arise in relation self-report on subjective states. Beyond the scope of this chapter, we recommend that readers consult one of several excellent discussions on the reliability and validity of self-report in the areas of spirituality and religiosity [20].

Section I

Definitions of Religiosity and Spirituality

> Now the whole earth had one language and a common speech. . .let us go down and confuse their language so they will not understand each other. . .That is why it was called Babel—because there the Lord confused the language of the whole world. Genesis 11

The struggle of defining spirituality and religiosity makes it clear how far we've come from a universally understood language. Researchers and practitioners posit opinions on how to define these constructs; the diversity in meanings clearly echoes the confusion, disagreement and lack of productivity described in the book

of Genesis. Zinnbauer and Pargament [64] have aptly called these terms the "definitional tower of Babel." As Zinnbauer and Pargament wrote regarding those in the field who study spirituality and religion, "[We] can agree on one thing: we have never agreed about anything" ([64], p. 4). There is little disagreement that spirituality and religion are constructs deserving of research and clinical attention, but since an important first step in researching a construct is how to operationalize and measure the construct, we begin in a tumultuous place.

Definitions of religion, and particularly spirituality, have changed and evolved over the years. Once representing a single construct, these constructs are now distinct [37] and some would say even incompatible. Spirituality is increasingly defined in contrast to religion rather than as interchangeable terms [64]. The definitions are marked by explicit and implicit philosophical and theological underpinnings, and thus remain vulnerable to claims that the definitions are either too broad or too narrow. Koenig [27] described religion as an expression that is institutional, formal, outward, doctrinal, authoritarian and inhibiting, and spirituality as an expression that is individual, subjective, emotional, inward, unsystematic and freeing. Pargament [46] reported that religion is moving "from a broadband construct—one that includes both the institutional and the individual, and the good and the bad—to a narrowband institutional construct that restricts and inhibits human potential." (p. 3). Apparent in the polarization of these two constructs is an underlying message is an exaltation of spirituality and a condemnation of religion.

It is common for scholars to begin manuscripts with caveats of the difficulty in defining these terms, discuss the divergent definitions, and then provide an entirely new definition all together. Other researchers approach the complexity by simply avoiding a definition; instead asking questions such as "do you consider yourself spiritual?" or "how important is religion in your life?" [35] While results from questions such as these contribute to our understanding of the perceived importance of religiosity and spirituality and other variables, this approach is limited in terms of not furthering our understanding of how these terms are uniquely understood and defined by participants.

It is evident that defining these constructs is difficult; however, research evidence supports the usefulness of this pursuit because of the clear connection between spirituality and religion and mental health [31]. In a recent review [30] of longitudinal studies, increased spirituality and religion seem to consistently promote a longer, happier life. For individuals suffering with mental or physical health problems, spirituality and religion enhance pain management, improve surgical outcomes, protect against depression, and provide coping resources, and reduce the risk of suicide. While religion and spirituality are relevant to many problems dealt with by practitioners and there is a consistent link between spirituality/religiousness and physical and psychological well-being, in few areas of mental health are these issues as central as addictive behaviors.

The Relationship Between Religiosity/Spirituality and Addiction

In some sense, addiction represents the antithesis of spirituality. For example, one of the four noble truths of Buddhism is "Suffering is caused by attachment," and a central focus for followers of this tradition is to relinquish craving and clinging to things. Yet the centrality of attachment is readily apparent in the diagnosis of substance use disorders—part of the criteria for a substance use diagnosis is that a great deal of time is spent in activities necessary to obtain the substance [2]. May describes the spiritual nature of addiction as "a deep-seated form of idolatry. The objects of our addictions become our false gods. These are what we worship, what we attend to, where we give our time and energy" [33]. Attachment to a substance is a futile attempt to impose direction in one's life, a direction that displaces one's prior values, meaning structures, and goals. Instead,

individuals become concerned with purposeful action toward their next drink or their next high. In Tillich's [54] terminology, the substance becomes the individual's ultimate concern.

Spirituality is also central to the most influential model of recovery in the United States. The recovery program of Alcoholics Anonymous views addiction as a fundamentally spiritual problem and has promoted spirituality and religion as a central factor to recovery since 1935 [59]. In the words of Bill W., the co-founder of Alcoholics Anonymous, those with substance abuse problems "have been not only mentally and physically ill, [they] have been spiritually sick" ([1], p. 34). The program of recovery is therefore based upon a model of prescribed spiritual practices.

In addition to the spiritual program of Alcoholics Anonymous and other 12-step programs, the literature is also quite clear that religious involvement is predictive of lower current and future rates of problem drinking. For instance, over 80% of the nearly 100 studies on alcohol and religion reviewed by Koenig et al. [27] reported a negative association between religiosity and problems with alcohol. It seems that those who are more active in a religion and for whom faith occupies a central place in their lives are less likely to develop dependence on a drug. Similarly, those entering treatment for alcohol/drug problems tend to have very low religious involvement, and are often quite alienated from organized religion.

Religiosity/Spirituality and Addiction Research: An Overview

In a review of the literature on spirituality and addiction, Cook [8] examined 265 publications in order to identify the definition of spirituality by different authors. Cook found that only 12% of the papers explicitly defined the term "spirituality", 32% offered a description of the concept of spirituality, 12% defined a related concept (such as "the spiritually healthy person"), and in 44% of the papers the term "spirituality" was left undefined. Breaking the conceptual content of the definitions into component parts, Cook classified the content of the various definitions into thirteen conceptual components. Cook found that the four components that were encountered most frequently and were most central to the definition of spirituality were transcendence, relatedness, core/force/soul, and meaning/purpose. On the basis of these components, Cook proposed the following definition:

> Spirituality is a distinctive, potentially creative and universal dimension of human experience arising both within the inner subjective awareness of individuals and within communities, social groups, and traditions. It may be experienced as relationship with that which is intimately 'inner', immanent and personal, within the self and others, and/or as relationship with that which is wholly 'other', transcendent and beyond the self. It is experienced as being of fundamental or ultimate importance and is thus concerned with matters of meaning and purpose in life, truth and values. ([8], pp. 548–549)

One particular conundrum, evident in Cook's [8] definition and many other definitions of spirituality, is that scholars have now begun to include aspects of mental health within the definition [26, 20]. If terms such as well-being and connectedness with others are considered part of the definition of spirituality, there is an inherent measurement problem when examining spirituality and religiousness in relation to positive mental health functioning. As Koenig [26] stated, "Defining spirituality in this way assures that those who are "spiritual" will be mentally healthy, and excludes those who are mentally ill from this desirable classification" (p. 351). In addition to this classification problem, there is also a concern in terms of measurement of treatment outcome. If a client shows improvement in mental health, we encounter the dilemma of whether this improvement is due to an increase in spirituality or religion or whether we are simply measuring improvement in quality of life.

Koenig's [26] concern is particularly relevant to how researchers understand addiction. Addiction involves a setting apart from one's self, others and the world—a direct opposition to spirituality's emphasis of oneness with all of humanity. There is therefore a clear confound as individuals with substance use problems begin

to succeed in recovery—they begin to reconnect with humanity and realign their values and goals. The use of substances offers a way to "avoid being present to oneself" ([33], p. 44). It is common for individuals with substance use problems to report that they feel disconnected from others, and as attachment to the substance increases there is a tendency to isolate from important relationships. In Alcoholics Anonymous, a common term is "terminal uniqueness," describing a feeling the feeling of the alcoholic who feels an extreme uniqueness and alienation from his or her peers. Conversely, during recovery from substances, there is a tendency for individuals to attach to a Higher Power and reaffirm important relationships.

Readers interested in further exploring the definitions and distinctions of spirituality/religiousness are encouraged to access Geppert et al. [16]. These authors have compiled a priceless annotated bibliography of 1,353 scholarly papers on spirituality/religiousness and addictions that are divided into 10 categories ranging from the measurement of spirituality with attitudes about spirituality and substance use.

Conceptual Models of Spirituality and Religiousness in Addiction Research and Four Religiosity/Spirituality Measures

While there are diverse definitions and applications of spirituality/religiousness topics in addiction research, two conceptual models serve as a framework for a majority of these endeavors. On one hand, the deficit model of spirituality/religiousness and addictions assumes that the process of deepening addiction involves the loss of spiritual/religious values, beliefs, and practices. Recovery, then, necessarily involves the acquisition or re-establishment of these values and beliefs. Here, the seeking of spiritual/religious values, practices and beliefs fills an existential void created by years of substance abuse. Tacit to this model is the assumption that the quest or search for spiritual/religious meaning is innate. The second model, the coping model of spirituality/religiousness and addiction, makes few, if any, assumptions about the etiology of substance abuse and dependency. Instead, this model focuses on the potentially buffering properties of spiritual/religious practices and beliefs in avoiding relapse. Specifically, spiritual/religious practices and beliefs are interpreted to severe the linkage between aroused negative emotional states and subsequent substance use and abuse. In this regard, the coping model has explicit connections to two popular cognitive behaviorally based strategies in the treatment of addiction, relapse prevention [32] and cognitive behavioral therapy [21]. Less obvious is the theoretical relationship between the coping and protective factor models in addiction research. One of the most consistent and enduring findings in spirituality/religiousness addiction research is the inverse relationship reported between spiritual/religious beliefs and practices and the *development* of substance abuse [16]. Essentially, spiritual/religious practices are interpreted to buffer or attenuate processes that promote substance abuse. Processes within the coping model operate in a similar fashion, but with the key difference that spiritual/religious practices now buffer against the re-establishment of addictive behaviors.

Knowledge of these two spirituality/religiousness models offers at least two benefits. First, understanding these two models provides a conceptual framework to judge, classify, and select from the plethora of spirituality/religiousness measures available to addiction researchers and clinicians. Too often, authors of spirituality/religiousness measures do not explicitly identify the conceptual basis of their respective tool. As such, spirituality/religiousness measures are frequently misused or they fail to provide a sensitive assessment of the process under investigation. Conceptual models offer clear predictions about causal relationships, and knowledge of the different predictions of these two models offers an important second benefit. Most striking, the deficit model ultimately predicts that the failure to enlarge upon spiritual/religious practices and beliefs will result, in the long run, in relapse to substances. Some of the most explicit examples of this model and its prediction on relapse

can be found in the core Alcoholics Anonymous literature [1]. The coping model of spirituality/religiousness and addictions does not lead to such a categorical prediction. Instead, failures to develop and apply spiritual/religious behaviors and beliefs may result in a continuum of adverse consequences given the absence of the presumed positive buffering effect, but alternative resources at multiple levels may offset the absence of spiritual/religious practices, e.g., social networks supportive of abstinence. With this background it is instructive to briefly review four spirituality/religiousness measures that have demonstrated psychometric properties and that are frequently encountered in the addiction literature.

Religious Beliefs and Behaviors [6] is a 13-item self-report measure with demonstrated psychometric properties. The tool yields two scales: Formal practices and God consciousness. Items in the God consciousness scale inquire about the frequency of prayer, meditation, and thoughts about God while items in the Formal practices scale inquire about attendance at worship service and reading of scriptures or holy writings. Strengths of the Religious Beliefs and Behaviors measure include fast administration, normative data are available based upon an alcohol treatment seeking sample ($N = 1{,}637$), and the Religious Beliefs and Behaviors measure has documented sensitivity to discriminate three groups of Alcoholics Anonymous-exposed adults over time in predictable directions, e.g., gains in God consciousness and Formal practices increased at a faster rate over time among adults with more Alcoholics Anonymous exposure. Religious Beliefs and Behaviors does, however, have limitations. Noted by Johnson and Robinson [20], one cannot determine from the Religious Beliefs and Behaviors measure if the behaviors of prayer and meditation occur independently of Formal practices, and findings are mixed about the ability of the Religious Beliefs and Behaviors scales to predict positive outcome [7, 24, 53]. The Religious Beliefs and Behaviors measure is not copyrighted and can be used free of charge.

The Brief Multidimensional Measure of Religiousness/Spirituality [12] is a 38-item self-report questionnaire that has 10 scales: Daily spiritual practices (6 items), Values/Beliefs (2 items), Forgiveness (3 items), Private Religious practices (5 items), Religious and Spiritual Coping (7 items), Religious Support (4 items), Religious/Spiritual History (3 items), Organizational Religiousness (2 items), Religious Preference (1 item), and Overall self-Ranking (2 items). The Brief Multidimensional Measure of Religiousness/Spirituality was a collaborative effort between the Fetzer Institute and the National Institutes of Health to construct a multifaceted measure of spirituality/religiousness that explicitly decoupled private and public spiritual/religious behaviors and practices. Widely recognized scholars developed spirituality/religiousness scales independently, often by reducing parent instruments into a brief scale. In addition to strong psychometric properties and partial normative data, the Brief Multidimensional Measure of Religiousness/Spirituality is especially useful because the manual provides the rationale, application, and psychometric citations for each scale. Based upon a treatment-seeking adult sample ($N = 123$), half of the scales showed significant increases over a 6-month period, and the Daily Experience scale was prognostic of reductions in heavy drinking even after controlling for a number of rival explanations, e.g., Alcoholics Anonymous involvement and gender [53].

The Spiritual Coping Questionnaire [47] is a 22-item questionnaire that measures perceived relationship to God, with the basic premise that different kinds of God relationships imply different coping mechanisms. Three relationship-coping scales have been empirically validated with Alcoholics Anonymous-exposed persons and are labeled: Cooperative ($\alpha = 0.93$), Deferring ($\alpha = 0.89$), and Self-directing ($\alpha = 0.91$) God relationships. Items pertaining to the cooperative God relationship stress mutual exchange between a deity and individual in making choices and decisions while the deferring style is characterized by items that endorse the release of all responsibility for decisions to a deity. Finally, the self-directed style characterizes individuals who

assume all responsibility for choices and who do not seek spiritual guidance. Spiritual Coping Questionnaire scales have been attractive to 12-step researchers because of the hypothesized developmental changes in spirituality that occur among Alcoholics Anonymous members as they work through the 12 steps. Specifically, steps 1-3 have been interpreted as reflecting a deferring relationship with a Higher Power, while later steps encourage a cooperative deity relationship, e.g., steps 11 and 12. To date, temporal changes in coping styles have been documented among 12-step members [53], but the nature and pattern of these changes appear to be more complex than originally thought. In particular, longevity and participation in Alcoholics Anonymous appear to be related with shifting preferences in spiritual coping style, but actual step work was not 19].

Purpose in Life [9] is a 20-item self-report questionnaire that uses a 7-point Likert scale (anchors: Never and Constantly). Used in a number of alcohol studies [4, 50, 51], the Purpose in Life is used to assess the extent that one experiences life meaning. Lower scores on the Purpose in Life reflect a relative lack of current life meaning. Little support has been found for this construct predicting later substance use among outpatient and aftercare adult alcoholics [57], and the item content measuring life meaning itself has been criticized [20]. Specifically, the Purpose in Life along with other measures of life meaning are correlated with measures of well-being and, equally important, it is problematic to determine whether experienced life meaning is the result of spiritual/religious behaviors or practices or not.

Section II

Empirical Religiosity/Spirituality Questions in Addiction Research

There are four types of research questions that can be asked about spirituality using prospective longitudinal studies. Heuristically, these questions are: (1) what *direct* effect does spirituality, or changes in spirituality, have on drinking? (Intervention question), (2) what *changes* in spirituality occur as a result of trying to mobilize and sustain addictive behavior change? (Dependent measure question), (3) How may spiritual/religious practices and beliefs *attenuate* or enhance receptivity to treatment, aftercare, or Alcoholics Anonymous (moderation question), and, most complex, (4) how may spirituality, or changes in spirituality, statistically *explain* the direct relationship between a cause (e.g., prayer) and a desired effect (e.g., abstinence) (mediation question). This latter question, first formally described by Baron and Kenny [3], entails four subquestions that focus on the temporal and causal relationships between, at a minimum, three measured variables. Figure 1 highlights, with a hypothetical example pertaining to spirituality and addiction, both the ideal temporal relationship between measures and the nature of questions that must be affirmed to declare that a measure, here spirituality, explains or accounts for, an observed and desired effect. For the interested reader, a detailed collection of papers specific to mediation and alcoholism can be found in Huebner and Tonigan [19].

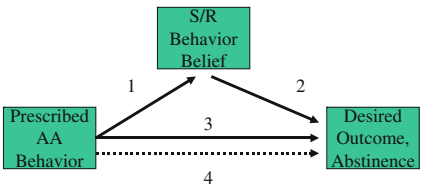

Fig. 1 Four conditions to establish statistical mediation in identifying spiritual or religious actions. AA = Alcoholics Anonymous; S/R = spiritual/religious. Condition 1: Active ingredient, prescribed AA behavior, mobilizes S/R practice or belief; Condition 2: S/R practice effects desired outcome, increased abstinence; Condition 3: Active ingredient, prescribed AA behavior, effects desired outcome; Condition 4: Strength of pathway from prescribed AA behavior and desired outcome is significantly reduced (eliminated) when statistically controlling for S/R practice or belief

Spirituality as an Intervention and Outcome

Investigations of spirituality/religiousness have used both cross-sectional and prospective longitudinal designs to address these empirical questions, with cross-sectional investigators frequently making the case that study findings offer insight into casual relationships. Although one-shot studies do offer some important perspectives on the correlational structure of domains of interest, a number of factors limit their value in understanding causality, not the least of which is the self-selected (and often) biased samples upon which study findings are based. As an example, Poage et al. [49] conducted a cross-sectional study of 53 Alcoholics Anonymous-exposed adults. From this volunteer convenience sample, the investigators asked if length of sobriety, spirituality, and general life contentment were associated. Consistent with predictions, Alcoholics Anonymous members with more years of sobriety reported significantly higher spirituality than Alcoholics Anonymous members with fewer years of sobriety, and spirituality and contentment were significantly and positively associated. Interestingly, years of sobriety and contentment were not associated. Pointed out by the authors, however, causal linkages between these three constructs remain unclear, at best. Did spiritual growth predict the sustaining of sobriety (or vice versa)? Alternatively, years sober and age were positively related ($r = 54$) in this sample. Did the enhanced spirituality of Alcoholics Anonymous members with more sobriety, then, simply reflect the well-documented phenomenon that as we age we become more open to religious and spiritual explanations for the human experience? While studies such as this certainly have value and should be conducted, they are generally avoided in this review because of the number of rival explanations for study findings.

With the exception of studies specifically focused on Alcoholics Anonymous (reviewed in Section III), there have been surprisingly few longitudinal studies that have investigated how, if at all, spirituality/religiousness-based interventions influence subsequent substance use. For clarity, the studies reviewed in this section are arranged according to the intensity of the spiritual/religious intervention, beginning with the studies that involved minimal or modest intervention efforts. Walker and colleagues [61], for example, sought to determine whether intercessory prayer impacted the drinking of 40 treatment seeking alcoholics. Consenting participants were randomized into treatment as usual, which consisted of individual and group counseling in an outpatient setting, and the other half of the sample was assigned to the intercessory prayer condition. Here, in addition to treatment as usual, volunteers prayed for the well-being and abstinence of individuals in the intercessory prayer group. No mean differences on key measure of drinking were observed between the two groups at the 3- and 6-month follow-ups. Findings suggested that prayer by the substance abuser did predict subsequent reductions in drinking in both groups, but this finding did not consider that prayer is a prescribed Alcoholics Anonymous-related behavior and, as such, this benefit may have reflected the social benefit of Alcoholics Anonymous as much as that of prayer. Counter to investigator predictions, alcoholics who reported that family members or close friends were praying for their welfare and treatment success tended to drink more frequently at follow-up relative to those alcoholics who did not report such prayer efforts by loved ones.

Extending this line of research, Miller et al. [36] tested the efficacy of a trained and monitored spiritual guide on later substance use. Here, the spiritual intervention intentionally went beyond Judeo-Christian beliefs and practices and included such Eastern practices as meditation. In the first of two companion studies, the investigators recruited 60 inpatients from a 30-day program to receive treatment as usual or treatment as usual plus 12 sessions with a spiritual guide. The spiritual intervention consisted of 13 modules that included such topics as prayer and meditation, gratitude, guidance, acceptance, fasting, service to others, and worship. While both intervention groups reported large pre-post gains

in abstinence, no between-group differences in substance use were observed between the treatment as usual and treatment as usual + spiritual guide groups at follow-up. Also contrary to prediction, the group receiving spiritual guidance did not report higher scores on three a priori selected measures of spiritual functioning: daily spiritual experiences (Brief Multidimensional Measure of Religiousness/Spirituality), meaning in life (Purpose in Life questionnaire), and private religious practices (Religious Beliefs and Behaviors). Not addressed in this study was whether the emphasis on 12-step attendance in treatment as usual adversely impacted the discriminability of the two interventions.

A second study at the same facility was done to increase exposure to the spiritual guide intervention. Here, facility counselors delivered the spiritual guide intervention and it was embedded into the treatment as usual program [15]. Employing a cohort design, 40 participants received treatment as usual and the following 40 received a spiritual guide in addition to the treatment as usual. In general, findings paralleled the earlier study: no group differences in substance use at 3- and 6-month follow-ups were found although both groups reported significant reductions across a variety of illicit drug use measures. Unlike the first study, modest between-group differences in daily spiritual experiences were found favoring the spiritual guide group at 4- and 6-month follow-ups, but this differential change in spirituality did not statistically mediate or explain increased abstinence for the spiritual guide group.

Bowen and colleagues [5] have provided tentative support for the effectiveness of Vipassana meditation in reducing substance use among incarcerated adults. While replication via a randomized clinical trial design is highly desirable, this work represents some of the more rigorous study of the effects of spirituality that is not Judeo-Christian in origin. Specifically, they reported that an intensive 10-day Vipassana meditation program housed in a minimum-security prison resulted in significantly lower substance use and alcohol-related consequences relative to self-selected control inmates. Also at 3-month follow-up the inmates who participated in the Vipassana meditation also reported significantly higher optimism scores and lower levels of psychiatric problems relative to controls. The Vipassana meditation protocol consisted of long hours of silence, teaching of Buddhist principles including the Four Noble Truths, and instruction in meditation.

Spiritually Based 12-Step Therapy

Twelve-step treatment is the final spiritual intervention to be addressed in this section. Placement of this intervention in this section, separate from our review on Alcoholics Anonymous, reflects the important albeit frequently forgotten distinction between formal 12-step treatment and community-based 12-step programs [5]. (See Ferri et al. [11] for an example of how confusing the two can lead to erroneous conclusions.) To be sure, both 12-step entities introduce and facilitate progress through the 12 steps of Alcoholics Anonymous and strongly encourage long-term Alcoholics Anonymous meeting attendance. In this regard, both 12-step entities can be regarded as sharing a common spiritual focus, e.g., 11 of the 12 steps makes reference to God or a Higher Power, and spiritual concepts such as acceptance, surrender, meditation, and belief in a Higher Power are the central content of the steps.

It is the *practice* of the prescribed 12-step behaviors that most clearly distinguishes community-based Alcoholics Anonymous and formal treatment, and these differences in practice fundamentally influence both the interpretation and impact of working the 12 steps. Some of the more obvious examples of how the two 12-step entities differ include: Community-based Alcoholics Anonymous encourages sponsorship to aid an Alcoholics Anonymous neonate through the 12 steps while formal 12-step treatment offers no analog to this important sponsor-sponsee relationship. Continuing Alcoholics Anonymous meetings are led by a non-professional member of the group and cross

talk in meetings is strongly discouraged. Just the opposite conditions are found in group-based therapy in formal 12-step treatment, with further distinctions made by the use of evidence-based treatment manuals [42]. And, finally, confrontation to accept the label of alcoholic frequently occurs in 12-step treatment (i.e., denial is a concept developed within the treatment context in response to this practice) while in community-based Alcoholics Anonymous the individuals elects if, when, and how, self-labeling of "alcoholic" is appropriate. Beyond the scope of this discussion, it is also important to note that 12-step treatment shares several features incorporated within cognitive behavioral therapy [34].

With this background, the focus of this section is to review those studies that investigated the independent effect(s) of the spiritual emphasis in formal 12-step treatment. To begin, several studies have investigated the plasticity of "Alcoholics Anonymous-specific" cognitions that are foundational to spirituality as it is expressed in 12-step programs. Morgenstern and Bates [41] for example, reported that cognitive shifts promoted by 12-step therapists at residential and intensive outpatient treatment centers did predict later improvement, e.g., commitment to abstinence, but others did not, e.g., negative expectancies. Interestingly, they also reported that severity of cognitive impairment did not influence or moderate the extent of desired cognitive shifts, yet more impaired individuals did not appear to benefit from such cognitive shifts to the extent of those who were less impaired. Likewise, using a composite measure of 12-step disease model beliefs Finney et al. [13, 14] found modest increases among 970 veterans assigned to 12-step treatment in Alcoholics Anonymous -related cognitions during therapy, but such changes did not explain later abstinence rates. Finney also reported that 12-step therapy led to a significant pre-post gain in the percentage of individuals endorsing an alcoholic identity (7% gain).

Project MATCH was one of the largest and most rigorous prospective studies of the efficacy of 12-step therapy to mobilize spiritual/religious practices and beliefs [50, 51]. At 12-month follow-up, no group differences were found in measures of drinking intensity and frequency of abstinent days between 12-step, cognitive behavioral, and motivational enhancement therapies although 12-step therapy did have a significantly higher rate of total abstinence relative to cognitive behavioral therapy and motivational enhancement therapy at 12 months. Tonigan and Miller [56] sought to identify those aspects in the 12-step facilitation that accounted for the relative parity in increased days abstinence and reductions in drinking intensity. No support was found for 12-step therapist emphasis upon total abstinence as an explanation for the relatively good outcomes in the 12-step condition although these therapist did endorse the goal of abstinence more than cognitive behavioral therapy and motivational enhancement therapists. Likewise, intended cognitive shifts in perceived powerlessness and loss of control over alcohol did occur within the 12-step treatment, but these shifts did not explain drinking outcomes at 12 months. Finally, a primary objective for the 12-step facilitation counselor was the encouragement of client spiritual development. As intended, at the end of 12 weeks of therapy, 12-step facilitation clients reported significantly higher God consciousness scores [6] relative to cognitive behavioral therapy and motivational enhancement therapy clients. Virtually no relationship, however, was found between increased God consciousness at the end of treatment and proximal abstinence 6 months after treatment, days to first drink and heavy drinking day, or 1-year total abstinence. Thus, while 12-step facilitation therapists were effective in evoking increased God awareness, this increase appeared to be unrelated to subsequent increases in abstinence.

Robinson and colleagues [53] have recently reported positive findings between increased spirituality and abstinence among 12-step-treated adults ($N = 123$), and some of the unique features of this study warrant special attention. As background, they recruited 154 adults with alcohol use disorders who were presenting for 12-step outpatient treatment and, following consenting procedures, administered a baseline assessment that included an array

of spirituality/religiousness measures along with semi-structured interviews for measuring alcohol consumption. Eighty percent of the sample was contacted and interviewed 6 months after recruitment and the assessment battery was re-administered. In this naturalistic study significant pre-post gains were reported on 5 of 10 spirituality/religiousness measures, nearly all of which were different than those measures described earlier in this section: Purpose in Life ($d = 0.26$), Positive religious coping ($d = 0.14$), Forgiveness ($d = 0.24$), Daily spiritual experiences ($d = 0.19$), and spiritual/religious practices ($d = 33$). Isolating the effects of spiritual gains in predicting the presence or absence of heavy drinking at 6 months by first controlling for gender, baseline heavy drinking, and pre-post changes in Alcoholics Anonymous involvement, they found that two spirituality/religiousness measures sustained their prognostic value in predicting abstinence, gains in purpose in life and daily spiritual experiences. This set of findings represents one of the rare examples of mediated spirituality/religiousness effects as defined by Baron and Kenny's [3] criteria. Why gains in spirituality/religiousness measures explained reductions in heavy drinking in the Robinson et al. [53] sample but not in previous investigations is unknown. Methodologically, earlier investigations used continuously scaled measures of drinking while the Robinson et al. group employed a dichotomous measure of relapse to heavy drinking over the 6-month period (yes/no). Further, the Robinson et al. team used spirituality/religiousness change scores in spite of voiced concerns that such techniques are prone to regression artifacts. Nevertheless, all investigations approached the topic of study with (1) standard recruitment and design choices, (2) psychometrically sound measures, and (3) achieved good follow-up rates.

In general, then, the weight of evidence suggests that cognitive shifts congruent with Alcoholics Anonymous ideology can be successfully mobilized in 12-step therapy. Demonstrations of such shifts have included beliefs in the disease model, endorsement of the alcoholic identity, commitment to abstinence, and a belief in a Higher Power. Applying a scotch verdict, the relative importance of these shifts is mixed, at best, in accounting for the generally good outcomes associated with 12-step therapy. The question is not decided, however. Work by Robinson et al. offers the possibility that previous studies have employed measures that were insensitive to the processes of interest.

Religiosity/Spirituality as a Moderator in 12-Step Therapy

Propst [52] reported that the effectiveness of cognitive behavioral therapy for depression was significantly enhanced for religiously oriented individuals when spiritual matters were discussed within therapy sessions. Here, a person's spirituality/religiousness orientation moderated the effectiveness of an evidence-based approach. In the treatment of alcoholism and addictions the moderator role of spirituality has not yielded as straightforward findings. At face value, for example, it would seem that spiritually focused treatments, e.g., 12-step program, would be received more favorably and be more effective for like-minded people.

Two investigators have examined this issue within the context of a randomized clinical trial. Connors et al. [7] essentially made this prediction when they argued that self-reported religiosity of an alcoholic would moderate the effectiveness of 12-step outpatient and aftercare therapy [50, 51]. The composite measure of spirituality/religiousness included responses to questions about the practice and frequency of prayer, meditation, and formal practice of religious attendance and reading of Holy Scripture. They predicted that alcoholics higher in endorsement of spirituality/religiousness would be more comfortable with the spiritual aspects of the 12-step therapy. Enhanced comfort with the 12-step model would become manifest in higher treatment retention, stronger therapeutic bond, and greater satisfaction with treatment, each of which is a positive and significant predictor

of increased abstinence after treatment. On the basis of drinking outcome no support for this matching hypothesis was found. Likewise, no support was found that comfortability with spiritual/religious beliefs and practices led to higher 12-step treatment retention, satisfaction, or therapeutic bond relative to individuals lower in spiritual/religious values.

Within the same study, Tonigan and colleagues [58] applied a more general and inclusive definition of spirituality in predicting a differential response to 12-step therapy. In particular, they computed a difference score that represented current perceived meaning in life after subtracting the seeking of life meaning [9]. Unlike the comfortability hypothesis, they reasoned that alcoholics high in meaning seeking (but perhaps not very high on spirituality/religiousness) would find the spiritual focus of the 12-step therapy more engaging and, hence, more effective. Consistent with the work by Connors et al. [7] no support was found for a differential response to 12-step therapy based upon the general measure of clients' meaning seeking when judged by percentage abstinent days or drinking intensity for the 12 months after treatment.

Several naturalistic studies have approached the question of whether client spiritual/religious beliefs and practices moderated treatment effectiveness. Oumilettee et al. [43], for example, made a similar prediction as Connors et al., with the key distinction that sampled alcoholics were veterans, and participants were not randomized to treatments. Here, substance abuse treatment programs were classified according to their dominant therapeutic orientation, i.e., cognitive behavioral, 12-step and milieu therapy, and matching of client characteristics and provider types was self-selective. Using similar spirituality/religiousness measures as Connors, (e.g., Religious Beliefs and Behaviors) [6] they, too, reported that 12-step treatment response was unrelated to baseline spirituality/religiousness status. Finally, Kaskutas et al. [24] investigated the role and influence of spiritual/religious practices and beliefs upon long-term sobriety and Alcoholics Anonymous involvement among 587 men and women presenting for treatment at private and public facilities in California. Although the sampled treatment centers represented a broad spectrum of services and therapeutic orientations nearly all encouraged 12-step attendance and included 12-step induction strategies as part of their services. At 3-yer follow-up no association was found between length of continuous sobriety and spirituality/religiousness endorsement at baseline.

Finally, Kelly et al. [25] conducted a unique single-group longitudinal 3-year study of substance-abusing adults who presented for intensive outpatient treatment (N = 227). Here, individuals were assessed at intake and at 1-, 2-, and 3-year follow-ups. In addition to concluding that mutual-help participation contributed to positive outcomes during the follow-up phase of the study Kelly et al. [25] tested several prospective hypotheses about the role and influence of religious/spiritual variables in recovery.

In sum, findings from both randomized clinical trials and naturalistic studies appear to have arrived at the same conclusion, namely that spiritual/religious practices and beliefs are relatively inert in the context of being offered a spiritually based 12-step program. Contrary to predictions, then, endorsement of spiritual/religious practices and beliefs does not seem to provide an advantage to a substance abuser when they are assigned to 12-step therapy. Conversely, substance abusers that report less interest in spiritual/religious practices and beliefs do not appear to be placed at a disadvantage when assigned to 12-step therapy. It should be stressed that almost all of the studies reviewed in this section relied on self-reported spirituality/religiousness status, generally a single item asking whether one was religious, spiritual, agnostic, or an atheist. Well known, single item responses lack reliability, and it is not clear whether more comprehensive spirituality/religiousness measures collected at the onset of 12-step treatment may offer a different picture than the one presented here. At this time, however, the limited evidence suggests that spiritual/religious beliefs and practices are relatively unimportant when determining whether or not

to assign substance abusers to spiritually based 12-step therapy.

Section III

Religiosity/Spirituality and Community-Based 12-Step Programs

Few topics in addiction research generate as much controversy as the question, does community-based Alcoholics Anonymous work and how, especially as a stand-alone intervention? Well documented, a majority of treatment seeking adolescents and adults in the United States report exposure to community-based 12-step programs prior to entering treatment. Likewise, in a survey of treatment providers, Kelly et al. reported that a majority of treatment providers encourage Alcoholics Anonymous attendance during and after inpatient and outpatient treatment, regardless of provider therapeutic orientation. Further, rates of referral to 12-step programs by treatment providers appear to be similar regardless of the nature of substance use dependency, e.g., alcohol, cocaine, and opioid dependency [62]. Given the widespread acceptance of the 12-step model and approach by the clinical community in the United States, why, then, has there been such reticence, ambivalence and, at times, outright hostility by researchers about community-based Alcoholics Anonymous?

The nexus of the conflict lies in Alcoholics Anonymous' pronouncements that alcoholism is a physical, emotional, and spiritual malady, that total abstinence is necessary for recovery, and that spiritual practices provide the foundation for sustained sobriety [1]. Disagreement, then, about Alcoholics Anonymous is rooted in ideological conflict. Derived from Judeo-Christian doctrines [29], the 12 steps of Alcoholics Anonymous are a concise statement of the prescribed and sequential program for recovery, and the 12 traditions are the blueprint for how the fellowship of Alcoholics Anonymous ought to be conducted. Both sets of prescriptions rest upon spiritual principles, and make frequent reference to the value of prayer and meditation, and the existence of God or a Higher Power. Tonigan and colleagues [60] point to five spiritual axioms in the core Alcoholics Anonymous literature: (1) the existence of a transcendent power, (2) the need to develop a personal relationship with God, (3) a belief in mysticism, (4) daily reaffirmation of a God relationship, and (5) the belief that emotional discord signals a departure from spiritual principles. At face value, the spiritual axioms of Alcoholics Anonymous are innocuous and would likely be accepted—with perhaps minor revision—by most theologians. Likewise, the emphasis in Alcoholics Anonymous upon incorporating these spiritual axioms into daily living is not unique, but the steadfast belief in the necessity of doing so to sustain sobriety is unique to 12-step programs.

Community-Based 12-Step Programs and Abstinence

Four of 5 meta-analyses [10, 15, 28, 60, 58] have concluded that Alcoholics Anonymous participation is predictive of increased abstinence although findings are mixed about improvements in other areas, e.g. psychological functioning. In general, effect size estimates of Alcoholics Anonymous-related benefit range between $d = 0.18$ and $d = 0.33$ which fall into the small to moderate range of "intervention" effect. The difficulty in addressing the question of benefit solely based upon community-based Alcoholics Anonymous is that a vast majority of the literally hundreds of empirical studies on Alcoholics Anonymous have been based upon treatment seeking adult samples [10]. Thus, the impact of treatment often confounds investigations into the unbiased benefit of Alcoholics Anonymous. Traditionally, two strategies have been used in an effort to isolate the influences of Alcoholics Anonymous, one statistical and the second based upon conducting distal follow-ups to minimize the direct and indirect influence of formal treatment, e.g., 5–10 years after treatment. Both strategies have important limitations although

both strategies have, to their credit, employed prospective designs. Statistical approaches to control for confounding treatment and self-selective factors, for example, may fail to adequately model all relevant factors. Alternatively, treatment-seeking substance abusers typically have frequent encounters with treatment over time, and is not clear how effective, if at all, distal follow-ups eliminate the influence of formal treatment on client functioning. Keeping these caveats in mind, these two approaches have tended to yield findings in agreement with those generated through the use of treatment-seeking samples, namely that 12-step participation is helpful in reducing problematic drinking for many alcohol abusers. Interested readers should review Kelly et al. [25], Moos and Moos [40], Connors et al. [7], and Kaskutas et al. [23] for exemplars.

What Spiritual Practices Predict Benefit?

Positive albeit modest associations between Alcoholics Anonymous meeting attendance and abstinence have been reported in most meta-analyses [10, 15, 60], and many investigators have reported that measures of commitment to, and involvement in, prescribed Alcoholics Anonymous behaviors are even stronger and more positive predictors of increased abstinence [38, 62]. While these Alcoholics Anonymous meeting and composite measures of Alcoholics Anonymous participation have utility, they do not shed light on the relevance, if any, on the specific spiritually focused behaviors that contribute to increased abstinence. Unfortunately, given the centrality of spirituality to 12-step programs it is surprising how few of these prescribed behaviors have been isolated and studied.

A majority of Alcoholics Anonymous-exposed individuals practice the steps of Alcoholics Anonymous and step work is routinely encouraged in Alcoholics Anonymous meetings [58]. Further, in a cross-sectional study of four Alcoholics Anonymous groups it was reported that steps 1–3, typically regarded as the surrender steps, and 10–12 (maintenance steps) were discussed significantly more often than steps 4–9 (action steps) [55]. Finally, in a second cross-sectional study Horstman and Tonigan [18] reported that Alcoholics Anonymous groups that were perceived to be more supportive and expressive were also judged to endorse the practicing of the 12 steps more frequently than Alcoholics Anonymous groups perceived to be more aggressive and less supportive. Here, Alcoholics Anonymous member perceptions of the social dynamics of Alcoholics Anonymous groups were assessed using the Group Environment scale [39]. It would appear, then, that practicing of the 12 steps is common in Alcoholics Anonymous that such practice frequently focuses upon those steps that endorse the existence of a benevolent deity, and that the extent that such discussion occurs in an Alcoholics Anonymous meeting is influenced by the perceived social dynamics of an Alcoholics Anonymous group.

Few studies have investigated the actual benefit associated with doing the 12 steps. Patton [48] conducted a single group longitudinal study ($N = 769$) of individuals who had received inpatient treatment at Hazelden. Twelve months after treatment a significant positive association was found between completing steps 6-12 and total abstinence. Likewise, to the question, "do you do step work?", a significant and positive relationship was reported between answering *yes* to this question and complete abstinence at 12-month follow-up ($r = 0.22$). In a second longitudinal study of a Hazelden sample ($N = 592$), Kammeier and Anderson [22] reported that there was no relationship between working steps 1-4 and abstinence at a 24-month follow-up, yet there was a significant and positive relationship between self-reported "step work" and total abstinence. Continuing, as part of a psychometric project Gilbert [17] recruited 183 veterans receiving substance abuse treatment to participate in a 12-month study. Here, Gilbert reported that completing step 1 during the first 3 months post-discharge significantly and positively predicted days sober at the 6- and 12-month

follow-ups. Finally, Tonigan and Miller [56] reported that, among 226 outpatients who had received treatment 3 years earlier, the number of steps completed at 3 years was significantly and negatively predictive of the amount of alcohol consumed at the 10-year follow-up. In general, then, these studies suggest that working through the steps is beneficial in reducing alcohol consumption although it must also be acknowledged that those individuals who heed the prescription to do step work are self-selected and may be more motivated and have a better prognosis.

Progression through the 12 steps of Alcoholics Anonymous is most commonly achieved with the guidance of a sponsor, a fellow Alcoholics Anonymous member who has already completed the 12 steps. In this context, a sponsor is a spiritual mentor and the acquisition of a sponsor signals a conscious decision to work the spiritual program of Alcoholics Anonymous. What is known about the benefits of acquiring a spiritual mentor in Alcoholics Anonymous? In a retrospective analysis of the Project MATCH study, Pagano et al. [44] reported that sponsorship led to a significant reduction in relapse rate at 1 year, e.g., 60% versus 78%. Kaskutas et al. [23] have likewise reported that having a sponsor was one of the few Alcoholics Anonymous-prescribed behaviors that predicted reductions in substance abuse, here in a community-based sample. Kaskutas et al. [23] have also reported findings that suggest that there may be indirect benefits associated with sponsorship, namely that Alcoholics Anonymous members with sponsors tend to have triple the rate of Alcoholics Anonymous meeting attendance than Alcoholics Anonymous members without sponsors. Given the documented advantage of continued Alcoholics Anonymous attendance to sustain long-term abstinence [40] this indirect benefit is worthy of further study.

An emerging line of research has addressed the related question of whether helping others in 12-step programs, a prescribed spiritual activity in Alcoholics Anonymous, benefits the helper as well as the person helped. In a retrospective study of 11 Alcoholics Anonymous members with long-term sobriety, for example, Pagano et al. [45] reported that, for these Alcoholics Anonymous members, helping other alcoholics increased with time, and that such helping was felt to enhance the quality of sobriety. In a second cross-sectional study Zemore and Kaskutas [63] reported findings similar to Pagano. Specifically, Zemore and Kaskutas found that among 198 recovering alcoholics in Alcoholics Anonymous that a composite measure of helping (Sponsorship and step work) was more strongly and positively related to length of sobriety than was a composite measure of Alcoholics Anonymous involvement.

Summary and Future Directions

Religiosity and spirituality are associated with improved health-related functioning, especially with regard to mental health. As described in this chapter, the relationship between spirituality and addiction is unique and quite distinct from other mental health problems. Except in rare cases, for example, few clinicians would conclude that the onset of depression was the process of spiritual bankruptcy. In the treatment of substance abuse in the United States, however, the dominant therapeutic model embraces this belief. As such, a majority of treatment providers will uniformly refer individuals to 12-step programs during and after treatment.

Distinctions between the religiosity and spirituality constructs are frequently blurred in addictions research, with many investigators failing to adequately define the constructs if they make any attempt at all. The point was stressed when presenting four popular measures of spirituality/religiousness constructs in this chapter that each construct is multidimensional in nature, and dimensions within each construct appear to have differential sensitivity to the effects of spiritual interventions and in predicting positive outcome(s). In this regard, investigators and practitioners need to be keenly aware of the subtle complexities in what, at first glance, appears

to be self-evident and face valid measures. The measurement of meaning in life exemplifies some of these complexities. On one hand, few would argue that the belief in, and practice of, religious/spiritual behaviors can offer feelings of contentedness and purpose. However, a sense of well-being can as easily result from non- religious/spiritual practices. General measures developed to assess changes in broadly defined spirituality are especially prone to such measurement confounding.

Strong evidence indicates that 12-step treatment is equally effective as more research-based interventions for substance abuse, including therapies that combine psychosocial interventions with pharmacotherapy, e.g., naltrexone. The factors accounting for this parity, however, are only beginning to be understood. Most often, efforts to understand the role and influences of religiousness/spirituality in recovery from addiction adopt one of two conceptual models. The deficit model of spirituality has clear linkages to the 12-step spiritual paradigm and posits that the spiritual void created by addiction ultimately must be filled in order to avoid relapse. In fact, the distinction made in 12-step literature between abstinence and sobriety suggests that spiritual growth is even necessary to achieve well-being. The coping model of religiousness/spirituality is gaining popularity among addiction researchers, and some of the implications of this model were identified. Foremost, the coping model does not imply that religiousness/spirituality development is essential for recovery, but the model does posit that such growth may offer individuals the means to more positively interpret and adjust to negative affect. In this light the coping model of religiousness/spirituality is wholly compatible to, and can be integrated with, cognitive behavioral and relapse prevention strategies.

Religious/spiritual measures have been used as dependent, independent, moderator, and mediator variables in addiction research. Reviewed in some detail in this chapter, there is strong evidence that psychosocial interventions can produce desired shifts in religious/spiritual measures. In both 12-step and non-12-step religious/spiritual interventions, for instance, significant gains have been reported in religious/spiritual beliefs, cognitions, and practices. Such gains in clients' beliefs and practices appear to occur in both individualized and group therapy and for alcoholics and polysubstance abusers. Mostly negative findings have been reported, however, about the effectiveness of religious/spiritual interventions to produce, as independent variables, reductions in substance use. To date, efforts to assess the effectiveness of a spiritual guide [36] have not produced desired effects on a reliable scale, and while 12-step therapy is effective it does not appear to be the result of the spiritual focus of the formal intervention. Important exceptions were identified. Work by Robinson et al. [53] using new religious/spiritual measures and with Vipassana meditation, for instance, offer promising possibilities about the use of religious/spiritual interventions in the treatment of addiction.

The consistent absence of a moderator effect in religious/spiritual research in addictions can be viewed several ways. On one hand, client-treatment matching offers an efficient way to improve treatment effects through the appropriate assignment of individuals with different characteristics to different kinds of interventions. Findings that some clients fared better in spiritually focused interventions than others would have thus provided important information. The lack of evidence for client-treatment matching, using a diverse number of religiousness/spirituality measures of client characteristics, is also good news for practitioners in the United States. Specifically, this information suggests that the assignment of clients low on religious/spiritual beliefs and practices to a spiritually based intervention does not place them at a serious disadvantage. It is estimated that about 6–9% of the population in the United States is atheistic, and their proportional representation among alcohol and polysubstanc abusers is unknown. Findings suggest that this infrequently studied group of substance abusers is not at higher risk of poorer outcomes when assigned to 12-step therapy relative to non-atheists.

The effectiveness of community-based 12-step programs as a stand alone intervention is not entirely clear because of standard sampling procedures in mutual-help research. With this caveat, strongest support for the effectiveness of spiritually focused practices in Alcoholics Anonymous was found for the guidance provided by having and or being a sponsor and for completing prescribed Alcoholics Anonymous steps. Cross-sectional work indicated that encouragement to do step work is associated with Alcoholics Anonymous groups that are more cohesive and supportive and that some steps are endorsed more than other steps. While some confidence can be placed on the findings that step work is relatively common in Alcoholics Anonymous, the findings about the conditions in which they are (or are not) stressed requires prospective study. Current prospective findings offer three relatively firm evidence-based recommendations: (1) encouragement to attend Alcoholics Anonymous meetings is important, especially during early efforts to reduce drinking, (2) encouragement to become engaged in prescribed Alcoholics Anonymous behaviors beyond that associated with simple meeting attendance increases the prospect for Alcoholics Anonymous-related benefit, (3) acquiring a sponsor reduces later relapse, and (4) religious/spiritual orientation of the client, while important, may not be important in determining whether or not to refer to Alcoholics Anonymous. Awaiting replication with prospective studies, it may be the case that helping other Alcoholics Anonymous members as prescribed in the Alcoholics Anonymous literature also increases Alcoholics Anonymous-related benefit for the helper.

At the beginning of the chapter the cautionary statement was made that ongoing 12-step research funded by the National Institute on Alcohol Abuse and Alcoholism may qualify the findings and recommendations in this paper. Currently, for example, there are at least six large-scale longitudinal studies of 12-step programs in the United States, and many of them are specifically investigating the mechanisms that account for Alcoholics Anonymous-related benefit. Clearly, findings from these studies will produce several new chapters on the narrative of the relative importance of spirituality in recovery. Also mentioned earlier, several excellent evidence-based monographs on 12-step programs in particular and spirituality in general have just been published. Perhaps the soundest recommendation that can be made is that readers interested in this topic need, over the next decade, to become actively engaged in the scholarly empirical literature that is focused on religiousness/spirituality and addictions.

Introduction

Acupuncture is currently used in the treatment of addictions by approximately 2,500 addiction treatment programs. Clinical evidence supports that it is effective in ameliorating withdrawal and craving symptoms associated with alcohol, opiate, and cocaine dependence, as well as symptoms associated with most other addictions. Acupuncture for cocaine dependence has been particularly recognized as an important innovation since there are presently no established pharmaceutical treatments for cocaine dependence. Acupuncture is used by programs as a foundation for later psychosocial recovery. It is a non-verbal, non-threatening, "first-step" intervention that has an immediate calming effect on clients regardless of the specific substance used and regardless of whether a coexisting

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_61,

psychiatric disorder has been diagnosed. Initial participation with acupuncture has been found to improve participants' overall treatment retention and to facilitate their subsequent involvement. In most programs, clients receive 3–5 ear acupuncture points while seated together in a large group room so that a substantial number of individuals can be treated conveniently. This safe and cost-efficient procedure has gained increasing acceptance from agencies responsible for overseeing addiction treatment. Evidence for the benefit of acupuncture in coexisting psychiatric conditions and other behavioral health settings also will be presented. This chapter will describe the practical use and research findings relating to acupuncture for addiction. Mechanisms of action that involve physiology and psychosocial process will be covered.

Acupuncture Basics

History and Method

Acupuncture is a major component of the ancient tradition of Chinese medicine. The principles and goals of this form of treatment have remained constant through time. The textbook that is still used today, the Nei Jing, was written 2,000 years ago. Acupuncture was used by numerous nineteenth century U.S. practitioners, including Sir William Osler, "the father of modern medicine", and the imminent physician/chemist Franklin Bache, the grandson of Benjamin Franklin. In the early 1970s, American interest was renewed when relations with China were opened. Most U.S. states have acupuncture licensing laws. Acupuncture is recognized by established medical organizations in virtually every part of the world. Veterinary medical journals cite many examples of objective clinical success, including treatment of potentially lethal arthritis in horses and congenital hip dysplasia in dogs. Effective treatment of animals is usually cited as proof that acupuncture is not merely a placebo procedure.

Acupuncture consists of the stimulation of specified locations on the surface of the body that alters and improves bodily function. The Chinese term for a treatment location is *xue*, which means opening. The traditional Chinese names for these locations often refer to flow on the surface of the earth such as valley, marsh, crevice, or stream. In the West, the term point is used. Acupuncture points are physiologically distinct from the immediate environment; they have less electrical resistance and, therefore, greater electrical conductivity. The points are warmer than the surrounding area by 0.1–0.2 of a degree. The difference in warmth and electrical activity can be detected by the human hand as well as by instruments. A painful response to pressure may also be used as a point indicator. The precise location of these phenomena varies within a small area that corresponds to the acupuncture point as denoted on an acupuncture chart. Descriptions of the location and functions of these points have remained fairly constant through the centuries.

Acupuncture points can be stimulated by various means: touch, movement, heat, electricity, and needling. Health-related procedures such as acupressure, shiatsu, reiki, and tai ji chuan work on the same principles as acupuncture even though no needles are used. Needling is the most convenient and efficient means of stimulating acupuncture points.

Acupuncture needles are stainless steel shafts of varying length and thickness. The handle of the needle usually has an additional spiral winding made of copper. The needles may be cleaned, sterilized, and re-used, as is the case with surgical equipment. Most Western facilities use the needles once and discard them. Acupuncture needles are provided in convenient sterile packages. Needles are inserted with a brief but steady movement. Ear needles penetrate 1/8 inch, contacting the cartilage if it is present in that location. Needles are twirled 180 degrees for smoother insertion. The client may feel a momentary sensation like a pinch. Occasionally, there is a brief, sharper sensation that may cause the client to complain. The procedure is nearly painless and causes the rapid

onset of a gratifying sense of relaxation. On first exposure, most clients express fear of the pain of needle insertion and are confused by the idea that little needles can cope with their big problems. This fear is easily solved by letting prospective clients observe others undergoing the actual process of treatment. It is a mistake to rely on leaflets and verbal explanation alone.

What the Clients Experience

Clients may notice local paresthesia effects such as warmth and tingling. There may be sensations of warmth, electrical movement, or heaviness in other parts of the body, although these reactions are more typical of body acupuncture rather than ear acupuncture. Clients may feel quite sleepy after each of the first several treatments. This reaction is part of the acute recovery process and passes readily. A few individuals develop a headache at the end of a treatment session. Shortening the length of the session or reducing the number of needles resolves this problem. Rarely, a needling reaction occurs in which the client feels dizzy and light-headed and may actually faint. This reaction (postural hypotension) also occurs in many medical and dental settings. When it occurs, one should remove the needles and help the client lie on a flat surface. The syncope will resolve within a few minutes, and the client will exhibit relaxed behavior as though the full-duration treatment had been given. Needling reactions occur more often in persons with a relatively labile autonomic nervous system. Fortunately, these reactions are quite rare in the treatment of addiction. Clients should be told to eat before coming for treatment in order to reduce the possibility of a needling reaction.

The insertion of acupuncture needles never causes bleeding. Hence, there is no need for special blood contact precautions during application of treatment. Based on our experience, treatment sites in the ear bleed about 1% of time after the needles are removed. Thus, 10–20% of clients will have such a reaction. There are several methods that are being used to cope with this problem in terms of appropriate risk management precautions. Commonly, clients are asked to remove their own needles and place them directly in a sharps container. Staff may remove needles by only touching the handle and giving the client a cotton pad to use if bleeding is noted. A small hematoma may also occur. Staff may press each location with a Q-tip as necessary. Most gloves do not provide dexterity in grasping small needles. It should be noted that ear needles are inserted so shallowly that about 10% fall out during the period of treatment. Therefore many needles must be retrieved which have fallen on the individual's clothing. Even wearing gloves will not protect staff who might try to search for such needles. Hence, clients must be instructed to locate any fallen needles and discard them properly. Often programs use a needle count procedure. Clients place needles in a paper cup or bowl so that staff can verify that all needles are present before they are discarded in the sharps container. This procedure is particularly appropriate if acupuncture is conducted in a room that is used for other purposes.

Suggested Physiological Mechanisms

There have been many efforts to determine the underlying physiological mechanisms of acupuncture. Some of the efforts were based on the misleading assumption that acupuncture is primarily a treatment for pain relief. Many acupuncture functions, such as autonomic and gastrointestinal effects, are independent of any aspect that relates to pain. In other cases, such as the treatment of frozen shoulder, pain is actually temporarily increased after successful acupuncture needling. More accurately, acupuncture is frequently an effective treatment for the circulatory, neurological, or inflammatory causes of pain.

Acupuncture charts have a superficial resemblance to Western neuron anatomical charts. The functions of the meridian channels on acupuncture charts differ substantially, however, from those of nearby peripheral nerve trunks. Ear acupuncture is a particularly clear example in

this regard. The acupuncture chart of the external ear identifies more than a hundred separate acupuncture points. These points relate primarily to different body locations and to various organic functions. One can easily verify some of these correlations by noting that the shoulder point on the ear shows abnormally low electrical resistance in patients with shoulder injuries, as does the ureter point in patients who are passing a kidney stone. The simple innervation pattern of the external ear cannot be used to explain these effects.

Researchers have noted the following variety of specific physiological effects associated with acupuncture [3]. It has been reported that acupuncture at traditional points produced dramatic effects in electroencephalogram, galvanic skin resistance, blood flow, and breathing rate. Various studies have linked acupuncture to the production of endogenous opiate peptides, such as beta-endorphin and metenkephalins, and it has been speculated that this is a physiological mechanism behind the treatment's effects on withdrawal discomfort. Acupuncture also has been related to changes regarding other neurotransmitters, including corticotropin and cortisol levels, serotonin, and norepinephrine. The impact of these neurotransmitters in addiction and behavioral health is well established. They are thought to be of key importance in understanding drug and medication effects in addiction and psychiatry. A review of research linking endogenous opiate peptide production to optimal immune system functioning concluded that acupuncture appears to have beneficial effects on the immune system. Substantial literature thus exists supporting that acupuncture has a variety of neurochemical and other physiological effects.

It should be noted that certain medications—namely, methadone, corticosteroids, and benzodiazepines—seem to suppress part of the acupuncture effect. Individuals taking these medications in substantial quantity experience clearly less relaxation effect during treatment and may have a slower response to treatment. Nevertheless, acupuncture is an effective treatment for secondary addiction in high-dose methadone recipients and in reducing benzodiazepine withdrawal symptoms. Acupuncture is also widely used to treat adrenal-suppressed individuals who need to be weaned off corticosteroid medication. This may suggest that part of the initial relaxation response is endorphin and steroid dependent but that the more important mechanisms relate to a different type of process.

Acupuncture effects have been documented in a wide range of organisms. Needling the stem of a plant at a low resistance point will correlate with a rapid increase in the temperature of the tips of the leaves as measured by thermography. Needling a point of normal resistance will produce no such effect (A. Eory, unpublished findings discussed at a Society for Acupuncture Research meeting, 1995).

It is too restrictive to define acupuncture mechanisms in terms of highly evolved structures such as the human brain and the endocrine system. Rather, it seems clear that acupuncture involves the primitive and pervasive functions that are common to all life. Such functions include circulation on a microscopic level, homeostasis, wound healing, immune function, and micro-neurological functioning. Acupuncture has an obvious impact on the autonomic nervous system that is an example of a relatively primitive and homeostatic system in human beings. Acupuncture seems to enhance the integrity of these basic life functions. Pharmaceutic medicine, at best, can only suppress one or more parts of these systems. The Society for Acupuncture Research meets yearly to discuss these issues of mechanism and research. Acupuncture research may provide a window of opportunity for us to enhance our understanding of basic and pervasive vital processes [18].

National Acupuncture Detoxification Association Protocol

Lincoln Hospital Experience

Acupuncture treatment for drug and alcohol problems was primarily developed at Lincoln

Hospital, a New York City-owned facility in the impoverished South Bronx. The Lincoln Recovery Center is a state-licensed treatment program that has provided more than 800,000 acupuncture treatments in the past 34 years. Dr. Yoshiaki Omura was the consultant who began the program [15].

Lincoln Hospital has trained more than 7,000 clinicians, usually referred to as acupuncture detoxification specialists, in the past 20 years. The National Acupuncture Detoxification Association was established in 1985 to increase the use of the Lincoln model and to maintain quality and responsibility in the field. Registered trainers from the National Acupuncture Detoxification Association have trained many thousands of acupuncture detoxification specialists. The Center for Substance Abuse Treatment, part of the Substance Abuse and Mental Health Services Administration, publishes a series of Treatment Improvement Protocols. In 2006, the Center for Substance Abuse Treatment's Treatment Improvement Protocol #45 on "Detoxification and Substance Abuse" included the use of acupuncture in its best practice guidelines for the treatment of addiction.

Initially, in 1974, Lincoln used Dr. H.L. Wen's method, applying electrical stimulation to the lung point in the ear [25]. Lincoln was a methadone detoxification program at that time; therefore, acupuncture was used as an adjunctive treatment for prolonged withdrawal symptoms after the 10-day detoxification cycle. Participants reported less malaise and better relaxation in symptom surveys. Subsequently, twice-daily acupuncture was used concurrently with tapering methadone doses. Reduction in opiate withdrawal symptoms and prolonged program retention were noted.

It was accidentally discovered that electrical stimulation was not necessary to produce symptomatic relief. Simple manual needling produced a more prolonged effect. Participants were able to use acupuncture only once a day and still experience a suppression of their withdrawal symptoms. A reduction in craving for alcohol and heroin was described for the first time. This observation corresponds to the general rule in acupuncture that strong stimulation has primarily a symptom-suppression or dispersing effect and that gentler stimulation has more of a long-term, preventive or tonification effect.

Gradually the acupuncture protocol was expanded by adding the shen men (spirit gate), a point known for producing relaxation. Other ear points were tried on the basis of lower resistance, pain sensitivity, and clinical indication during a several-year developmental process. The author added the sympathetic, kidney, and liver points to create a basic five-point formula (Fig. 1). Numerous other point formulas using body acupuncture points were tried on an individual basis without any significant improvement.

A standard acupuncture textbook [10] describes the functions of each of the five points in the basic formula as follows: *Sympathetic* is used for numerous diseases related to disruption in both sympathetic and parasympathetic nervous systems. It has a strong analgesic and relaxant effect upon internal organs, and it dilates blood vessels. *Shen men* regulates excitation and inhibition of the cerebral cortex. It produces sedative and anti-allergy effects and

Fig. 1 Acupuncture point locations for National Acupuncture Detoxification Association protocol

is used for many neuropsychiatric disorders. *Lung* is used for analgesia, sweating, and various respiratory conditions. *Liver* is used for hepatitis, anemia, neuralgia, muscle spasms, and eye diseases. *Kidney* is a strengthening point for the cerebrum, hematopoietic system, and kidneys. It is used for neurasthenia, lassitude, headache, and urogenital problems. Traditional Chinese theory associates the lung with the grieving process, the liver with resolving aggression, and the kidney with willpower, coping with fear, and new growth.

Clinical Value of a Standard Protocol

The value of using one standard group of acupuncture points became increasingly clear. The standard formula seemed to be equally effective for different drugs of abuse and at different stages of treatment. Participants responded better when acupuncture treatment was administered quickly without an intrusive, diagnostic prelude. Since acupuncture produces a homeostatic response, it was not necessary to adjust the formula for mood swings, agitation, or energy.

From the point of view of Chinese theory, using a single basic formula for such generally depleted individuals is appropriate. In traditional Chinese medicine, the lack of a calm inner tone in a person is described as a condition of empty fire (*xu huo*) because the heat of aggressiveness burns out of control when the calm inner tone is lost. It is easy to be confused by the empty fire that many addicts exhibit and to conclude that the main goal should be the sedation of excess fire. Addicts themselves take this approach in the extreme by using sedative drugs. The empty fire condition represents the illusion of power, an illusion that leads to more desperate use of substances and to senseless violence. Acupuncture helps those with this condition to restore their inner control.

A group setting enhances the acupuncture effect. A group size of less than six members seems to diminish symptom relief and retention significantly. Clients receiving acupuncture in an individual setting are often self-conscious and easily distracted. These problems are more evident in the management of new clients. General acupuncture treatment sessions need to last 20–25 min. Because chemically dependent individuals are more resistant and dysfunctional, they should be instructed to remain in the acupuncture group setting for 40–45 min so that a full effect is obtained. The atmosphere of the treatment room should be adjusted to fit varying clinical circumstances. Programs with a significant number of new intakes and/or socially isolated individuals should use a well-lit room and allow a moderate amount of conversation to minimize alienation and encourage social bonding. On the other hand, programs with relatively consistent clientele who relate to each other frequently in other group settings should dim the lights and not allow any conversation in order to minimize distracting cross-talk. Background music is often used in the latter circumstance.

The location of ear points and the technique of insertion can be taught effectively in a 70-h apprenticeship-based program. Most acupuncture components can be staffed by a wide range of addiction clinicians such as counselors, social workers, nurses, medical doctors, and psychologists. Training must include a clinical apprenticeship because coping with the individual distractions and group process is more important and more difficult to learn than the technical skill of repetitive needle insertion. Each clinician can provide about 15 treatments per hour in a group setting. General supervision should be provided by licensed or certified acupuncturists. This arrangement allows for acupuncture to be integrated with existing services in a flexible and cost-effective manner.

Numerous states have enacted specific acupuncture detoxification specialist laws. These states include New York, Vermont, Connecticut, Maryland, Virginia, Tennessee, Georgia, South Carolina, Indiana, Missouri, Louisiana, Texas, New Mexico, and Arizona. Other states have specific arrangements that allow nurses and counselors to provide National Acupuncture Detoxification Association acupuncture services. According to Substance Abuse and

Mental Health Services Administration statistics [21], acupuncture is used in more than 900 state-licensed chemical dependency programs. Almost all of these programs are located in states with acupuncture detoxification specialist laws. The limited availability of fully licensed acupuncturists (or physicians) and the expenses of hiring such providers seem to be limiting factors.

Summary of National Acupuncture Detoxification Association Protocol

The National Acupuncture Detoxification Association model can be summarized and defined as follows: (1) Clinicians use three to five ear acupuncture points including sympathetic, shen men, lung, kidney, and liver. Three points (sympathetic, shen men, and lung) are used in third-world settings to save money without any apparent loss of effectiveness. (2) Treatment is provided in a group setting for 40–45 min. (3) Acupuncture treatment is integrated with conventional elements of psychosocial rehabilitation. (4) Several components of the Lincoln program are frequently combined with acupuncture in other treatment facilities. These items include: a supportive non-confrontational approach to individual counseling; an emphasis on Narcotics Anonymous and other 12-step activities early in the treatment process; an absence of screening for appropriate clients; the use of herbal sleep mix; the use of frequent toxicologies; a willingness to work with court-related agencies, and a tolerant, informal, family-like atmosphere [19].

The author developed an herbal formula known as sleep mix, which is used in most acupuncture for addiction settings and many other health care settings as well. The formula includes chamomile, peppermint, yarrow, skullcap, hops, and catnip. These are inexpensive herbs, traditionally used in Europe, that are reputed to calm and soothe the nervous system and tend to stimulate circulation and the elimination of waste products. The herb formula is taken as a tea on a nightly basis or frequently during the day as symptoms indicate. Sleep mix can be used for the treatment of conventional stress and insomnia as well as providing adjunctive support in addiction treatment settings. Sleep mix is particularly appropriate for the management of alcohol withdrawal symptoms. Individuals receiving conventional benzodiazepine treatment will often voluntarily refuse this medication if sleep mix is available.

Lincoln has used a reiki circle for the past 10 years. Reiki is a type of therapeutic touch that is related to acupuncture. A reiki circle can involve 20 people if several practitioners are involved. Reiki provides similar benefits to National Acupuncture Detoxification Association acupuncture. In addition, reiki is more socially interactive and helps clients learn more about their own process of change. Lincoln and many programs use magnetic beads for weekend treatments. The beads are attached to a square of adhesive. They are usually placed on the lung point, the shen men point, or the back of the ear in a "reverse shen men" position. Only one point should be used bilaterally. Beads remain in place for 1–2 weeks if necessary. In addition to addiction-related treatment, beads have been used for general stress relief and for attention-deficit hyperactivity disorder and other childhood problems. A pilot study at Reed Academy in Framingham, Massachusetts shows potentially promising results for autism spectrum disorders [17].

Controlled Studies

Randomized Placebo Trials

H. L. Wen, MD, of Hong Kong was the first physician to report successful use of acupuncture treatment of addiction withdrawal symptoms [25]. He observed that opium addicts receiving electro acupuncture as post-surgical analgesia experienced relief of withdrawal symptoms. The lung ear point was used. Subsequently, Wen conducted several basic clinical pilot studies that formed the basis of subsequent research.

Results from available placebo-design studies support the conclusion that acupuncture's

effectiveness in facilitating abstinence with alcohol, opiate, and cocaine abusers is not due to a simple placebo effect [3]. Seven published studies involving animal subjects (i.e., mice or rats) indicate that electro acupuncture reduces opiate withdrawal symptoms with morphine-addicted subjects. In these studies, experimental and control animals show behavioral differences regarding rodent opiate withdrawal symptoms, such as hyperactivity, wet dog shakes, and teeth chattering. Each of these studies notes significantly fewer withdrawal symptoms with subjects receiving electro acupuncture relative to controls. Significantly different hormonal and beta-endorphin levels post-electro acupuncture are noted between experimental and control subjects in several of these studies.

A number of controlled studies have been conducted on human subjects using various modified versions of the Lincoln Hospital ear point formula. Washburn and colleagues [24] reported that opiate-addicted individuals receiving correct site acupuncture showed significantly better program attendance relative to subjects receiving acupuncture on placebo sites. Two placebo-design studies provide strong support regarding acupuncture's use as a treatment for alcoholics. Bullock and colleagues [7] studied 54 chronic alcoholics randomly assigned to receive acupuncture either at points related to addiction or at nearby point locations not specifically related to addiction. Subjects were treated in an inpatient setting but were free to leave the program each day. The setting also provided frequent 12-step meetings and a supportive atmosphere typical of an aftercare facility.

Throughout the study, experimental subjects showed significantly better outcomes regarding attendance and their self-reported need for alcohol. Significant differences favoring the experimental group were also found regarding: (1) the number of self-reported drinking episodes, (2) self-reports concerning the effectiveness of acupuncture in affecting the desire to drink, and (3) the number of subjects admitted to a local detoxification unit for alcohol-related treatment. Bullock et al. [5] replicated Bullock et al. [7] using a larger ($n = 80$) sample over a longer (6-month) follow-up period. Twenty-one of 40 participants in the treatment group completed the 8-week treatment period as compared with 1 of 40 controls (Table 1). Significant differences favoring the experimental group were again noted. Placebo subjects self-reported over twice the number of drinking episode reported by experimental subjects. Placebo subjects were also re-admitted to the local hospital alcohol detoxification unit at over twice the rate of experimental subjects during the follow-up period.

Table 1 Completion rates in Hennepin study

	Treatment group	Control	p Value
Phase I (daily acupuncture for 2 weeks)	37 (92%)	21 (52%)	0.001
Phase II (3 times a week for 4 weeks)	26 (65%)	3 (7%)	0.001
Phase III (twice a week for 2 weeks)	21 (52%)	1 (2.1%)	0.001

Research Problems

There are several potential distortions of research data that are particular to acupuncture detoxification studies. Controlled studies must often rely on "soft outcomes" including interim measurements from questionnaires or short-term attendance or toxicology. Acupuncture is not "Valium in a needle". Conventional researchers usually assume that acupuncture has an exclusively sedating effect. They assume that treatment success can be measured by responses on a one-time, one-dimensional questionnaire that equates more relaxation with a greater treatment effect. The reality of National Acupuncture Detoxification Association acupuncture is quite different. It has a balancing effect, which includes arousal and increased energy in some treatment. Some other acupuncture treatments lead to a moderate sense of well-being; the significant effects primarily occur hours or days after treatment. The most important effects of acupuncture detoxification have little to do with

immediate sedation effects. Meditation and rejuvenation are very different from sedation.

Addiction treatment is not merely the suppression of the indications of illness. Most people in the field agree that best outcome of addiction treatment is the development of self-responsibility. We focus our effort so that the client takes charge of his or her own recovery. This situation is very different from the conventional model in which there is an active pharmacologic agent and a passive client. From the point of view of research design, clients' own efforts become an unwanted variable. How do we know whether the medicine did it or the client did it?

Note the results of the pilot study from Reed Academy cited in this chapter [17]. Halfway through the study, four boys decided that they wanted to "take control of their lives" and have the magnetic beads removed. Statistically, they were removed from the study database. Clinically, however, they continued to do well and gained a level of success that had not seemed possible before. This effect is widely accepted in the outcome evaluation of long-term treatment. Clients who drop out of therapeutic communities after 6 months are seen to have a comparable success rate to those who complete the whole program. Self-actualization, not simple obedience, is the more significant trait. Many forms of treatment do not fit easily with the process of self-actualization. Other forms of treatment—acupuncture, 12-step, Drug Court, for example—fit easily with a client's growing independence.

The social context for a research study is often a critical variable that is overlooked. The pilot study for the Cocaine Alternative Treatments Study at Yale [1] showed promising results. In this case, acupuncture was embedded in a well-functioning methadone program, and the link between the participants, the program, and the study was constructive. When the large Cocaine Alternative Treatments Study was done, the Yale site data showed no significant effect. The intervention and controls were identical; the variable was a less functional social bond between the program and participants, which led to the need to pay research participants in order to get enough of them [13].

It is often difficult to design or identify a social context that will be appropriate to test a claim that acupuncture is an effective supportive context-dependent treatment. The Cocaine Alternative Treatments Study tested an inappropriately optimistic claim that acupuncture can reduce cocaine use as a virtual stand-alone treatment [12]. The Fairview Study by Bullock and colleagues [6] sought to measure a treatment enhancement where little enhancement was possible due to the already comprehensive schedule in that rehab program.

Placebo Points May Be Active

The five National Acupuncture Detoxification Association points are not the only acupuncture points for acupuncture detoxification. Several points can give about the same effect. This causes problems when researchers look for placebo points. Konefal et al. [9] examined the efficacy of different acupuncture point protocols with individuals who had various alcohol and other drug problems. Subjects ($n = 321$) were randomly assigned to one of three groups: a one-needle auricular treatment protocol using the shen men point; the five-needle Lincoln protocol, or the five-needle Lincoln protocol plus selected body points for self-reported symptoms. All groups showed an increase in the proportion of drug-free urine tests over the course of treatment. Subjects with the single needle protocol, however, showed significantly less improvement compared with the other two groups.

During the trial-and-error search conducted at Lincoln Hospital for a more effective ear acupuncture formula for addiction treatment, it was clear that a large number of points had some effect on acute withdrawal symptoms. Ear acupuncture charts indicate that all areas on the anterior surface of the ear are identified as active treatment locations. Using a placebo or sham acupuncture technique is actually an effort to use relatively ineffective points in contrast to the

conventional use of totally ineffective sugar pills in pharmaceutical trials. Sham points are usually located on the external helix or rim of the ear, although there is no consensus about the level of effectiveness of this procedure. Bullock's alcoholism studies used highly failure-prone subjects and, hence, may have revealed the difference between active and sham points more effectively.

Landmark Shwartz Study

While focusing on the complexities of randomized controlled double-blind studies, it is easy to forget that a controlled study is never more than an approximation of reality. Real-life surveys tend to have explicit "hard" outcomes that represent prolonged significant change. Consequently, the large Boston Target Cities Study conveyed more potentially valid information than any of the randomized controlled studies than have been done on acupuncture detoxification [16].

Shwartz et al. [16] surveyed 8,011 complete treatment episodes that were totally blinded because no "study" was being conducted. Low-volume studies must be carefully monitored (controlled) because relatively small variations can create significant distortions in the results. Surveying a high volume of treatments tends to minimize this problem.

The Shwartz study used data from the federally funded Target Cities program, which provided assessment and referral of all detoxification patients in Boston during 1993–1994. Consequently, Target Cities provided a uniquely convenient database for referral and subsequent referral comparison. At the time of the study, Boston had three outpatient detoxification programs that used acupuncture instead of pharmaceutical medication. These were long-standing programs, so the study measured outcomes from existing established programs rather than a new or experimental design. Shwartz and colleagues compared the recidivism rates of the three outpatient detoxification programs with the recidivism of four residential detoxification programs. Recidivism is defined as re-admission for detoxification within 6 months of discharge from the prior admission for detoxification.

Of 8,011 individuals discharged during the study period, 6,907 (86%) had their first detox discharge from an inpatient program and 1,104 (14%) from an outpatient acupuncture program. As might be expected, the acupuncture group tended to be more educated, employed, and well housed. The modality of outpatient acupuncture treatment was selected by the clinical referral staff. Participants had to be educated about acupuncture before they agreed to this modality.

Shwartz et al. [16] took the necessary step of matching 740 of the acupuncture recipients with a similar group of residential patients with similar baseline characteristics. So, 67% of the acupuncture recipients with a similar group of residential patients were able to be included in the matched sample. The outcomes of the study were fairly clear-cut. The odds that an acupuncture recipient was re-admitted with 6 months were 71% of the odds that a residential patient was re-admitted (p= 0.02; 95% CI, 0.53–0.95). Acupuncture appeared particularly beneficial for those individuals with a primary alcohol diagnosis (odds 0.53) (Table 2) and those with two or more detox admissions in the past year (Table 3). Looking at the overall database, repeat recent detox admissions are the primary predictor of recidivism.

The characteristics of the two modalities being compared in the Shwartz study need to be examined. Residential detoxification lasts about 1 week and billed at $850–$900 in Boston in 1993. Most individuals are referred to other treatment after referrals. Outpatient detoxification has an initial intensive period of daily treatment and then a stabilization period up to a total average duration of 4 months.

Outpatient detoxification involves a lot of individual and group counseling as well as acupuncture. Acupuncture is valuable in the initial retention of clients and helping the client to be calm and receptive to benefit from counseling and social support. Target Cities processed a mixed group of addicts (alcohol 42%, cocaine and crack 33%, and heroin 24%). Outpatient use

Table 2 Percentage of clients re-admitted to residential detox or acupuncture within 6 months and the multivariate model odds ratio associated with acupuncture re-admission as a function of primary drug

		Residential detox		Acupuncture	Multivariate model
Primary drug	*n*	% re-admitted	n	% re-admitted	Odds ratio[a]
Alcohol	2,919	37.3	358	10.9	0.53 (0.29–0.98)
Cocaine	1,122	31.0	183	19.7	1.03 (0.52–2.04)
Crack	1,099	28.8	223	21.5	0.97 (0.54–1.74)
Heroin	1,699	40.6	210	31.4	1.11 (0.63–1.96)

of pharmaceutical agents is not a useful method of detoxification for most of this population, especially the cocaine subgroup.

Residential detoxification is more expensive than outpatient detoxification. The greater cost is usually justified by greater retention. Inpatient treatment is thought to have more impact on the individual so that further treatment will be sought. This study does not reveal how many successful referrals were made by the residential programs. However, the net effect of those referrals has been measured by the recidivism rate. Outpatient acupuncture treatment is less expensive and more flexible than residential detoxification. Showing that outpatient detoxification is even equally effective on a large-scale review has clear policy implications. This finding is especially pertinent because the outcomes are better with the most common drug of abuse (alcohol) and for the most problematic subgroup (multiple prior admissions).

Tweed Study

An article from the Centre for Addiction and Mental Health in Toronto showed that acupuncture is an effective supportive treatment in a comprehensive treatment program for women with concurrent mental health and substance use problems. The Jean Tweed Centre in Toronto provides a 21-day residential/day treatment program for women experiencing problems with alcohol and/or drugs. Women are either self-referred to the program or referred by others, such as physicians and self-help groups. The structured program offers daily therapeutic activities that address diverse aspects of women's

psychological and physical health. These aspects include group and individual therapy, addiction education, self-esteem, anger management, family and relationships, recreation and leisure in recovery, women's health, life skills, relapse prevention, relaxation, stress management, sexuality, assertiveness training, journal writing, nature walks, reading, and self-reflection [8].

A National Acupuncture Detoxification Association acupuncture component was added to the basic program for eight 21-day cycles. As a control, five cycles were monitored without the acupuncture enhancement. Randomizing participants within each cycle was not possible because almost all of them wanted the acupuncture experience once they saw it. By alternating cycles, the control participants were unaware of acupuncture in any manner. The control participants were given a time for meditation and reflection comparable to the time the other participants spent on acupuncture.

The most commonly abused substance was alcohol (44%). Demographics showed 40% employed, 10% university graduates, and 64% single or separated. Anxiety and depression were the primary mental health findings. Women with psychotic symptoms were excluded from the unit. Results showed that women receiving acupuncture (n=185) reported having reduced physiological cravings for substances, felt significantly less depressed and less anxious, and were better able to reflect on and resolve difficulties than women in the control group ($n = 101$).

Possible Broader Range of Effectiveness

National Acupuncture Detoxification Association acupuncture can have an effect on symptoms not related to addiction. A British researcher, Beverley de Valois, used National Acupuncture Detoxification Association acupuncture as a treatment for hot flushes and night sweats in women using adjuvant hormonal treatment for breast cancer. Women who had had the treatment were invited to retrospective focus groups. Most of the 16 attendees found that acupuncture was helpful and relaxing. Many reported a reduction in hot flush frequency as well as improvements in overall emotional and physical well-being [23].

Impact on Different Abuse Patterns

Acupuncture is being used in numerous diverse treatment settings. Outcome reports have been published only to a limited degree because of the journals' emphasis on placebo-controlled studies. Unless otherwise noted, these outcomes are based on clinical experiences at Lincoln Hospital or personal observation of other programs made by the author.

Opiates

Opiate addiction was first treated by Dr. Wen in Hong Kong and has been treated at Lincoln Hospital since 1974. Acupuncture provides nearly complete relief of acute observable opiate withdrawal symptoms in 5–30 min. This effect lasts for 8–24 h, and its duration increases with the number of serial treatments provided. Clients often sleep during the first session and may feel hungry afterward. Clients who are acutely intoxicated at the time acupuncture is administered will behave in a much less intoxicated manner after the session. Surprisingly, these clients are gratified by this result, in contrast to reports of discomfort after naloxone administration.

Acupuncture for opiate addiction is typically administered two to three times daily in acute inpatient settings. Alternatively, it may be administered only once a day with clonidine or methadone on an outpatient basis. Many individuals do well on once-daily acupuncture because they taper their illicit opiate usage over a 3- to 4-day period. Heroin addicts usually seek detox to reduce the size of their habit, so this arrangement fits their immediate goals. The addition of an acupuncture component to an opiate detoxification program typically leads to a 50% increase

in retention for completion of the recommended length of stay.

Alcohol

Directors of the acupuncture social setting detox program conducted by the Tulalip Tribe at Marysville, Washington have estimated a yearly saving of $148,000 due to less frequent referrals to hospital programs. Inpatient alcohol detoxification units typically combine acupuncture and herbal "sleep mix" with a tapering benzodiazepine protocol. Individuals report fewer symptoms and better sleep. Their vital signs indicate stability, and, hence, there is much less use of benzodiazepines. One residential program in Connecticut noted a 90% decrease in diazepam use when only herbal "sleep mix" was added to their protocol.

Retention of alcohol detox patients generally increases by 50% when an acupuncture component is added to conventional settings. Some alcoholics who receive acupuncture actually report an aversion to alcohol. Woodhull Hospital in Brooklyn reported that 94% of the individuals in the acupuncture supplement group remained abstinent as compared with 43% of the control group who only received conventional outpatient services [11]. The widely quoted controlled study by Bullock et al. [5] showed 52% retention of alcohol-dependent individuals as compared with a 2% sham acupuncture retention rate.

Cocaine

Cocaine addiction has provided the most important challenge for conventional treatment because there are no significant pharmaceutical agents for this condition. Acupuncture recipients report more calmness and reduced craving for cocaine even after the first treatment. The acute psychological indications of cocaine toxicity are visibly reduced during the treatment session. This improvement is sustained for a variable length of time after the first acupuncture treatment. After three to seven sequential treatments, the anti-craving effect is more or less continuous as long as acupuncture is received on a regular basis.

Urinalysis outcomes were examined for Lincoln Hospital patients using cocaine or crack who had more than 20 treatment visits and were active during the 1-week study period in March 1991. At Lincoln, patients typically provide urine samples for testing during each visit. Of the entire study group of 226 individuals, 149 had more than 80% negative tests during their entire treatment involvement. Of those remaining, 39 had at least 80% negative tests during the 2 weeks prior to data collection.

Methamphetamine

Methamphetamine users experience similar dramatic increases in treatment retention. Hooper Foundation, the public detoxification center in Portland, Oregon, reported 5% retention of methamphetamine users prior to the use of acupuncture and 90% retention after adding acupuncture to their protocol. Increased psychological stability and decreased craving were cited.

Methadone

Individuals on methadone maintenance receive acupuncture in a number of different settings. They report a decrease in secondary symptoms of methadone use such as constipation, sweating, and sleep problems. Typically, there is a substantial drop in requests for symptomatic medication. Treatment staffs usually notice decreased hostility and increased compliance in methadone-acupuncture clients. The most important impact of acupuncture in maintenance programs is reduction of secondary substance abuse—primarily involving cocaine, even in clients with minimal motivation [14]. Reductions in secondary alcohol use are also frequently described. Acupuncture is effective with individuals on any dosage level of methadone.

Lincoln Hospital used methadone and acupuncture together from 1974 to 1978. Several hundred individuals on methadone maintenance were detoxified during that period using tapered doses of methadone and acupuncture. Based on our previous non-acupuncture experience, we observed that clients were much more comfortable and confident when they received acupuncture. Even though clients regularly complained about withdrawal symptoms, there were very few requests for a dosage increase. The large majority completed the entire detoxification process and provided at least one negative toxicology report after the cessation of methadone.

Methadone dosages were decreased 5–10 mg/week, with a slower schedule during the final 10 mg. Starting levels of methadone ranged from 20 to 90 mg, with a median of 60 mg. Acupuncture was provided 6 days per week and continued up to 2 months after the last methadone dose. Although many of these participants had been referred for administrative or mandatory detoxification due to secondary drug use, toxicologies were usually drug-free after the first 2–3 weeks of treatment.

Methadone withdrawal is notable for unpredictable variations in symptoms and significant post-withdrawal malaise. Symptoms such as depression, low energy, and atypical insomnia are quite difficult to manage without acupuncture. Clients are usually fearful and have considerable difficulty participating in psychosocial therapy during the detoxification period. Acupuncture is particularly valuable in the methadone-to-abstinence setting because clients' future well-being depends on their ability to utilize psychosocial support during the detoxification period.

Marijuana

At Lincoln, we have had a significant number of primary marijuana users seeking care. These individuals usually report a rapid reduction in craving and improved mental well-being. Secondary marijuana use is usually eliminated along with the detoxification of the primary drug (e.g., cocaine).

Tobacco

The use of the National Acupuncture Detoxification Association protocol can be helpful in residential treatment where the clients are unable to continue using tobacco. Its use in a 90-day inpatient, tobacco-free, dual-diagnosis treatment program demonstrated improved retention in treatment, with longer length of stay and improved participation in those individuals who received the needles. The use of acupuncture appeared to help both those planning to smoke and those wanting to stay quitting after discharge. For those planning to smoke as soon as possible after discharge, significantly more (57%) completed the program successfully if they had 8 or more acupuncture detoxification sessions versus <8 sessions ($p<0.05$). Those receiving needles reported significant improvement in sleep, anger, pain, concentration, and energy compared with those not receiving needles. Combined with education, acupuncture detoxification allows individuals to move forward in their stage of change regarding tobacco use after discharge [20].

For those in outpatient treatment who are motivated to quit smoking, the National Acupuncture Detoxification Association protocol can be very helpful. Bier et al. [2] demonstrated that the combination of acupuncture with education resulted in an effectiveness rate of 40% cessation and 53% post-treatment reduction in total cigarettes smoked. This result is comparable to that produced by pharmacological treatment of nicotine addiction combined with behavioral support.

Clinical Effectiveness

Retention and Recidivism

The beneficial effects of acupuncture in cocaine treatment often lead to dramatic increases in

retention of cocaine users. Women in Need, a program located near Times Square in New York, reported the following outcome figures in their treatment for crack-using, pregnant women: (1) Individuals with conventional outpatient treatment averaged three visits/year. (2) Those who received acupuncture in addition to conventional treatment averaged 27 visits/year. (3) Participants in an educational component in addition to acupuncture and conventional treatment averaged 67 visits/year. Those averaging three visits/year would be unlikely to participate in an educational component. Therefore, it seems likely that the increased retention correlated with acupuncture set a foundation for successful participation in the educational component.

Acupuncture detoxification programs report substantial reduction in their recidivism rates. Hooper Foundation cited a decrease from 25 to 6% in comparison with the previous non-acupuncture year. Kent-Sussex Detoxification Center (in Delaware) reported a decrease in recidivism from 87 to 18%.

Substance Abuse Recovery (Flint, MI) noted that 83% of a group of 100 General Motors employees were drug- and alcohol-free productive workers a year after entering acupuncture-based treatment. Most of them had repeated prior attempts at treatment and frequent relapse. Everyone in the 17% failure group had fewer than five program visits. Seventy-four percent of the success group continued to attend Alcoholics Anonymous and Narcotics Anonymous meetings after completing the treatment program. Programs specifically designed for adolescents, such as the Alcohol Treatment Center in Chicago and a Job Corps-related program in Brooklyn, have shown retention rates comparable to adult programs.

Frequency and Duration of Treatment

Acupuncture treatment is generally made available to clients 5–6 days per week. Lincoln offers treatment during an 8-h period, but many smaller programs offer acupuncture during 1- to 2-h periods each day. Morning treatment hours seem to be more beneficial. Active participants will receive treatment three to six times per week. Initially, acupuncture should be defined as an expected part of the program. If one describes acupuncture as a voluntary or optional part of the program, this description is not useful to a crisis-ridden addicted person. Such a person cannot handle choice and ambivalence effectively. Initially, clients need direction and clarity. They should be asked to sit in the treatment room without needles if they are unsure about receiving acupuncture. New clients will learn about acupuncture from other more experienced clients, and they will observe the process of treatment on a first-hand basis. Sometimes a client will be willing to try just one or two needles at first. Eventually, a high percentage will be active participants.

The duration of acupuncture treatment depends on many factors. Inpatient programs will want to stress acupuncture in the beginning for detoxification and stabilization and prior to discharge for separation anxiety. Outpatients in a drug-free setting typically receive acupuncture for 1–3 months on an active basis. About 10% of these outpatients will choose to take acupuncture for more than 1 year if possible. Such individuals usually have significant difficulties bonding on a psychosocial basis.

Lincoln Hospital used to provide acupuncture 7 days a week for the benefit of those in crisis. Eventually, it became clear that full weekend coverage did not appreciably improve clinical results. Individuals who began the treatment program on Friday had essentially the same outcomes as those who began the program on Monday. Acupuncture is not primarily a dose-related phenomenon, as is pharmaceutical treatment. Acupuncture more appropriately represents a qualitative service comparable to a schoolroom class or psychotherapy session.

People who are using acupuncture appropriately should be allowed to choose how often they receive acupuncture treatment. Duration of the effect of each individual treatment increases as the person becomes more stable. Since this

treatment is a private personal process, it should come under the client's control as soon as possible. Some clients will discontinue acupuncture too quickly, but they should be able to learn from the resultant loss of well-being in order to make better decisions in the future. Participation in acupuncture is a different kind of decision from participation in group or individual psychotherapy.

Effect on the Whole Treatment Process

Relapsing individuals are often able to continue to be involved in acupuncture even though they are no longer constructive participants in psychotherapy. Acupuncture recipients do not tend to burn their bridges as quickly; hence, retention and eventual success are increased in an acupuncture-based program.

A wide range of clients can be accepted for the initial stage of treatment because there is no verbal motivational requirement. Also, acupuncture is effective for most drugs and a wide range of psychological states. A low-threshold, easily staffed program can be established for new clients. Ambivalent street-wise individuals find the acupuncture setting almost impossible to manipulate. The setting is so soothing and self-protective that even extremely anti-social people are able to fit in. Problems relating to language and cultural differences are diminished. For new clients, frequent acupuncture treatment permits the gradual completion of assessment on a more accurate basis. Clients can be evaluated and triaged according to their daily response to treatment and testing rather than merely on the basis of the initial interview.

The tolerant, non-verbal aspect of acupuncture facilitates retention during periods when the client would otherwise be ambivalent, fearful, or resentful within a more intense verbal interpersonal setting. Ear acupuncture makes it easy to provide outpatient treatment on demand, without appointments, while the client is being acclimated to the interpersonal treatment setting. Clients are often willing to be tested even when they know that their toxicology result is positive, thereby showing respect for the value system of the overall treatment process. Those same individuals may be unable or unwilling to share their crisis and failure verbally until they have time to reach more solid ground. In the acupuncture setting, time is on our side.

Acupuncture has many characteristics in common with 12-step programs such as Alcoholics Anonymous and Narcotics Anonymous. It uses group process in a tolerant, supportive, and present-time-oriented manner. Participation is independent of diagnosis and level of recovery. Both approaches are simple, reinforcing, nurturing, and conveniently available. The emphasis on self-responsibility is common to both systems. In practice, acupuncture provides an excellent foundation for 12-step recovery. Clients seem less fearful and more receptive when they first enter the meetings. The traditional advice—listen to learn and learn to listen—fits this model well. Acupuncture reduces "white knuckle sobriety" considerably. There is less guarding and a greater ability to support each other warmly. The increased ability to use 12-step meetings provides more stable support for continuing treatment on an outpatient basis.

AIDS-Related Treatment

Easy access and better retention encourage the outpatient management of difficult clients with less need for additional drugs or services. One can select times for hospitalization more appropriately. An outpatient continuum also facilitates primary health care management for AIDS, tuberculosis, and sexually transmitted diseases. Acupuncture is used in a large proportion of AIDS prevention and outreach programs in New York and London, as well as other cities. These facilities include needle exchange and harm reduction programs and recovery readiness and pre-treatment programs, as well as health service providers for people with HIV and AIDS. In relation to addiction treatment, each of these

programs faces similar dilemmas. Their clients are likely to have ever-increasing addiction-related problems; however, these clients minimize their need for help. Furthermore, the clients are often overwhelmed by problems relating to immune deficiency. Acupuncture is uniquely appropriate entry-level treatment because it is convenient, relaxing, and not dependent on any mutually agreed-upon diagnosis or treatment plan. Acupuncture also provides treatment for emotions such as fear and depression. Many of these clients may be ashamed and confused, not knowing how to describe their ever-changing feelings in a conventional therapeutic context.

Maternal Treatment

The use of acupuncture has led to a considerable expansion of treatment services for cocaine- and crack-using women. The Lincoln program was cited as a model innovative program for prenatal care in a monograph, *Hospital and Community Partnership*, issued by the American Hospital Association in 1991.

The average birth weight for babies at Lincoln with more than 10 maternal visits is 6 pounds, 10 ounces. The average birth weight for less than 10 visits is 4 pounds, 8 ounces, which is typical of high-risk cocaine mothers. There is a high correlation between clean toxicologies, retention in the clinic program, and higher birth weights. Seventy-six percent of our pregnant intakes are retained in long-term treatment and give birth to non-toxic infants.

Premature birth is a serious health risk. The Hospital of St. Raphael in New Haven used the Lincoln acupuncture model for 8 years. The director of obstetrics, Dr. Wilfredo Requero, reported a drop in perinatal death rate from 18.5 to 7.1 from 1990 to 1992 following the use of acupuncture and other innovative outreach techniques. Special acupuncture-based components have also been developed for women with children in long-term foster care in the Drug Strategies Institute program in Baltimore. Acupuncture is used during high-risk prenatal home visits conducted by public health nurses in Washington state.

Female clients are often trapped in destructive and exploitative relationships and, therefore, have special difficulty with any therapeutic relationship. A consistently tolerant and non-confrontational approach prepares the way to establish a trauma survivor support service for clients at an early sobriety stage of recovery. The supportive atmosphere makes it relatively easy for clients to keep children with them during treatment activities. The acupuncture point formula used for addictions is also specific for the kind of emotional and muscular guarding associated with early sexual trauma. These clients will suffer intermittent crises and experience profound challenges to their physical and spiritual identity. All of their relationships will be strained and transformed. Acupuncture is a very appropriate adjunct to trauma survivors' support work.

Criminal Justice-Related Treatment

Individuals referred by court-related agencies often enter treatment in total denial or with a basic conflict with the referring agency. The non-verbal aspect of acupuncture allows the intake staff to get beyond these protests and offer acupuncture for stress relief, instead of forcing the issue. Using acupuncture, one is able to wait until the clients feel more comfortable and less threatened so they can admit their addiction and ask for help.

Addicts have trouble with discipline. They need order in their lives but cannot develop internal structure. Addicts also have trouble liking themselves. They are depressed and depersonalized and cannot accept good things. The end result is self-destruction and adherence to a masochistic lifestyle. The ability to like oneself builds the foundation for internal discipline. Acupuncture provides significant advantage in meeting the paradoxical requirement of tough love. Verbal interpersonal intensity is reduced. Clients feel that their immediate needs and

their urges toward independence have been satisfied. A tolerant, flexible atmosphere exists. Acupuncture delivered in a consistent and caring manner provides the basis for the love side of the equation. The foundation for the development of more effective discipline has been set.

Frequent urine testing provides an objective non-personalized measure of success that can be accepted equally by all parties. In this system, the counselor is the good cop and the urine machine is the bad cop. The counseling process can be totally separated from the process of judgment and evaluation. Discipline is separated from the difficulties of interpersonal relationships. Within this context, discipline or leniency by the judicial authority leads to constructive not escapist behavior. Positive toxicology results are primarily used to require a more prolonged or intense commitment to treatment.

The well-known Drug Court program in Miami uses the acupuncture-based model that we have described. This program diverts thousands of felony drug possession arrestees into treatment each year. More than 50% of these individuals eventually graduate from the program on the basis of providing 90 consecutive negative toxicologies over the period of a year or more. Drug Court diversion and treatment programs have been established in thousands of settings nationwide. This expansion represents a valuable increased commitment to addiction treatment throughout the U.S. The majority of the largest and oldest Drug Court programs (Miami, Broward, Las Vegas, and Portland) used acupuncture as a primary component of their protocol. Acupuncture is also being used in many jails and prisons in the U.S. and abroad. A follow-up study in Santa Barbara, California, for example, showed that women who received acupuncture were 50% less likely to be rearrested after being released from the county jail [4]. Sex offenders in a maximum security prison in Oak Park Heights, Minnesota received acupuncture on a regular basis. There was a significant reduction in anger and violent intrusive sexual fantasies as compared with a control population (P. Culliton and L. Leaf, personal communication, 1996).

Coexisting Mental Health Problems

Serious and Persistent Mental Illness

There is little substantive published literature on the use of acupuncture in the treatment of primary psychiatric problems. During the past 20 years at Lincoln Hospital, we have noted numerous effects of acupuncture on clients with coexisting addiction and psychiatric conditions. Agitated individuals fall asleep routinely while receiving acupuncture. Those with chronic paranoia have a higher-than-average retention rate. We have seen many examples in which grossly paranoid addicted persons have made special efforts to access acupuncture treatment. Our clients do not express paranoid ideas about acupuncture although they may remain otherwise quite paranoid. These clients experience a gradual reduction in psychiatric symptoms as well as a typical response in terms of craving and withdrawal symptoms. Psychotropic medication does not interact with acupuncture. Clients should remain on psychotropic medicines while using acupuncture since the improved level of compliance that correlates with acupuncture often makes the process of medication more reliable and effective.

A pilot program used acupuncture according to the Lincoln model in the public mental health system in Waco, Texas with a goal of reducing the rate of re-hospitalization. Highly disturbed, non-compliant, drug-addicted individuals with serious and persistent mental illness were deliberately selected for this trial. Rates of hospitalization dropped from 50 to 6% in the group of 15 participants. Harbor House, a residential program for mentally ill substance abusers in the Bronx, reported a 50% reduction in psychiatric hospitalization in the first year of acupuncture utilization. Their dropout rate during the first month of treatment decreased 85%. The participants in Waco, Texas participated more enthusiastically. They listened better and were more cooperative. The context of treatment became even more important to these individuals.

Acupuncture has an obvious advantage in the treatment of mentally ill substance abusers, especially those with serious and persistent mental illness. Mentally ill substance abusers have particular difficulty with bonding and verbal relationships. Acupuncture facilitates the required lenient supportive process, but, at the same time, it provides an acute anti-craving treatment that is also necessary. The use of acupuncture can resolve the contradictory needs of mentally ill substance abusers.

In the last decade, the National Acupuncture Detoxification Association acupuncture protocol has been used widely in large general psychiatric hospitals in Germany and Scandinavia. In Sweden, hospitals typically request training for 50–150 nurses. Training is conducted for 24 nurses at a time. One Swedish nurse summarized the changes: "Acupuncture reduces anxiety even for patients who are waiting for hours in the emergency unit. With quite aggressive people we use acupuncture. It seems to reduce hallucinations and make them less frightening. The more paranoid the patient is, the greater the effect from acupuncture. Depressed patients often get more active. Their anti-depressant medications seem to work better. Prescriptions for benzodiazepines are often reduced."

Dr. Elizabeth Stuyt of Pueblo State Hospital in Colorado reported similarly that "the worse patients seem to do better with acupuncture" [20].

Trauma and Violence

The World Trade Center in New York City was attacked on September 11, 2001. St. Vincent's Hospital became the receiving hospital where volunteer medical personnel gathered. As the stress intensified, a nurse from the hospital's alcoholism program offered their acupuncture protocol for stress relief for staff and visitors. More than 1,000 people received the ear acupuncture protocol during the next 2 weeks. This response led to a realization that this protocol has a much wider applicability than just addiction-related treatment. A full-time acupuncture service is still used by the New York City Fire Department for 9/11-related stress. Acupuncturists were invited to New Orleans after hurricane Katrina, specifically to treat homeless police and fire personnel. These treatments have been so successful that the medical board and the State of Louisiana are planning to have all first responders have access to ear acupuncture training.

In recent years the ear acupuncture protocol has been used in a wide variety of settings: parenting classes (Washington), suicide prevention in border security forces (India), schools for violent youth (England), recovery programs for commercial sex workers (San Francisco and Ethiopia), street children (Mexico, Peru, and Philippines), victims of sexual abuse (U.S.), and menopause-like side effects of tamoxifen (U.K.).

Ear acupuncture was used for stress relief for the inmates of Dartmoor Prison (U.K.) in the 1990s. Correction officials discovered a dramatic reduction of inmate violence and a greater interest in drug-free dormitories. Support for acupuncture spread quickly through the prison system. By 2006, 130 prisons in England were using ear acupuncture. More than 500 correctional officers have been trained to provide ear acupuncture in the prisons. The atmosphere between the officers and inmates has changed very positively as a result of this systemic transformation.

Psychosocial Mechanisms of Action

Personal Behavior

It is essential to understand acupuncture's psychological and social mechanisms of action to use this modality effectively. Acupuncture has an impact on the individuals' thoughts and feelings that is different from conventional pharmaceutical treatments. Subsequently, one can discuss how the use of acupuncture has a valuable and profound impact on the dynamics of the treatment processes as a whole. We should emphasize

that acupuncture for addictions is provided in a group setting. The new acupuncture client is immediately introduced to a calm and supportive group process. Clients describe acupuncture as a unique kind of balancing experience. "I was relaxed but alert. I was able to relax without losing control." Those who are depressed or tired say that they feel more energetic. This encouraging and balancing group experience becomes a critically important basis for the entire treatment process.

The perception that a person can be both relaxed and alert is rather unusual in Western culture. We are used to associating relaxation with somewhat lazy or spacey behavior and alertness with a certain degree of anxiety. The relaxed and alert state is basic to the concept of health in all Asian culture. Acupuncture encourages a centering, focusing process that is typical of meditation and yoga. Therapists report that clients are able to listen and remember what we tell them. Restless impulsive behavior is greatly reduced. On the other hand, discouragement and apathy are reduced as well. It is a balancing, centering process.

One of the striking characteristics of the National Acupuncture Detoxification Association acupuncture treatment setting is that each client seems comfortable in his or her own space and thinking process. One client explained, "I sat and thought about things in a slow way like I did when I was ten years old." Acupuncture treatment causes the perception of various relaxing bodily processes. Clients gradually gain confidence that their minds and bodies can function in a more balanced and autonomous manner. A hopeful process is developed on a private and personal basis, laying a foundation for the development of increasing self-awareness and self-responsibility.

Addiction is about trading present experience for past and future realities. Addicted individuals hang onto the present because the past and future seem to offer nothing but pain. Unfortunately, conventional treatment efforts tend to focus on assessment of past activities and planning for the future. Clients are obsessed by present sensations and problems. They often feel alienated and resentful that we cannot focus on their immediate needs. Acupuncture is one of the only ways that treatment staff can respond to a client's immediate needs without using addictive drugs. We can meet clients in the present time reality—validating their needs and providing substantial relief. Once a comfortable day-to-day reality support is established, we can approach past and future issues with a better alliance with the client.

The nature of recovery from addiction is that individuals often have quickly changing needs for crisis relief and wellness treatment. Many persons in recovery have relatively high levels of wellness functioning. Even so, a crisis of craving or past association may reappear at any time. Conventional treatment settings have trouble coping with such intense and confusing behavioral swings. Often merely the fear of a possible crisis can sabotage clinical progress. Acupuncture provides either crisis or wellness treatment using the same ear point formula. The non-verbal, present-time aspects of the treatment make it easy to respond to a client in whatever stage of crisis or denial may exist.

Internal Change

Clients readily accept that it is possible to improve their acute addictive status. They seek external help to provide hospitalization and medication for withdrawal symptoms. The challenge develops when they encounter the necessity for internal change. Addicts and others perceive themselves as being unable to change from within. Their whole life revolves around powerful external change agents. Each addict remembers countless examples of weakness, poor choices, and overwhelming circumstance that led to the conclusion that they cannot help themselves become drug-free. Indeed, many influential members of society agree that once an addict, always an addict.

Many of the complicating factors in our clients' lives echo this challenge of past internal failure. Persons leaving prison are confronted

with a bleak uncaring world. Their own feelings of inadequacy frequently become so overwhelming that a return to prior drug and alcohol use may occur within hours of release. When a person learns that they are HIV positive, their self-esteem drops precipitously. A drug-abusing seropositive person typically feels punished for past weaknesses by their HIV status. How can such a person have the confidence to seek out internal personal strength in the future?

Victims of incest and childhood abuse are well known to have been robbed of an internal sense of value. Their innermost physical and emotional responses have become sources of betrayal. It is not surprising, therefore, that a large majority of female addicts have been injured in this way.

All of us pass through a period of fearful internal inadequacy during the process of adolescence. Powerful trends of self-doubt and internal vulnerability are manifested at that time. No amount of external support will eliminate the need to confront internal fears on a private, personal basis. Hopefully, adolescents gradually learn to accept and appreciate themselves. They may also learn to rely on internal resources in their efforts to improve their circumstances. This archetypal challenge of adolescence is echoed in the struggle to become drug-free, as well as countless other efforts to become more internally resourceful and resilient in daily life. The question "does treatment work?" is comparable to asking whether internal self-discovery and re-definition are possible.

Acupuncture provides uniquely valuable assistance in coping with this challenge of internal redefinition. Clients often begin acupuncture treatment seeking external escape and sedation as they do when they use drugs. When there is a rapid calming effect, they often assume there was some sort of chemical agent in the acupuncture needle. After a few treatments, they come to the astonishing conclusion that acupuncture works by revealing and employing their internal capability rather than by inserting an external chemical. Individuals begin to realize that their mind is capable of calm, focused thoughts on a regular basis. There seems to be no indication of permanent damage to their thinking and consciousness. On the contrary, their ability to listen, think, and learn seems to be growing steadily each day.

Inevitably, a critical point will be reached. The newly drug-free individual will enter treatment one day with the feeling that "I don't deserve to be relaxed today because of all the bad things that I have done in the past." Such feelings frequently sabotage early treatment achievements. In an acupuncture program, however, the client realizes that his or her mind can become calm and clear even in the face of such overwhelming feelings of inadequacy. This lesson demonstrates that change based on internal resources is possible. In other words, successful treatment is possible. Regular participation in acupuncture helps a client take advantage of his or her internal resources much faster than conventional treatment processes. This effect contributes to the calm, cooperative atmosphere in most acupuncture settings. It reduces dropouts based on fears of failure and low self-esteem that typify the early stage of treatment.

Foundation for Autonomy

The use of acupuncture sets a foundation so that clients can have more autonomy in developing their own plan of treatment. A calmer, less resentful atmosphere is created. The tolerant, self-validating process helps individuals find their level and type of involvement in a productive manner. Clients must choose to talk sincerely with their counselor just as they must choose to avoid temptation and return to the program each day. These choices may fluctuate widely and be mistaken at times, but such independence is the only path toward growing up. When a program properly encourages structure but ignores the client's own independence efforts, these actions undermine future success. Acupuncture creates a better atmosphere so that treatment staff can spend their energies helping clients make choices rather than being fatigued by trying to impose authority on a resistant clientele.

One can describe acupuncture as a foundation for psychosocial rehabilitation. In the beginning of treatment, building a proper foundation is very important. If we are building on a weak, "sandy" personality, work on the foundation may take many months or years before it is strong enough to support any significant psychosocial treatment efforts. However, once a foundation is established, the focus of treatment should shift away from acupuncture toward building a "house" of psychosocial recovery on that foundation. When one of our clients testified at city council hearings, she described how important it was to attend daily Narcotics Anonymous meetings and barely mentioned acupuncture. For an individual with 3 months sobriety, this emphasis was appropriate. Of course, during her first 2 weeks in our program, she was quite angry and ambivalent and was only able to relate to the acupuncture component of the program.

Non-verbal Therapy

Acupuncture is a non-verbal type of therapy. Words and verbal relationships are not necessary components of this treatment. We do not mean that the therapist should not talk with the client. Verbal interaction can be quite flexible so that a client who does not feel like talking can be accommodated easily and naturally. Acupuncture will be just as effective even when the client lies to us.

The most difficult paradox in this field is the common reality that addicted persons usually deny their need for help. Such individuals do not say anything helpful to the treatment process. Nevertheless, resistant clients often find themselves in a treatment setting due to referral or other pressures. Using acupuncture can bypass much of the verbal denial and resistance that otherwise limit retention of new and relapsed clients. Addicts are frequently ambivalent. Acupuncture helps us reach the needy part of their psyche that wants help. Acupuncture can reduce stress and craving so that individuals gradually become more ready to participate in the treatment process.

Addicted individuals often cannot tolerate intense interpersonal relationships. Using a conventional one-to-one approach often creates a brittle therapeutic connection. It is easily broken by events or any stress. Clients have difficulty trusting a counselor's words when they can hardly trust themselves. Even after confiding to a counselor during an intake session, clients may feel frightened and confused about expanding that relationship. Many of their concerns are so complex and troublesome that talking honestly about their lives could be difficult in the best of circumstances. The ambivalence typical of addicts makes it easy to develop misunderstandings. All of these factors support the usefulness of non-verbal techniques during early and critical relapse phases of treatment and critical periods of relapse.

A woman who was 6 months pregnant entered our clinic several years ago. She said, "I can't tell you much about myself because my husband is out in the street with a baseball bat, he'll hit me in my knees if I say too much." We provided an emergency acupuncture treatment and conducted a simplified intake interview. Two weeks later, this client told us, "This is my husband. He doesn't have a drug problem, but he is nervous. Can you help him?" Both of them received acupuncture that day. The woman needed non-verbal access to treatment because of real physical danger. Overprotective spouses often forcefully oppose all social contacts outside the marriage. This client was protected because there was no premature verbal bonding that would have threatened the husband. The whole process was so supportive that the husband was able to trust his wife and seek help himself. Like many fearful people, he was literally unable to make any verbal approach on his own.

A certain mistake in treatment interaction should be highlighted. One should avoid reverbalizing the acupuncture interaction. Anxiety and depression are common indications for acupuncture. However, it is a mistake to require that the client admit to anxiety or depression in order to qualify for acupuncture. Addicts who have significant anxiety or depression will

usually not admit these feelings. They will avoid anyone who asks such questions. At a later stage of sobriety and recovery, talking about these feelings will be important, but at an early stage of treatment, verbalizing these feelings can lead to dropout. Likewise, it is not productive to ask clients why they have missed a previous acupuncture session. Use the advantage that acupuncture will be effective even if we don't know the issues involved.

Improving Treatment Program Function

Treatment programs without acupuncture are compelled to screen for individuals who are able to talk readily with authority figures. Many verbally needy clients become quite dependent on the program and quite involved with numerous staff members. Such individuals may be the focus of many conferences, but they are often too needy to remain drug-free outside the hospital. In contrast, acupuncture-assisted intake can retain clients who are relatively more paranoid, independent, assertive, and hostile. Noisy, troublesome individuals who are frustrated with the world and with themselves actually may be more likely to sustain a drug-free lifestyle than those with verbal dependency needs.

Acupuncture helps a program develop an underlying environment of acceptance, tolerance, and patience. There is ample space for the ambivalence and temporary setbacks that are a necessary part of any transformation. Clients can have a quiet day by attending the program and receiving acupuncture without having to discuss their status with a therapeutic authority figure. Since acupuncture reduces the agitated defensive tone in the whole clinical environment, clients are able to interact with each other on a much more comfortable level. Their increased ability to listen to others and accept internal changes have a profound effect on the quality and depth of communication in group therapy sessions and 12-step meetings. Being a sympathetic witness to a description of past tragedies can be easier to achieve in a setting that is not charged with defensive self-centered associations. The primary community agenda can focus on the acceptance of each person and a tolerant encouragement of change rather than coping with defensive and antagonistic interactions.

Clinical Examples

Using acupuncture can be a catalyst for unique personal development, as the following two examples show.

(1) The author was demonstrating ear acupuncture at a dual-diagnosis program in a university medical center. The clients were able to see sample acupuncture treatments, but they were not specifically introduced to me. After sitting for a few minutes, one woman asked me in a strong voice, "Does this treatment help incest survivors?" I answered "sometimes". The client volunteered for the treatment and soon after she fell asleep. Later on, she asked me if she could talk to the local professional acupuncturists who were sitting nearby. She said, "This treatment helps me; I want to make an appointment in your office. . . . I can pay for the treatment." I was impressed and shared this experience with the rest of the staff.

    The staff replied that they could have made the appointment and could have paid for the treatment. The process of observing and requesting acupuncture was part of this client's survival process. She was able to express herself and make decisions on her own. A potentially cumbersome therapeutic and case management issue was resolved by the client's healthy initiative.

(2) The author was visiting an outpatient treatment program run for the Cook County Jail in Chicago. As an effort to reduce overcrowding, jail officials would release 50 pre-trial inmates per month to a brief intervention program. Part of the program was

a large acupuncture group. One of the participants came to me and said, "Do you see the blue ribbon on my belt? That means I belong to XXX gang. I have to kill anyone with a red ribbon on his belt, like this guy in YYY gang walking toward us." I didn't know what to do. "Why are you telling me these things?" I said. The two men met in the middle of the room. They gave each other a big hug. "This is a peace zone," they said. "Who made it a peace zone?" I said. "We did," they replied. Gang members are separated in jail lockup, but referral to the program had not taken that simple measure. The acupuncture led to self-affirming, gentle communication and a simple special outcome that no amount of counseling could have achieved.

Conclusion: Clients' Own Stories

To really know the power of acupuncture in the treatment of addiction, listen to clients who have experienced it as part of their recovery transformation:

> Acupuncture has gotten me where I don't have a really manic life and I'm not depressed. I'm able to deal with everything that comes my direction because I have a lot of support also. I am energized, not miserable. I feel great about myself. I can smile today and the smile has feelings behind it. Acupuncture has hooked me up spiritually. I found my higher power—God—and he leads me each and every day.
>
> I was into prostitution and pornography—a violent woman. I behave differently today. I live with principles that I believe were ignited, sparked in me with acupuncture. As cumulative as acupuncture is, it has reached me in this level that I am able to change my beliefs more comfortably. I am given courage to take a look at my beliefs and empower myself, and now empower other women. I stand under reality strong truth that women can recover, and I know that acupuncture is the most valuable tool I know for recovery.
>
> Talking to [counselors], getting acupuncture treatment—hate, anger, jealousy, vengefulness, vindictiveness, all that changed into compassion and love. The acupuncture treatment just helped the process change in the detoxin (sic) and everything.
>
> Someone helped me find a simple way to just be with my self long enough to see what I need to work on—where I was wounded and how I could heal. And it is like a quiet way for one person to help to give treatment to another person. Acupuncture is a way to help sand the rough edges of what is going to be changed. It will give you a place to take all your other things into, and help create the change [22].

Part X
Computer Modeling

In Silico Models of Alcohol Kinetics: A Deterministic Approach

Marc D. Breton

Contents

Introduction

In recent years, the mathematical representation of physiological systems and its use in computer simulations have come of age. Initially restricted to pharmacokinetics and pharmacodynamics studies, they are now used in many different fields of medicine—e.g., diabetes and metabolic syndrome—to explore previously inaccessible metabolic markers, develop candidate treatments, and even obtain authorization of regulatory agencies for clinical research, therefore bypassing animal testing. The field of alcohol addiction is of particular interest for such applications; it is both very developed (e.g., in modeling the dynamics of ethanol in blood or the diffusion from blood to brain tissues) and in its infancy, with only two simulation studies in the past 20 years [3, 4]. It also requires modeling of behavioral system and medication effects that are not yet mainstream (see Chapter "In Silico Models of Alcohol Dependence Treatment: Stochastic Approach"). In this chapter, we present several published and novel models of ethanol blood distribution, leading to simulation studies linking system-level characteristics to clinical outcomes.

Mechanisms of Alcohol Intoxication

Ethyl alcohol, also known as ethanol, is the substance found in alcoholic beverages. It is a colorless liquid that mixes in all proportions and, therefore, is readily distributed throughout the body in the aqueous bloodstream after consumption. Also because of this water solubility, it readily crosses important biological membranes, such as the blood-brain barrier. After it reaches the brain, alcohol affects multiple molecular targets, some of which remain unknown. In particular, alcohol causes gamma-aminobutyric acid receptors to remain open longer, allowing

more chloride ions to enter brain cells and, therefore, causing relaxation, sedation, and overall inhibition of brain activity. At low concentrations, alcohol sensitizes the glutamate system, which stimulates areas of the brain associated with pleasure such as the cortico-mesolimbic dopamine system. With chronic exposure to alcohol, the brain undergoes long-lasting biochemical changes including neurological adaptation of the ion channels. Alcohol also is responsible for structural changes in the brain, such as loss of neuronal mass and brain shrinkage, which, in turn, is responsible for impaired cognitive function. Interestingly, the maximum quantity of alcohol consumed, such as in binge drinking, seems to be a better predictor of alcohol-related impairment. Hence, understanding the elimination process of alcohol will, to a certain degree, help us predict the extent of the neurological adaptation that takes place with chronic alcohol use.

Alcohol Metabolism

When we consume alcohol, the majority of it is absorbed from the small intestine (approximately 80%) and the stomach (approximately 20%). Generally, drinking more alcohol within a certain period of time will result in increased blood alcohol concentrations due to more alcohol being available for absorption into the bloodstream. More than 90% of the alcohol that enters the body is completely metabolized in the liver. The remaining 10% is not metabolized and is excreted in the sweat, urine, and breath. There are several routes of metabolism of alcohol in the body. The major pathways involve the liver and, in particular, the oxidation of alcohol by alcohol dehydrogenase to produce acetaldehyde, a highly toxic substance. The second step is catalyzed by acetaldehyde dehydrogenase. This enzyme converts acetaldehyde to acetic acid, a non-toxic metabolite. Acetic acid is eventually metabolized to carbon dioxide and water. Another system in the liver oxidizes ethanol via the enzyme cytochrome P450IIE1. This microsomal ethanol-oxidizing system seems to play a more important role at higher concentrations of ethanol.

Individual Differences in the Rate of Alcohol Metabolism

There are genetic variations in the P450E1 enzyme system that lead to individual differences in the rate of ethanol metabolism among people [5]. The rate of alcohol metabolism depends, in part, on the amount of metabolizing enzymes in the liver, which varies among individuals and appears to have some genetic determinants. After the consumption of one standard drink, the amount of alcohol in the drinker's blood usually peaks within 30–45 min. (A standard drink is defined as 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of 80-proof distilled spirits, all of which contain approximately the same amount of alcohol.) The concentration of alcohol in the entire body, including the brain, is always less than that in the blood; human tissues contain a much lower percentage of water compared with the blood. However, organs having a rich blood supply, such as the brain, will quickly reach alcohol diffusion equilibrium with arterial blood. This explains why most people experience intoxication very quickly after taking a couple of drinks and then sober up rapidly as other bodily tissues with less blood supply, such as the muscle, start to absorb alcohol from the blood, meaning that less alcohol is circulating in the bloodstream.

Methods: Mathematical Modeling of the Pharmacokinetics of Ethanol

Ethanol elimination has been assumed to exhibit a zero-order metabolism, which means that constant amount of alcohol is eliminated per unit of time regardless of blood levels. However, a number of studies have identified that

elimination of ethanol follows different clearance models including first-order kinetic and a combination of zero- and first-order kinetic together. This, coupled with individual genetic differences, makes it hard to predict blood alcohol concentration based on total amount of alcohol consumed [12]. Since the early twentieth century, efforts have been directed toward the understanding of alcohol dynamics in humans and, more specifically, the blood concentration of ethanol.

Numerous models have since been devised, beginning with the early Widmark zero-order model assuming a constant clearance rate β_0 (equation (1)) and modeling the human body as one compartment (concentration, or blood alcohol level, BAL(t) and constant volume V) [14] (Fig. 1).

$$\frac{\partial BAL}{\partial t} = -\beta_0 BAL + \frac{D(t)}{V} \tag{1}$$

where $D(t)$ is the dose of ethanol received. This zero-order model is still commonly used in forensic sciences for its ease of use and the relative simplicity of its structure (very few parameters, easily identifiable). Nonetheless, this oversimplification of the clearing process of ethanol is responsible for additional variability in the model coefficients, within and more importantly between subjects. It is this between-subject variability, in particular, that makes the Widmark model ill defined for simulation purposes.

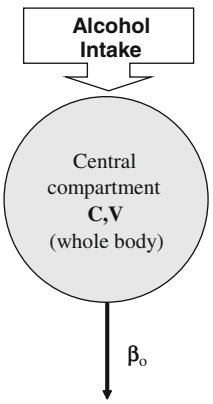

Fig. 1 Widmark's zero-order model

A deeper understanding of the processes involved and novel measuring tools have allowed more precise measurement and understanding of ethanol pharmacokinetics and the development of more complex non-linear multi-compartment models [7–9, 11]. Most of these models are compartmental—e.g., they represent the human body as a set of homogeneous (i.e., the ethanol concentration is the same everywhere) compartments of specific concentration and volume linked by diffusion or rate-limited pathways. The study of ethanol kinetics in vivo has led to a better representation of the ethanol-aldehyde-acetate process, leading to Norberg's model of alcohol dynamics [8] (Fig. 2), which introduces a Michaelis-Menten rate of alcohol clearance—a common enzyme-catalyzed, rate-limited clearance model; see Equation (2).

$$\begin{cases} \dfrac{dC_B}{dt} = -\left(CL_R + CL_d\right) C_B - \dfrac{V_{\max} C_B}{K_m + C_B} \\ \dfrac{dC_T}{dt} = -CL_d \left(C_T - C_B\right) \end{cases} \tag{2}$$

where C_B stands for blood ethanol concentration, C_T is the tissue concentration, CL_R is the renal clearance, and CL_d is the diffusion constant.

It is now widely accepted that alcohol clearance is a Michaelis-Menten controlled reaction—an enzyme-enhanced chemical reaction with limited supply [6]. These previously introduced models allow for a mathematical description of alcohol clearance following intravenous alcohol injection (Fig. 3).

Though it is able to represent closely the clearance processes of ethanol in blood, this type of model is often unwieldy compared with the first-order Widmark model. The larger number of parameters and the non-linearity of the model make the parameter estimation procedure difficult and sometimes yield imprecise estimates. For example, $V_{\max}$ and K_m are often highly correlated, as are the variances of their estimates. These numerical limitations can be alleviated by proper design of clinical data collection—e.g., the ethanol dose should be greater than two standard drinks, and numerous samples should be obtained at low levels. These restrictions should

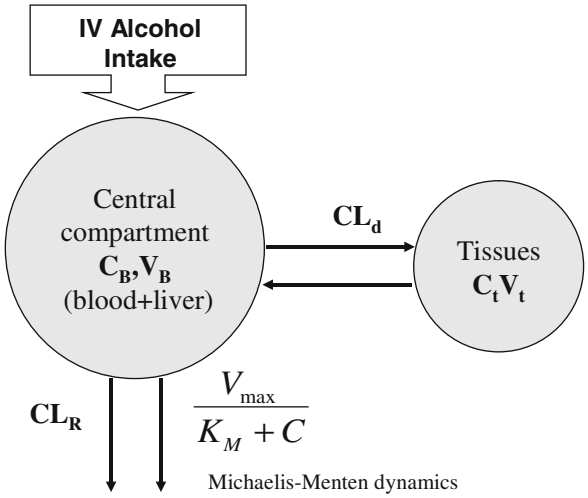

Fig. 2 Norberg's alcohol clearance model featuring Michaelis-Menten dynamics. Suitable for description of intravenous (IV) ethanol injection

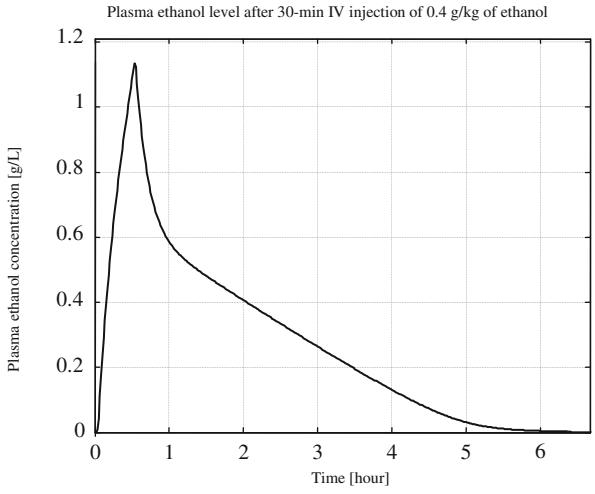

Fig. 3 Blood alcohol level following intravenous (IV) ethanol injection

be supplemented by specific numerical techniques such as initialization of the minimization procedure (see the section below) [9].

However, the dynamics of orally ingested alcohol has not been well quantified. The compartmental model in Fig. 2 cannot reproduce the dynamics of blood alcohol level presented in Fig. 4. In particular, the increase in blood alcohol level after alcohol ingestion is poorly described.

This is partly due to the slow diffusion of ethanol from the gastrointestinal tract to blood; whereas with intravenous injection the total dose of ethanol is immediately present in blood and its concentration is at equilibrium after a couple of minutes, orally ingested ethanol can take much longer to percolate fully from the digestive system to blood, therefore allowing for clearance even before the full dose has transferred to the blood. Modeling this process is difficult as ethanol diffuses to the blood from both the stomach and the intestines and at different rates; the speed of gastric emptying (and, therefore, the content and amount of what is ingested with alcohol) also plays a critical role in the dynamics of absorption.

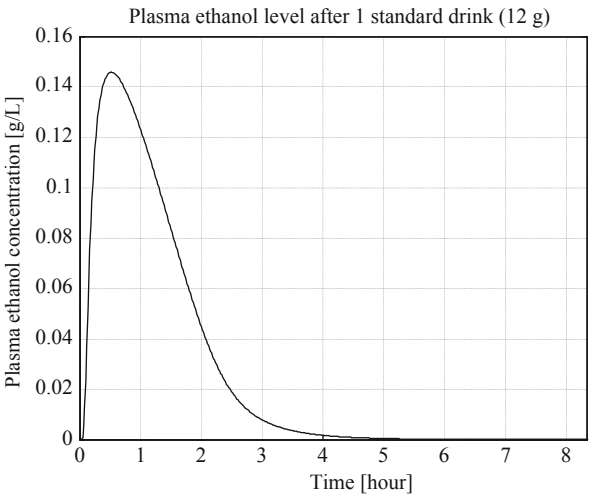

Fig. 4 Blood alcohol level following oral alcohol ingestion

The Minimal Model of Ethanol Kinetics

Here, we present a model directly derived from the work of Norberg (see above) but including a two-compartment model of the gastrointestinal tract. This allows us to make use of the simplicity of Norberg modeling, keeping the model complexity to a minimum (the number of equations and parameters to estimate), while also allowing for a semi-physiological representation of ethanol absorption and clearance, ultimately leading to the possibility of simulation of ethanol ingestion and finally drinking behavior.

Figure 5 presents the compartments included in the Minimal Model of Ethanol Kinetics. To represent properly oral alcohol intake, the model needs to include at least two compartments of the gastrointestinal tract: the stomach and gut. Following the minimal model approach, we do not need to add more compartments unless it is proven that the two-compartment gastrointestinal tract model is inherently insufficient. Further, the processes linking these compartments include one-way diffusions from the stomach and the gut into the bloodstream (ethanol in the blood cannot diffuse back to the gastrointestinal tract). Final assumptions of the model

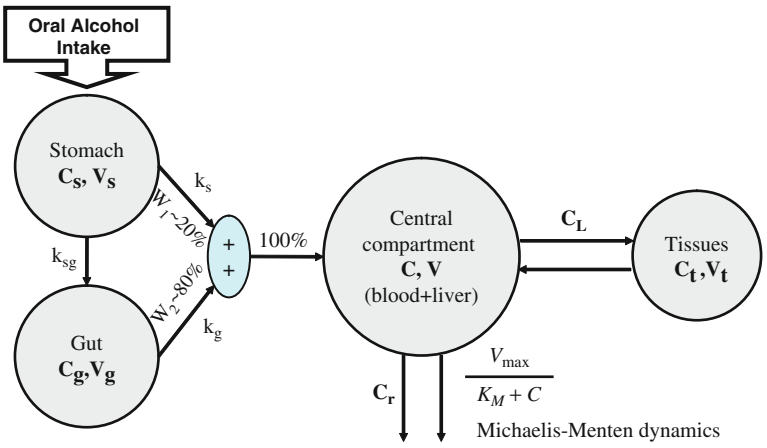

Fig. 5 The minimal model of ethanol kinetics following oral alcohol intake. The model allows the computation of the idiosyncratic Alcohol Sensitivity Index

include gastric emptying following an exponential decay with a certain half-life (e.g., 50 min [15]) and the proportion of gastric diffusion from the stomach W_S versus diffusion from the gut W_G (e.g., $W_S = 20\%$ versus $W_G = 80\%$ [1]).

The differential equations governing the processes depicted in Fig. 5 are as follows:

1. Ethanol is transported from the stomach to the gut with a rate constant k_{SG} and diffuses from the stomach into the bloodstream with a rate constant k_G.

$$\frac{\partial C_S}{\partial t} = \frac{1}{V_S W}\left(I(t) - k_S C_S - k_{SG} C_S\right) \quad (3)$$

2. Ethanol diffuses from the gut into the bloodstream with a rate constant k_G.

$$\frac{\partial C_G}{\partial t} = \frac{1}{V_G W}\left(-k_G C_G + k_{SG} C_S\right) \quad (4)$$

3. The total ethanol diffusion into the bloodstream is then given by the combination of diffusions from the stomach and the gut.

$$D(t) = k_G C_G + k_S C_S \quad (5)$$

4. Michaelis-Menten clearance of ethanol from the bloodstream occurs.

$$C(t) = \frac{V_m}{K_m + BAL(t)} BAL(t) \quad (6)$$

5. Two-way diffusion of ethanol between the bloodstream and tissues/liver occurs, including ethanol transport to the brain.

$$\begin{cases} \dfrac{\partial BAL}{\partial t} = \dfrac{1}{V_C W}(D(t) + CL_d(TAL(t) \\ \qquad\qquad -BAL(t)) - CL_r BAL(t) - C(t)) \\ \dfrac{\partial TAL}{\partial t} = \dfrac{CL_d}{V_T W}\left(BAL(t) - TAL(t)\right) \end{cases} \quad (7)$$

Identification of Model Parameters: From Population Averages, Through Individuals' Specific Profiles, to the In Silico Population

Population Averages

Using the previously described model, one can fairly easily extract the population average values from the literature. In particular, parameters common to Norberg's two-compartment model can be found in Norberg and colleagues [9]. Tuning of the gastric model is somehow more complex but can be done to reflect the generally admitted equilibrium between the stomach and gut of 20% versus 80% and the 50-min half-life of gastric emptying. While these values are enough to simulate the dynamics of ethanol and to extract interesting general characteristics of the addiction process, they do not reflect the large variability observed in vivo and, therefore, do not allow the study of a specific group of subjects and, *a fortiori*, a particular subject.

Subject-Specific Identification

We propose a clinical data collection based on the 20-point sampling protocol presented in Fig. 6. This protocol is similar to the standard profile used for determination of insulin resistance [2, 13] and is modified to account for the specifics of ethanol dynamics. Under this protocol, plasma blood alcohol level samples are collected at times $(t) = -30$, 0, 5, 10, 15, 20, 30, 40, 50, 60, 75, 90, 120, 150, 180, 210, 240, 300, 360, and 420 min. Time 0 is the time of initiation of oral alcohol intake. The total amount of ingested alcohol is equivalent to three standard drinks (45 g of ethanol), and, therefore, the average blood alcohol level profile of a person would be similar to the profile presented in Fig. 4. The blood alcohol level measurement prior to initiation of alcohol intake provides a baseline used for calibration; denser sampling is anticipated during the expected increase in blood alcohol

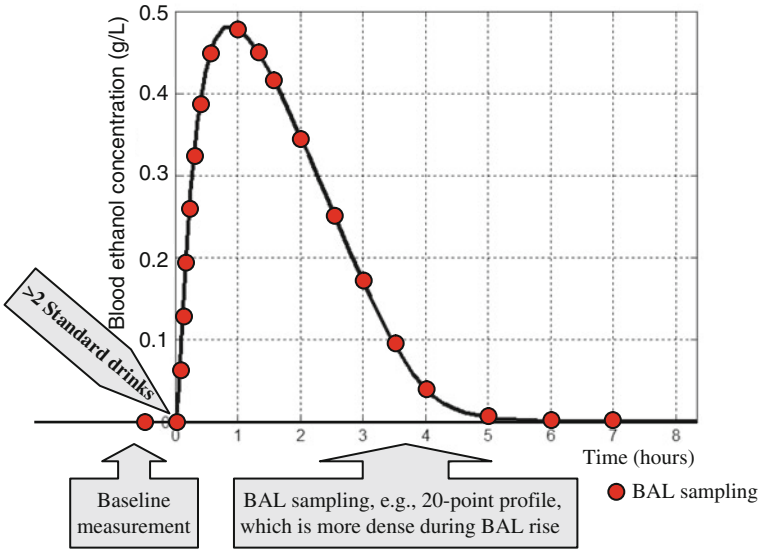

Fig. 6 Common features of a clinical testing protocol collecting data for an individual ethanol dynamics profile. The blood alcohol level (BAL) sampling can be done directly through blood samples, or using a breath analyzer

level, and less frequent sampling is anticipated during blood alcohol level decay.

A gradient search, simplex, or other nonlinear optimization technique is used to minimize the distance between the predicted blood ethanol concentration course of the model and the data collected as described above. Examples of distances include—but are not restricted to—the Euclidian norm (least square), infinite norm (maximum), and weighted least square, the most common being the Euclidian norm.

At convergence, the optimal parameters for this specific subject are fixed, and the model can be used to study the reaction of this subject to different scenarios, including some not easily reproducible in vivo (e.g., extreme/dangerous drinking).

In Silico Population

By repeating the procedure above on a large number of individuals, in different conditions (e.g., fasting versus fed, with a meal or not), we can start to understand the distribution of the model parameters—their mean, bounds, spread, and correlation with each other. With such a distribution, it then becomes possible to create an entirely simulated population spanning the entire (or a chosen subset of) space of possible reactions. In turn, this population can be used for simulated trials, as described in detail in Chapter "In Silico Models of Alcohol Dependence Treatment: Stochastic Approach".

Results: In Silico Studies of Blood Ethanol Time-Concentration

To illustrate the use of such models, we present in silico experiments reproducing key features of the ethanol metabolism system reported in the literature. The parameters of the Minimal Model of Ethanol Kinetics were first estimated using data available in the literature and from prior studies; then, the model was applied to study the behavior of the system during simulated drinking of 1 through >10 standard drinks dispersed randomly throughout an average day.

Experimental Setting of the Computer Simulation

The computer reproduced the system behavior over 72 drinking days. The simulation of a day of

drinking was based on the generation of a typical drinking day, taking into account the given average number of drinks per day. For example, with 4 preset drinks/day on average, the computer generated a 72-day sequence of drinking days with any number of drinks (i.e., between 1 and 15) dispersed throughout each day, amounting to 4 drinks/day on average.

This was done by modeling a drinking day as a Wiener stochastic renewal process, which means that the time between drinks is a Gaussian (normal) random variable. To follow a more reasonable pattern of drinking, we also limited the drinks to be between 7 A.M. and 11 P.M.—i.e., what we considered a standard daytime. The mean time between drinks was set at the ratio of the number of daytime minutes to the average number of drinks per day, and its coefficient of variation was set at 20%.

Each drink was standardized and set to be equivalent to a glass of wine—12 g of ethanol in 100 ml (3.5 oz)—consumed in 5 min. The simulation was run for 72 days (100,000 min) in a standard human model (i.e., a weight of 70 kg). The time course of blood alcohol level was recorded for each run. The range of average drinks per day was bounded between 1 and 15. Initial settings for identifying the Minimal Model of Ethanol Kinetics were adopted from the literature: $C_{max} = 0.1614$ g/L, $t_{max} = 47$ min, and AUC = 0.23 g × h/L (area under the curve) [5, 9, 10].

Two outcome measures were analyzed from this in silico experiment: the minimum of blood ethanol concentration over daytime and over 24 h. Each measure was calculated for each day between days 10 and 72, avoiding the initiation period of 9 days to allow the system to become stationary; the mean blood alcohol level was computed as well.

Figure 7 presents the minimum blood alcohol level during daytime as a function of the average number of drinks per day. In other words, the line represents whether or not the blood alcohol level would ever go down to zero during the day. The computer simulation shows that with up to 5 *drinks/day on average*, the minimum blood alcohol level during daytime is zero, indicating that the system reaches its steady (sober) state at least for a while during the day. Between 5 and 11 drinks/day, there is a linear increase of the minimum blood alcohol level (slope = 0.0235, $R^2 = 0.99$). After 11 drinks/day, the slope of the linear relationship increases dramatically to 1.71 ($R^2 > 0.99$).

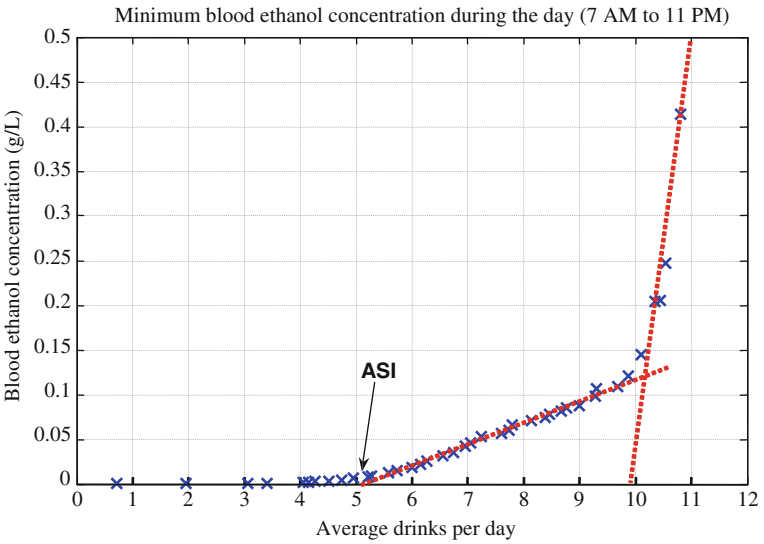

Fig. 7 Minimum blood alcohol level during daytime (7 A.M.–11 P.M.) as a function of average number of drinks per day. ASI = Alcohol Sensitivity Index

Thus, the computer simulation indicates that there are two well-defined threshold points defining abrupt system changes: 5 and 11 *drinks/day on average*. The first threshold point, at 5 drinks/day, indicates the transition of zero versus non-zero daily (7 A.M.–11 P.M.) blood alcohol level minimum. This means that with 4 drinks/day or less, the system is still capable of metabolizing fully the ingested alcohol, whereas at 5 or more drinks/day, there is always a certain residual amount of alcohol. From a system biology point of view, this first critical point indicates a phase transition from stable to unstable system dynamics. This is well visualized by the Poincaré plots in Fig. 8.

As seen in Fig. 8, 5 or more drinks/day would cause metabolic perturbations, never allowing the system to come to rest; the left panel represents a sustainable system dynamics, while the right panel represents a system that is clearly out of control.

This computer simulation result is consistent with—and to some degree explains at a system physiology level—the generally accepted understanding of heavy drinking defined as 5 or more drinks/day. *It appears that this critical value is not only an empirically established threshold but also an indication of an abrupt metabolic phase transition*.

To explain the second threshold value of 11 drinks/day, we need to look at the nighttime. As presented in Fig. 9, the minimum blood alcohol level during the night (11 P.M.–7 A.M., which was simulated as free of drinking) reaches zero for up to 11 drinks consumed during the day (7 A.M.–11 P.M.). When the number of drinks during the day exceeds 11, the system cannot metabolize the amount of consumed alcohol even during the nighttime hours, which are free of drinking.

Thus, 11 or more standard drinks/day results in a transition of the system dynamics to a higher blood ethanol value, which never goes down to zero. Because every morning there is still residual ethanol in the bloodstream, there is a very steep rise of blood alcohol level after 11 drinks/day. This explains the abrupt change in the slope of the dependence of blood alcohol level on average number of drinks per day depicted in Fig. 7.

Conclusion

In summary, the Minimal Model of Ethanol Kinetics is capable of reproducing (via computer simulation)—and to some degree explaining—the well-known empirical definition of heavy drinking, i.e., 5 or more standard drinks/day for men. The model also suggests other extreme situations, such as those that would occur with

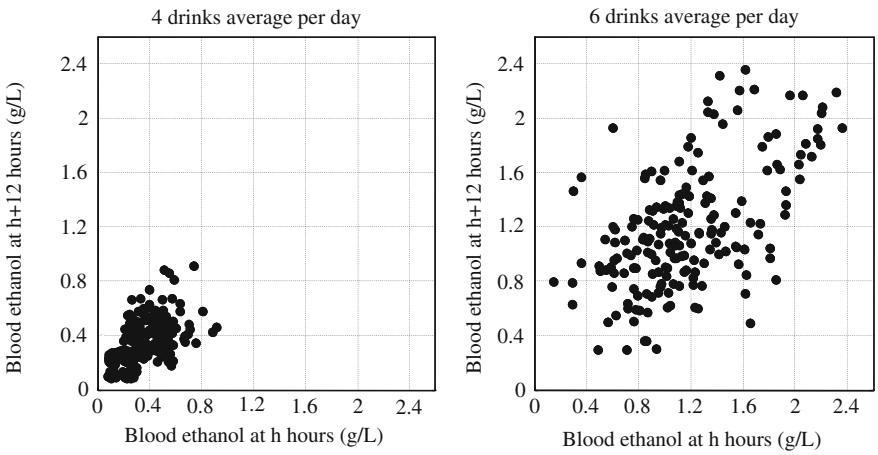

Fig. 8 System phase transition from stable to unstable dynamics indicated by Poincaré plots of the system attractor

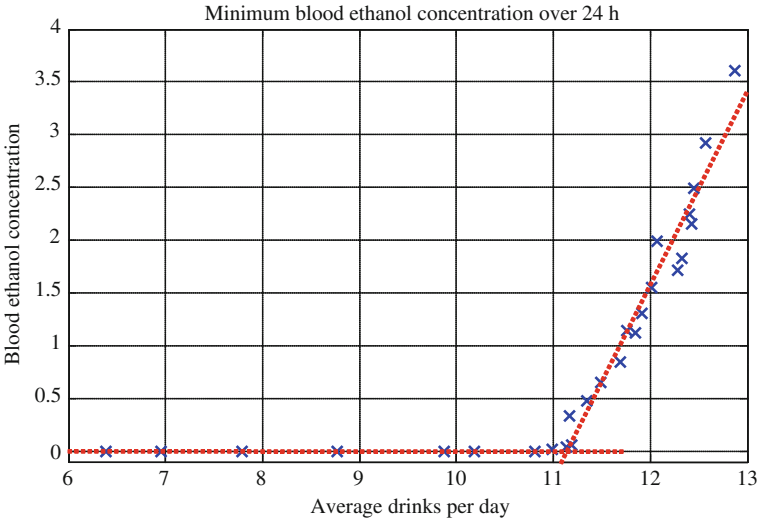

Fig. 9 Minimum blood alcohol level during the night (11 P.M.–7 A.M.) as a function of average number of drinks during the day (7 A.M.–11 P.M.)

more than 11 drinks/day, which theoretically should result in a protracted cognitive impairment due to continuous alcohol intoxication.

In this computer simulation, we used average parameters of alcohol metabolism. The Minimal Model of Ethanol Kinetics will allow for the computation of such parameters for each individual. This, in turn, is expected to facilitate the tailoring of individualized treatment.

This approach can be expanded to in silico studies of alcohol addiction, as presented in Chapter "In Silico Models of Alcohol Dependence Treatment: Stochastic Approach". With the creation of an in silico population, spanning the large observed variability in absorption and clearance of alcohol, it would become possible to study further drinking behavior as part of a high-order metabolic system, thereby applying long-held methods pertaining to system engineering to supplement/enhance well-known techniques used in the actual prevention/treatment of alcohol addiction. Further along, it will become possible to run preclinical testing of varied treatment strategies, as was done recently in the case of an artificial pancreas study, bypassing long-term animal studies and greatly accelerating the transition from medication development to human testing.

Introduction

In the past two decades, computer simulation and computer-aided design have made dramatic progress in all areas of development of complex engineering systems. A prime example is the Boeing 777 jetliner, which has been recognized as the first airplane to be 100% digitally designed, assembled, and tested preflight in silico, e.g., in a computer simulation environment. This virtual design has eliminated the need for many costly experiments and accelerated immensely the development process. The final result has been impressive; the 777s flight deck and passenger cabin received the Design Excellence Award of the Industrial Designers Society—the first time any airplane was recognized by the society [4]. There is an enormous body of literature on computer simulation methods applicable to physics, engineering, economics, biology, metabolism, aerospace, meteorology and climatology, warfare, and just about any other subject of investigation that can be approximately described by a mathematical model. The review of this literature is beyond the scope of this chapter; here we will only mention a few biomedical modeling and simulation projects that are relevant to the topic at hand—in silico prediction of the effects of alcohol dependence treatment. For example, accurate prediction of the outcome of clinical trials has been achieved using the Archimedes diabetes model [10, 11]. Entelos, Inc., specializes in predictive biosimulation, introducing in its Physiolab suite in silico models for various physiological systems: cardiovascular, metabolic (diabetes), and others [27].

These in silico models are typically based on mathematical models of the studied physiological system, which are developed from extensive

data collection examining underlying physiology in sufficient detail to allow for formal modeling. The models are then used to develop algorithms and software that power up simulation experiments. According to Winsberg [41], simulation experiments are typically classified with respect to the type of algorithm that they employ: "Discretization" techniques transform continuous differential equations into step-by-step algebraic expressions. "Monte Carlo" methods use random sampling algorithms even when there is no underlying indeterminism in the system. "Cellular automata" assign a discrete state to each node of a network of elements, and assign rules of evolution for each node based on its local environment in the network. In this chapter, we will utilize both discretization and Monte Carlo (or generally stochastic) methods, but first we will discuss three types of mathematical models of biosystems, classified according to the purpose of modeling: models to *measure*, to *simulate*, or to *control* the biosystem under consideration.

Models to Measure

The models to measure are generally simpler, allowing hidden relationships to be evaluated by estimating underlying parameters. Most of these models are compartmental; e.g., they represent the human body as a set of homogeneous compartments of specific concentrations and volumes linked by diffusion or rate-limited pathways. Classic examples include the Widmark Model of Ethanol Pharmacokinetics Assuming, which offers a straightforward interpretation with a constant ethanol clearance rate and the human body modeled as one compartment [40], and the more complex Minimal Model of Glucose Kinetics suggested by Bergman and Cobelli almost 30 years ago to measure insulin resistance in health and diabetes [5]. More recently, with the advent of the digital biology paradigm, various models to measure have been developed addressing pharmacokinetics, physiology, and human behavior. Deeper understanding of the processes involved and the development of novel measuring tools have allowed for more precise measurement of ethanol pharmacokinetics and the development of more complex non-linear models [28, 29, 30, 39]. The study of ethanol kinetics in vivo has led to a better representation of the ethanol-aldehyde-acetate process via the Michaelis-Menten rate of alcohol clearance introduced by Norberg [29]. It is now widely accepted that alcohol clearance is a Michaelis-Menten controlled reaction—i.e., an enzyme-enhanced chemical reaction with limited supply [39]. These and other pharmacokinetic models are discussed in detail in Chapter "In Silico Models of Alcohol Kinetics: A Deterministic Approach".

Models to Simulate

The models to simulate are maximal multiparameter models describing the complexity of the system as comprehensively as possible [7, 8]. For example, the recently published meal model of glucose-insulin dynamics is a descendant of the Minimal Model, which encompasses several metabolic subsystems including the gastrointestinal tract, renal function, hepatic glucose production, and others [7, 8]. When a maximal model is built, the computer simulation of the observed biosystem becomes possible, leading to in silico trials involving virtual "subjects" rather than real people. Such in silico trials can serve as precursors guiding expensive and time-consuming clinical investigations by outruling ineffective treatment approaches. For example, a recently developed simulator of the human metabolic system has received Food and Drug Administration approval and recognition for the preclinical testing of control strategies in artificial pancreas studies [21]. Using this simulator, the time for refining and safety testing of new algorithms that target the closed-loop control of diabetes has been reduced from years to several months [19, 24, 31]. Therefore, realistic computer simulation is capable of providing valuable information about the effectiveness, safety, and

limits of various treatments. Computer simulation allows experiments with extreme situations and testing of extreme failure modes that are unrealistic in animals and clinically impossible in humans. Besides extreme experiments, various treatment scenarios can be efficiently tested and either rejected or accepted for inclusion in future clinical experiments, which allows for rapid, comprehensive, and cost-effective clinical trial design. *We need to emphasize, however, that good* in silico *performance of a treatment does not guarantee* in vivo *performance. Computer simulation should* only *be used to reject inefficient treatments; it cannot confirm the efficacy of an intervention.*

Models to Control

External control of a complex technical or living system is generally achieved by control algorithms that are based on a certain mathematical representation of the system—a model to control—combined with the ability to observe the system in real time and make immediate decisions for correction of the system state. The models to control are typically simplified (frequently linearized) models that allow for rapid observation and computation of the corrective action. A prime example of medical devices that use adaptive control algorithms is the cardiac pacemaker, which in the past two decades has been incorporating automated control functions such as automatic capture and sensing control, self-adjusting rate response settings, sinus rhythm and atrioventricular conduction preference, and others [13, 17, 37, 42]. In diabetes, successful attempts at external closed-loop control have been made using various systems and algorithms, from cumbersome intravenous systems and implantable devices [1, 33, 36] to external subcutaneous control [15, 18, 38]. Relating control to simulation, comprehensive in silico testing of control algorithms is an efficient strategy if a model to control is tested against a much more complex model to simulate. In other words, the effectiveness of a controller can be judged if it is tested in realistic in silico conditions, which can be achieved by a comprehensive simulation model.

Formal Description of Human Behavior and Social Conditioning

In the context of in silico models of alcohol dependence treatment, applicable quantitative strategies include models to measure and models to simulate. In order to build such models, a formal mathematical description of human behavior and environmental conditioning is needed. However, the behavioral and social modeling field is still quite limited. Whilst several theoretical models based on internal somatic perception have been proposed [3, 22, 23], their heuristic approach has not permitted their development in sufficient mathematical detail to guide data analysis. For example, the stages of change described by the Transtheoretical Model of DiClemente and Prochaska [9] refer to a stochastic sequence—of readiness to change, stage of change status, temptation, and confidence—that has consistently shown predictive and explanatory ability for clinical outcome in alcohol dependence treatment studies. However, this sequence has not been identified as stochastic and has not been formalized to the extent that would permit computerized assessment and simulation. Another example can be provided in the context of non-specific treatment effects, such as the Hawthorne effect, which describes the tendency of an individual to change his or her behavior as a consequence of being observed or studied [26, 35]. While this effect provides evidence for the importance of environmental conditioning and external reinforcement for all stages of the progression of alcohol dependence—from acquisition of alcohol dependence, through treatment, to potential relapse—there is no formal description of environmental conditioning that would allow its inclusion in an integrated in silico model encompassing physiology, behavior, and social conditioning. Therefore, to advance the field, we have proposed a formal stochastic bio-behavioral

model of the sequence leading to self-regulation decision, in which the first three steps of the process were described by continuous variables while the decisions at Step 4 were binary [19]. The general concept is that decisions concerning self-regulation behaviors are often based on perception and appraisal of the body's internal state. Thus, the sequence preceding a certain action includes at least four sequential steps: internal condition perception environmental conditioning self-regulation decision. We have applied this general framework to evaluate the relationship between self-treatment behavior and the development of hypoglycemia in diabetics [6, 12], as well as the psycho-physiological factors associated with the attention impairment experienced by those with attention deficit hyperactivity disorder [20, 32, 34].

Combining Biology and Behavior In Silico

In this chapter, we view alcohol dependence and the response to alcohol dependence treatment as a recurrent bio-behavioral process developing in time. Such an approach captures the dynamics of sequential changes occurring during acquisition of alcohol dependence, successful treatment, or relapse. We will provide a rigid mathematical framework describing formally these dynamics. To do so, we first will introduce a stochastic model of behavioral and social conditioning describing the frequently random[1] effects of human behavior and social reinforcement. We then will merge this stochastic model with the deterministic model of alcohol metabolism described in Chapter "In Silico Models of Alcohol Kinetics: A Deterministic Approach". In combination, these two models provide the background for in silico interpretation of biology and behavior in their relationship to treatment effect. To represent formally behavioral and social conditioning, we will identify several sequential steps. Each step is represented by a probability distribution, and the set of these distributions across all steps regulates the feed-forward relationships of the process from internal condition to self-regulation decision. *Each person* is represented by an individual treatment effect profile, defined as the set of transition probabilities between the sequential steps of the model specific to that person. This model serves as a stochastic behavioral generator of events, each event being a drink, which is supplied as an input to an individualized model of alcohol metabolism. In other words, the in silico experiments with alcohol dependence treatment use behavioral and social parameters that serve as generators of metabolic disturbances to the system (person), which are then processed through an individualized metabolic model, thereby allowing the formal decomposition and reconstruction of the patterns of drinking behavior and their modulation by placebo or medication treatment. We will illustrate our proposed approach by re-analyzing data from a study of ondansetron for the treatment of alcohol dependence [16] and will include in the model the non-specific placebo effects that occurred before the active treatment phase of the study [32], with a special emphasis on the highly significant differences between heavy and non-heavy drinkers observed during the study.

[1] Here we need to make a distinction between the lay and scientific understanding of randomness: scientifically a random variable is a variable that can assume a set of values with certain probabilities comprising its distribution. For example, any constant is a random variable assuming its only value with probability 1 and all other values with probability 0. Other random variables have normal (Gaussian) distribution; others have uniform distribution, etc. The lay understanding of randomness typically refers to uniformly distributed variables that can assume any of multiple values with equal probabilities.

Methods

Recurrent Bio-Behavioral Process of Alcohol Dependence and Treatment

Figure 1 presents the general concept of the self-reinforcing recurrent bio-behavioral process

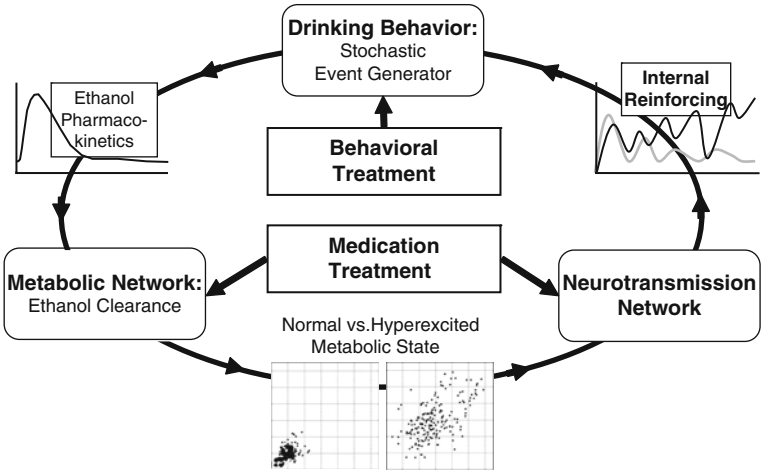

Fig. 1 Recurrent bio-behavioral process of alcohol dependence and treatment

describing the progression of alcohol dependence, its remission through medication or behavioral treatment, and potential relapse.

As presented in Fig. 1, the system (person) is represented by several blocks (components) linked via a circular pattern of sequential steps. First, a behavioral event generator actuates system disturbances (e.g., drinks), which cause metabolic disturbances that can be different for each person, depending on his or her individual parameters of alcohol pharmacokinetics. Further, when the metabolic network is subjected to recurrent stress, the intensity of stress determines whether or not a phase transition to a hyperexcited metabolic state would occur. (Metabolic phase transitions are discussed in Chapter "In Silico Models of Alcohol Kinetics: A Deterministic Approach".) A chronic hyperexcited metabolic state would influence the neurotransmission network, potentially leading to alcohol dependence. This in turn would result in a high degree of internal reinforcing (craving), which accelerates the behavioral event generator by triggering excessive drinking. Medication treatment would typically target the neurotransmission or the metabolic component of this recurrent process, while behavioral treatment would attempt to reduce the frequency of firing of the behavioral event generator. With this formal overall understanding, we shall now proceed to a mathematical description of the general components of the alcohol dependence process that would be used for its in silico representation and treatment evaluation: (1) a mathematical model of the human metabolic system specifically targeting ethanol kinetics; (2) a stochastic model of behavioral and social conditioning, and (3) a comprehensive population of in silico "subjects" spanning the observed in vivo inter-individual metabolic and behavioral differences.

In Silico Models of Ethanol Metabolism

As presented in the Introduction, several models of ethanol metabolism exist [28–30, 40]. Based on these models, we have proposed the Minimal Model of Ethanol Dynamics (see Chapter "In Silico Models of Alcohol Kinetics: A Deterministic Approach"). To properly represent oral alcohol intake, the model includes two previously unexplored compartments of the gastrointestinal tract—the stomach and gut (Fig. 2). Following the classic minimal model approach [5], we determined that we did not need to add more compartments. Further, the processes linking these compartments include one-way diffusions from the stomach and gut into the bloodstream. (Ethanol in the blood cannot diffuse back to the gastrointestinal tract.) The assumptions of

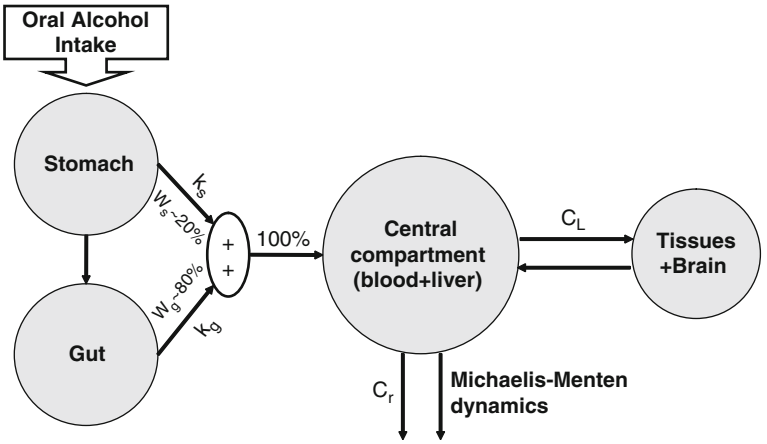

Fig. 2 The metabolic minimal model of alcohol dynamics following oral alcohol intake

the model include gastric emptying following an exponential decay with a certain half-life (rate constants k_s and k_g) and the proportion of gastric diffusion from the stomach, W_s, vs. diffusion from the gut, W_g (e.g., W_s=20% vs. W_g=80% [30]).

The alcohol clearance is represented by a Michaelis-Menten controlled reaction, e.g., an enzyme-enhanced chemical reaction with limited supply [25, 39], which has individual parameters (rate constant C_r) for each person. The mathematical details of this model and the process of its derivation and validation are discussed in Chapter "In Silico Models of Alcohol Kinetics: A Deterministic Approach".

Stochastic Model of Behavioral and Social Conditioning

Figure 3 presents the four steps of the alcohol intake self-regulation sequence introduced above: internal condition perception environmental conditioning self-regulation decision.

The basic idea behind the model of Fig. 3 is that its steps are linked by a *continuum of possible pathways*: i.e., there are a variety of possible perceptions of internal alcohol-induced neuromodulation (Step 1–Step 2); there is no single environment corresponding to a perception (Step 2–Step 3), and there is no uniquely predetermined decision arising from a specific environment (Step 3–Step 4). We, therefore, proposed a formal mathematical model in which the first three steps of this sequence are described by continuous variables, while the decisions at Step 4 are binary. In detail, the transition probabilities between Steps 1, 2, and 3 are modeled as conditional probabilities of a continuous outcome, given a continuous condition. The transition probabilities at Step 4 are conditional probabilities of a binary outcome, given a continuous condition. This reflects the clinical reality: the level of alcohol dependence, its perception, and environmental reinforcement are, by nature, continuous factors while the final decision to have or not to have another drink is binary—Yes/No. This model serves as a *stochastic behavioral generator of events*, each event being a drink that is supplied as an input to the metabolic model of Fig. 2. In other words, the in silico preclinical experiments use behavioral and social parameters that serve as generators of metabolic disturbances to the system (person), which are then processed through the metabolic model, thereby allowing the formal decomposition and reconstruction of the patterns of drinking behavior and their modulation by placebo or medication treatment. To be able to conduct in silico experiments, we need to describe our stochastic bio-behavioral model in algorithmic

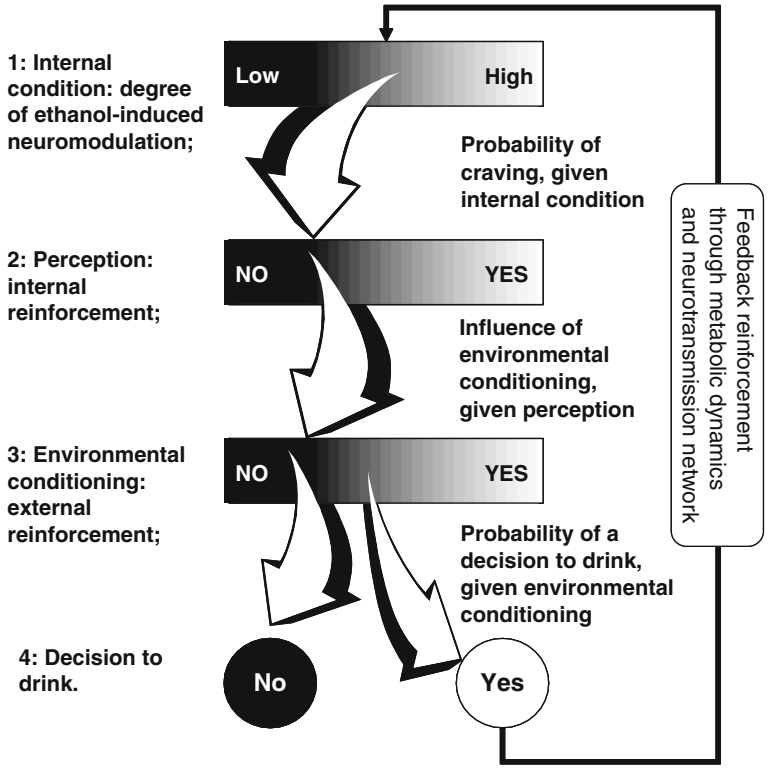

Fig. 3 Stochastic model of behavioral and social conditioning

terms. We use a discrete-time stochastic process ξ that goes through sequential steps. The basic building block of such a process is the *stochastic transition* from one step to the next, i.e., a transition that allows identical precursors at one step to have different consequences at the next, which is described by the following scheme: Suppose that at its Step n ($n = 1, 2, 3, 4$), the process $\xi(n)$ is described by a univariate or multivariate random variable x_n, having its values in some set X_n. Let S be a subset of X_n (we write $S \,\delta\, X_n$). A structure S_n of all subsets of X_n that satisfies certain conditions is called *σ-algebra* on X_n. A stochastic transition of the process ξ from X_n to its next stage X_{n+1} is defined by the conditional probabilities $P(\xi(n+1) = x_{n+1} \,|\xi(n) \in S)$ for any $x_{n+1} \in X_{n+1}$ and $S \in S_n$. The introduction of the structure S_n is a necessary mathematical complication, which makes the model capable of incorporating continuous as well as binary variables at each step.

Population of In Silico "Subjects"

Given the models in the previous sections, each person's ethanol metabolism is described via a set of several parameters (k_s, k_g, C_r, ...), and one set of fixed values of these parameters defines the metabolism of one in silico "subject". The in silico "population" is then derived by estimating the across-subject variance of these parameters and generating a number of parameter sets to span the metabolic diversity observed in vivo. Similarly, the behavioral and social specifics of each in silico "subject" are defined by an individual behavioral/social profile, e.g., by his or her own set of transition probabilities (p_1, p_2, ...) between the sequential steps of the model of Fig. 3 that are specific to that subject. The diversity of behaviors and social interactions of the in silico population is then described by diverse sets of transition probabilities.

While a comprehensive population of in silico subjects can be built only by collecting extensive data spanning the observed in vivo inter-individual metabolic and behavioral differences, to illustrate the proposed concepts we shall now use data derived from the database of a large clinical trial of ondansetron conducted at the University of Texas – Houston Health Science Center. This study had three clearly differentiated phases: (1) a 7-day baseline period, (2) a 7-day placebo treatment, and (3) several weeks of active ondansetron treatment. This sequential design made the collected data very suitable for interpretation via the sequential stochastic model of behavioral and social conditioning that is conceptualized here.

Subjects: Subjects were 321 DSM-III-R [2]–diagnosed alcohol-dependent individuals, who had: a mean age of 41.50 ± 1.34 years; a gender distribution of 73.81% male and 26.19% female; an ethnic distribution of 76.05% White, 22.10% Black, and 1.85% Hispanic and other; a social class [14] distribution of 39.25% I–III, 49.05% IV–VI, and 11.70% VII–IX, and a mean drinking level of 8.04 ± 5.80 drinks/day in the past 90 days prior to enrollment.

Procedure: This study received ethics approval from the Committee for the Protection of Human Subjects at the University of Texas – Houston Health Science Center. Subjects were recruited by newspaper or radio advertisement in the Houston area. Following recruitment, subjects were scheduled to return to the clinic to commence 1 week of placebo treatment with an inert pill to be taken twice per day for 7 days. After a study calendar week (7–10 days), subjects returned to the clinic to obtain their randomized double-blind medication (ondansetron) in doses of 1, 4, or 16 μg/kg twice daily or matching placebo for a further period of 11 weeks. For the purposes of this reanalysis, we selected the homogeneous subgroup of 87 subjects who were randomized to the 4-μg/kg twice daily ondansetron condition, and concentrated on their initial placebo period and 6 weeks of ondansetron treatment data. The complete results from this clinical trial have been published elsewhere [16].

Computational Algorithms

Given the theoretical basis established in this section, we deduce that each in silico subject is identified by two vectors: metabolic= $(k_s,\ k_g,\ C_r, \ldots.)$ and behavioral= $(p_1,\ p_2, \ldots.)$. The limits of the space occupied by these vectors are identified from literature and study data. The in silico population is, therefore, a population of vectors spanning this combined bio-behavioral space. Such an approach ensures unified numerical representation of physiological, behavioral, and social interactions, and enables the two-stage simulation procedure that we employ in this chapter:

Stage 1 – behavior: Computer-simulated idiosyncratic drinking patterns using the behavioral/social span of the set of vectors $\{(p_1,\ p_2, \ldots.)^1,\ (p_1,\ p_2, \ldots.)^2, \ldots, (p_1,\ p_2, \ldots.)^N\}$. Each of these patterns would result in a decision to drink or not to drink for each in silico subject. These decisions serve as behavioral event generators, and the generated events (i.e., drinks) are supplied to initialize the metabolic simulation model. In other words, the Stochastic Model of Behavioral and Social Conditioning creates the basic building block for in silico evaluation of treatment effect—the probability of a subject having a drink at any given point in time.

Stage 2 – metabolism: Computer-simulated idiosyncratic alcohol intoxication patterns using the span of the set of metabolic vectors $\{(k_s,\ k_g,\ C_r, \ldots.)^1,\ (k_s,\ k_g,\ C_r, \ldots.)^2, (k_s, k_g, C_r, \ldots.)^N\}$. This is done as follows: at each simulated drink for each in silico subject, this subject's metabolic model produces a specific trace in time of alcohol intoxication. The next simulated drink will come somewhere in this trace and, depending on this "individual's" specific metabolic and drinking behavior, will hit at different stages of alcohol clearance. If the simulated drinks are sufficiently infrequent so that this "individual" can fully metabolize the ingested alcohol, the system (subject) will remain in a subcritical drinking

pattern; conversely, if the drinks are too frequent, the system (subject) will transit to a super-critical pattern. Metabolic patterns are discussed in detail in Chapter "In Silico Models of Alcohol Kinetics: A Deterministic Approach".

This simulation procedure was programmed in MATLAB®, a high-level programming language widely adopted for technical computing.

Results

The following results are provided as an example of how the stochastic model can be applied.

Empirical Findings

The average number of drinks per day during the baseline period for the selected subgroup of 87 subjects was 8.01 (SD=5.28). Thus, the selected subgroup was representative of the entire study cohort, which reported an average of 8.04 (SD = 5.80) drinks/day for the 90 days prior to recruitment. During the placebo treatment period, the alcohol consumption in the selected subgroup was reduced to 5.03 (SD=4.64) drinks/day, followed by a further gradual reduction to 1.88 (SD=2.21) drinks/day after 6 weeks of active ondansetron treatment (F=56.1, p<0.0001) using repeated-measures analysis of variance. (This empirical pattern of passive and active reduction in drinking is included in Fig. 4.)

During the baseline period, 54 subjects (62%) in the illustrative subgroup were classified as heavy drinkers, consuming ≧5 drinks/day and ≧4 drinks/day for men and women, respectively. This classification had a significant ($F = 20.1$, $p < 0.001$) effect on the outcome from non-specific placebo treatment: the number of drinks per day in heavy drinkers changed from 10.70 (SD=5.02) at baseline to 6.06 (SD=5.31) at the end of the placebo period; in non-heavy drinkers, there was no change: 3.61 (SD=1.06) drinks/day at baseline vs. 3.65 (SD=2.94) drinks/day at the end of the placebo period. The difference between heavy and non-heavy drinkers became negligible during the first week

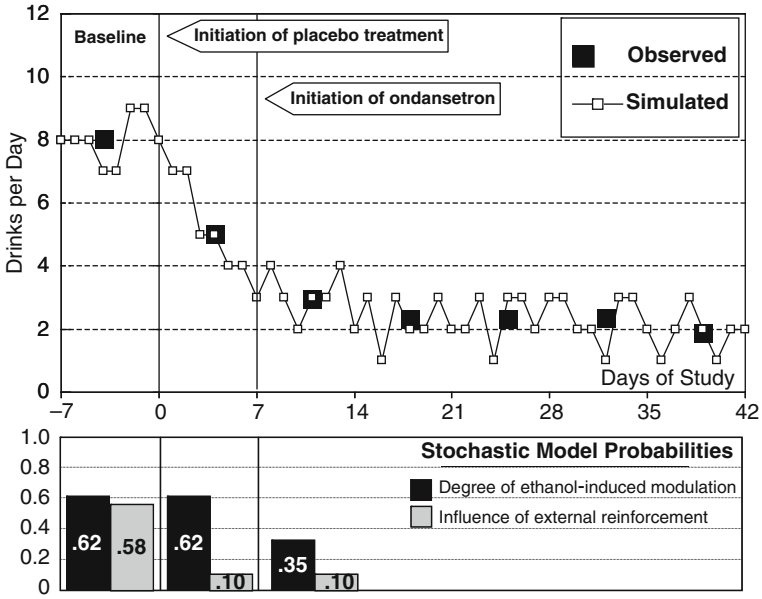

Fig. 4 Model-predicted and observed effect of placebo and ondansetron treatment

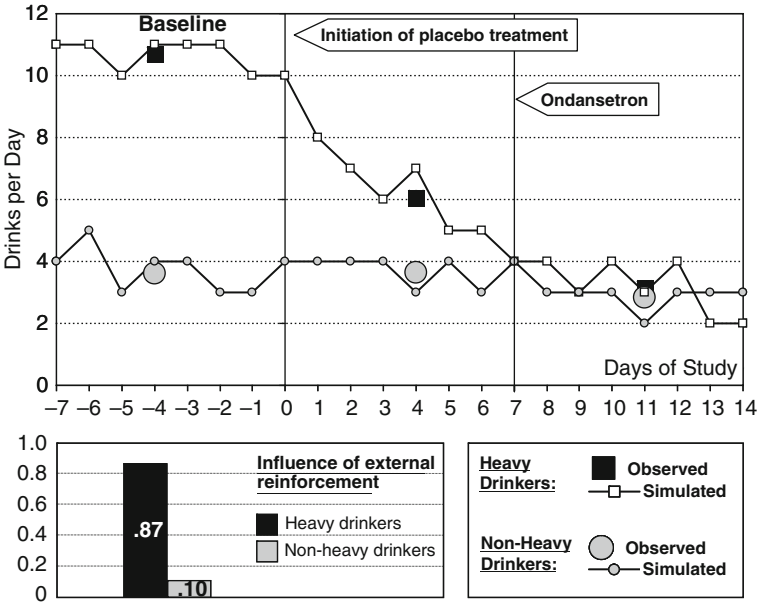

Fig. 5 Model-predicted and observed treatment effect in heavy and non-heavy drinkers

of active ondansetron treatment and remained negligible throughout the rest of the observation period. (The empirical patterns of these two groups are included in Fig. 5.)

In Silico vs. In Vivo Responses to Placebo and Ondansetron Treatment

To evaluate the closeness of in silico prediction to observed clinical outcome, we compared the computer-simulated and clinically observed patterns of treatment response. Throughout the simulation, we kept the metabolic parameters (Fig. 2) of the simulated "subjects" constant and used the stochastic model of Fig. 3 to decompose the observed drinking patterns into two sections explained by different model steps:

1) The response to initial placebo treatment was attributed to the influence of study enrollment, which was modeled as a reduction of the probability for environmental conditioning (Step 3 in Fig. 3) from its baseline value of 0.58–0.10. Because this effect occurs relatively quickly (within a week) and no active medication was provided, no other system changes were anticipated, such as feedback down-regulation through modulation of the neurotransmission system.
2) The response to ondansetron was attributed to neurotransmission changes influenced by the degree of ethanol-induced neuromodulation. This was modeled via reduction of the probability of Step 1 from its baseline value of 0.62–0.35.

Figure 4 compares the results of this in silico treatment experiment to the clinically observed treatment effects. Black squares represent the empirical pattern of baseline drinking (Days –7 to 0) and the pattern of drinking reduction due to placebo (Days 1 to 7) and ondansetron treatment (Days 8 to 42). The in silico-generated pattern (black line) follows closely these empirical observations, confirming that in silico experiments could provide realistic representation of treatment effect. The lower panel of the figure includes the change in environmental reinforcement probability, which is responsible for the "placebo" effect, and the reduction in the degree of ethanol-induced modulation describing the effect of ondansetron.

Modeling Idiosyncratic Treatment Response

The empirical results presented above suggest highly significant differences between heavy and non-heavy drinkers in their responses to placebo treatment, followed by a regression into a common pattern of response to ondansetron. Figure 5 focuses on the first three weeks of observation, where these idiosyncratic differences were most evident [32]. Following the assumption that the placebo effect is primarily due to reduced environmental reinforcement, we model the difference between these two groups of subjects via different probabilities at Step 3.

Indeed, environmental reinforcement probabilities of 0.87 and 0.10 for heavy and non-heavy drinkers allow for excellent simulated approximation of the observed empirical patterns of placebo response. (Note that the overall baseline probability of environmental reinforcement, 0.58, is the weighted sum of the probabilities in the two subject subpopulations.) As is empirically established and evident from Fig. 5, non-heavy drinkers (gray circles) were non-responsive to the effect of study enrollment. In contrast, heavy drinkers (black squares) appeared to be vulnerable to environmental conditioning effects, and, therefore, their response to placebo treatment was highly significant. Further, these two subject subpopulations were approximately equally responsive to the effect of medication, which explains the similarities in their patterns during the period of active ondansetron treatment. The environmental probabilities used for simulation are included in the bar graph in the lower section of Fig. 5.

Conclusions

The principal utility of in silico modeling efforts is three-fold. First, models allow the measurement of latent factors that cannot be observed directly but that frequently predetermine the behavior of a biosystem. A classical example is the Minimal Model of Glucose Kinetics suggested by Bergman and Cobelli almost 30 years ago to measure insulin resistance in health and diabetes [5]. Second, models allow for computer simulation and in silico studies involving virtual "subjects" rather than real people. Such in silico trials can serve as cost-effective precursors, guiding expensive and time-consuming in vivo investigations by ruling out ineffective treatment approaches. For example, a recently developed simulator of the human metabolic system has received Food and Drug Administration approval and recognition for the preclinical testing of control strategies in artificial pancreas studies [21]. Third, when a system (person) is adequately modeled, its control via engineering means becomes possible. Examples include cardiac pacemakers and, more recently, the artificial pancreas emerging as a means for control of blood glucose levels in diabetes.

The basic premise of in silico modeling of alcohol dependence is that alcohol dependence and the outcome of its treatment result from the action of a stochastic self-reinforcing bio-behavioral process, combined with each individual's metabolic specifics. In other words, the interplay between biology and behavior, which develops in a certain time frame, would trigger (with a certain probability) metabolic and neurobiological changes that in turn would reinforce uncontrolled or poorly controlled drinking behavior. Treatment would, therefore, be expected to modulate, attenuate, or reverse these changes with a certain level of probability. Such a quantitative approach has several potential advantages:

First, the overall treatment effect can be decomposed into meaningful steps, with each step serving as a target for a specific treatment. For example, Step 1 (internal condition) would reflect pharmacological treatment, while Step 3 (environmental conditioning) would reflect the placebo effect of study enrollment, or any type of socio-behavioral intervention. Such a decomposition of the treatment effect allows for better understanding of the time course

of treatment and the relationships among the various treatment components.

Second, the proposed model would allow for individualized treatment tailoring. For example, it appears that in heavy drinkers, environmental conditioning is a significant predictor of treatment response, while in non-heavy drinkers the effect of the environment is minimal. The effect of ondansetron is similar in the two groups but occurs faster in non-heavy drinkers.

Third, one of the advantages of a model-based investigation is that separate steps can be estimated in different studies and then the results can be integrated via the model. For example, neurotransmission or physiological parameters can be evaluated in animal studies and then related to human behavior parameters. That is, the proposed concept is *species invariant*, capable of bridging results from human and animal studies.

Most importantly, the stochastic process described here serves as an event generator of behavioral disturbances (i.e., drinks), which in turn influence the internal condition. Thus, the initial entry conditions for a person change with each repetition of the cycle presented in Fig. 1. This recurrence provides powerful tools for in silico analysis of the progression of alcohol dependence and treatment response, taking into account both biological and environmental factors.

To illustrate this concept, we conducted in silico experiments that reproduced patterns observed in a clinical trial of ondansetron. It became evident that placebo and ondansetron, as well as their interaction, contribute to the overall therapeutic response. There might, however, be other nonspecific effects that can affect clinical outcome and that we need to discover. Hence, the in silico model presented here is less developed than the metabolic models adopted for the study of diabetes. Nevertheless, this text represents an initial step to introduce the concept of in silico analysis to the area of alcohol dependence research. Because the first results appear promising and explanatory for the observed phenomena, we think that with the accumulation of data (both existing and from future clinical studies), in silico analysis would find its place in the arsenal of tools to help decipher the mechanisms that govern treatment response among alcohol-dependent individuals.

Dynamic and Systems-Based Models for Evaluating Hypotheses Related to Predicting Treatment Response

Scott F. Stoltenberg

Contents

Introduction

Approaches to treating alcohol dependence are heterogeneous, ranging from group therapy in 12-step programs to pharmacotherapy. Such treatment heterogeneity is a reflection of client heterogeneity that results from the complex biopsychosocial architecture underlying multiple alcoholism types with different developmental trajectories [39].

While each treatment approach is successful in reducing the number of drinking episodes and the amount of alcohol consumed per episode, no single treatment approach is superior to the others in all cases. One size does not fit all when it comes to treatment for alcohol dependence. If no single alcoholism treatment is equally effective for all individuals who seek treatment, is there some way to identify those who will respond best to a particular treatment? In other words, is there some way to *personalize* treatment for alcohol dependence? While the relevant individual differences among treatment seekers have not been fully elucidated, it is likely that at least some of those relevant individual differences result from genetic variation in mechanisms crucial to etiology or to treatment response. In this sense, alcoholism treatment providers are in the same situation as much of the medical profession in the quest for personalized medicine. Also, while there is much to anticipate about developments in the area of personalized medicine, progress has not kept pace with the clamor. As interest intensifies in personalized medicine, it seems prudent to consider the ways in which investigators will endeavor to make sense of often conflicting empirical results in an effort to understand complex biological systems across levels of analysis from gene to physiological systems to treatment outcome. In this chapter, an approach is presented that focuses on genetic variation in neurotransmitter systems and utilizes dynamic system modeling to understand better the contribution of genetic variation to pharmacological treatment for alcohol dependence.

The goals of this chapter are to: (1) discuss personalized treatment and pharmacogenetics as it applies to alcoholism, (2) describe the Johnson Model of individual differences in response to pharmacological treatment for alcoholism, (3)

discuss a dynamic control system model developed to examine the Johnson Model, and (4) discuss the potential for the use of control system modeling to test hypotheses regarding the pharmacogenetics of alcoholism.

Personalized Alcoholism Treatment

Substantial efforts to identify personal traits that can inform choice of alcoholism treatment have not yet borne fruit. The most notable of such efforts is Project MATCH (Matching Alcoholism Treatment to Client Heterogeneity). Project MATCH was a large, multi-site psychotherapy trial that ran for over a decade and enrolled over 1,700 clients [22]. It was designed to test 21 matching hypotheses by assigning clients randomly to three treatment groups—cognitive behavioral therapy, motivational enhancement therapy, or 12-step facilitation—and measuring the associations among matching characteristics and multiple alcohol outcomes across five follow-up periods [4]. Project MATCH examined both primary (alcohol involvement, cognitive impairment, gender, meaning seeking, motivation, psychiatric severity sociopathy, support for drinking, and Babor's Typology) and secondary (alcohol dependence, anger, antisocial personality disorder, interpersonal dependency, Axis I psychopathology, Alcoholics Anonymous history, readiness to change, religiosity, self-efficacy, and social functioning) matching hypotheses [15].

Clients in each of the Project MATCH treatment conditions showed rates of improvement, as measured by drinks per drinking day and abstinent days, similar to other treatment studies [22]. Disappointingly, Project MATCH did not succeed at identifying personal traits associated with significant differences in treatment outcomes for the three alcoholism psychotherapies. Client anger, psychiatric comorbidity, and level of alcohol dependence were some of the client traits that provided limited prognostic utility [22].

Recently, a large trial to test alcoholism treatment matching hypotheses was conducted in the United Kingdom [34]. In the UK Alcohol Treatment Trial, investigators conducted 3- and 12-month follow-ups on clients ($n = 742$ at baseline) who were assigned to either motivational enhancement therapy or social behavior and network therapy. The matching hypotheses in the UK study included: (1) size of social network, (2) readiness to change/negative expectancies, (3) psychiatric severity, (4) anger, and (5) degree of alcohol dependence. The investigators found no evidence for matching effects on these client characteristics to the two types of treatment studied.

While this brief review of personalized alcoholism treatment is not exhaustive, it does provide powerful evidence that easily observable client characteristics do not appear to be useful for matching individual clients to particular psychosocial treatments. Much of the excitement regarding personalized medicine, however, has to do with a better understanding of the biological underpinnings of disease and disorder, as well as the promise of applying this understanding to improving pharmacotherapy by informed dosage practices, increased response rates, and a reduction in the number and severity of side effects. This area, known as pharmacogenetics, is the major thrust of personalized medicine and is reviewed in the next section.

Pharmacogenetics

Pharmacokinetics is an area of focus within pharmacogenetics that studies how genetic differences influence the bioavailability of an agent [19]. Individual differences in the rate of an agent's metabolism produce variability in treatment response and may be crucial in serious or fatal adverse reactions to the medication [27]. The cytochrome P-450 enzymes are located on organelles in liver cells and are one of the most studied components in agents' metabolism. Approximately 7% of Caucasians can be classified as "poor metabolizers" on the basis of their

genotype at the CYP2D6 polymorphism, which is known to be involved with the breakdown of many psychotropic medications [27]. The end result of metabolizing psychotropic agents at a slower than average rate is that higher levels of the agents remain in the bloodstream, effectively raising the dose to levels that could potentially be harmful.

Pharmacodynamics is an area of focus within pharmacogenetics that studies the ways in which genetic differences in the proteins at which medications act produce individual differences in treatment response [19]. An example of pharmacodynamic research that is important to psychiatry is the examination of the association between genetic variation in the gene that codes for the serotonin transporter and the response to depression treatment with selective serotonin reuptake inhibitors. Because reuptake of serotonin from the synapse via the serotonin transporter is the primary mode for inactivating serotonin's actions and because the serotonin transporter is the primary target of selective serotonin reuptake inhibitors, it is logical to assume that genetic variation that influences serotonin transporter function would also affect efficacy of selective serotonin reuptake inhibitor treatment.

For more than a decade, the most studied genetic polymorphism in psychiatric or behavior genetics has been the so-called 5-HTTLPR insertion/deletion in the regulatory region located upstream of the structural gene that codes for the serotonin transporter [32]. A recent search on PubMed for the term "HTTLPR" resulted in over 500 hits. The polymorphism is both functional and common, which makes it an excellent candidate for association studies. The "L" allele is a high-functioning allele that results in 2–3 times higher transcriptional efficiency than the "S" allele [20]. Recently, investigators have been using functional magnetic resonance imaging to study associations between the 5-HTTLPR genotype and the activity of different brain regions. Specifically, amygdala activity in response to fearful or threatening facial expressions is greater in individuals who carry at least one S allele compared with those with the LL genotype [11]. In addition, the functional connectivity between the amygdala and the prefrontal cortex is weaker in those who carry an S allele, which suggests that those individuals may be less able to dampen amygdala activity following an assessment of the potential threat [11].

Because the serotonin transporter is the primary target of selective serotonin reuptake inhibitors, it is of interest whether the 5-HTTLPR polymorphism is associated with a different response to selective serotonin reuptake inhibitor treatment. In a recent meta-analysis of 15 studies of selective serotonin reuptake inhibitor treatment for depression including a total of 1,435 subjects, the L allele was associated with better treatment outcomes [29].

In addition to response to selective serotonin reuptake inhibitor treatment for depression, the 5-HTTLPR polymorphism is also associated with differences in the personality trait of neuroticism [28], suicide [2], impulse control disorders [21], and eating disorders [8]. Importantly, in the context of the present chapter, a meta-analysis of 17 published studies examining the association between 5-HTTLPR polymorphisms and alcohol dependence showed that the S allele was associated with an increased risk for alcohol dependence and that this association was strongest in the presence of psychiatric comorbidity [6].

The pharmacogenetics of alcoholism presents a complicated picture with a plethora of molecular targets for both ethanol and the medications used in alcoholism treatment. An examination of the pharmacokinetics of alcohol reveals genetic variants in ethanol-metabolizing enzymes that are associated with different levels of risk for alcohol dependence and that vary across ethnic groups [5]. The well-studied enzymes in ethanol metabolism, alcohol dehydrogenase and aldehyde dehydrogenase, clearly affect the bioavailability of ethanol and a toxic by-product, acetaldehyde. Alcohol dehydrogenase converts ethanol to acetaldehyde, which is then quickly converted by aldehyde dehydrogenase to acetate. If these two conversions take place at similar rates, levels of the toxic acetaldehyde stay rather low in the blood. However, if the alcohol

dehydrogenase enzyme is "fast" or if the aldehyde dehydrogenase enzyme is "slow", toxic levels of acetaldehyde result. The medication disulfiram (Antabuse®) inhibits aldehyde dehydrogenase, and when an individual drinks alcohol while taking disulfiram, severe nausea and other aversive symptoms result. This reaction is similar to the "flushing" response that occurs when individuals with one or two copies of a mutant version of aldehyde dehydrogenase-2 that produces a non-functioning version of the enzyme drink alcohol.

The pharmacodynamics of alcohol is complicated by its many targets. Ethanol facilitates the activity of gamma-aminobutyric acid-A receptors, inhibits the activity of *N*-methyl-*D*-aspartate glutamate receptors, and, at high doses, inhibits many voltage-sensitive calcium channels. Ethanol also has direct influences on neurotransmission via serotonin, dopamine, and norepinephrine neurons and modulates opioid neuropeptides [17]. The endogenous opioid system is implicated in the rewarding effects of alcohol consumption and in alcohol craving [35]. Genetic variation at these many sites of action is likely to be responsible for variation in responses to ethanol exposure.

Both Project MATCH and the UK Alcohol Treatment Trial focused solely on psychosocial therapies and excluded pharmacotherapy to simplify the designs of such large complicated studies [4, 34]. Clearly, there are biologically based individual differences that are likely to influence treatment outcome. Interestingly, the Project MATCH investigators have recently begun to explore how variation in specific genes may prove to be predictive of drinking behavior and of the outcome of psychosocial treatment for alcoholism [1]. A "high-risk" genotype of the GABRA2 gene (A/A) was associated with less variability in treatment outcome and higher risks for drinking and heavy drinking.

The pharmacodynamics of agents used in alcoholism pharmacotherapy is also of interest. Examples of medications used for the treatment of alcoholism include: opiate antagonists (e.g., naltrexone); medications that interact with glutamate (e.g., acamprosate); modulators of both glutamate and gamma-aminobutyric acid systems (e.g., topiramate); agents that influence serotonin uptake (e.g., selective serotonin reuptake inhibitors), and those that modulate serotonergic function and, as a consequence, dopaminergic neurotransmission (e.g., ondansetron). There are known genetic variants for neurotransmitter system components (e.g., receptors and enzymes) in all of these systems in which medications to treat alcoholism might act.

In this section, I provide a general description of pharmacogenetics along with a more specific discussion of the pharmacogenetics of alcohol and of medications used to treat alcoholism. It is clear that there are sufficient pharmacogenetics targets to begin examining the best candidates empirically. In the next section, a pharmacogenetics theoretical model is described that takes important steps toward the goal of better understanding how genotypes can be used to identify the most effective pharmacotherapy for alcoholism treatment.

The Johnson Model

Because both the serotonin and dopamine neurotransmitter systems are intimately involved with alcoholism in ways that are complex and not yet fully understood, theoretical models focusing on the impact of genetic variation at the level of the synapse may provide a productive approach to understanding better the individual differences in response to alcoholism treatment. Such work combines empirical data from several different areas of study, such as human alcoholism treatment trials, candidate gene association studies, and pharmacological studies with both human and non-human animals. Alcoholism treatment trials can provide information regarding subjects' characteristics that are predictive of treatment response or of etiological significance. Candidate gene association studies can identify allelic variants associated with different alcohol phenotypes. The best of these candidates also will produce functional differences in the physiological systems

of interest and are often targets of pharmacological agents. Pharmacological studies provide evidence regarding the effects of agonists and antagonists on system function and on alcohol phenotypes. The development of theoretical models that attempt to elucidate the impact of variation at functional candidate genes on the response to pharmacological treatment for alcoholism is an important stage in a systematic approach to personalized alcoholism treatment. Johnson and Ait-Daoud [14] presented a theoretical model that was elaborated upon by Johnson [12] and aimed at better understanding the role of genetic variation in the serotonin transporter promoter region (5-HTTLPR) and differential response to two pharmacological treatments for alcoholism (hereafter called the Johnson Model). In this section, I provide details of this model, on which a subsequent control system model was based.

The development of the Johnson Model was motivated by the desire to understand better the contribution of allelic variation at components of neurotransmitter systems to individual differences in pharmacological alcoholism treatment response [12, 14]. As such, these efforts should constitute a pharmacodynamic approach because the genetic differences examined are hypothesized to influence the proteins at which the medications act [19].

Figure 1 presents the Johnson Model schematically. The main premise of the model is that relative serotonergic hypofunction, a result of efficient reuptake for individuals with the 5-HTTLPR LL genotype, produces an upregulation of serotonin-3 receptors and an enhanced "urge to drink". This heightened urge to drink is the result of dopaminergic activation due to the action of serotonin at postsynaptic serotonin-3 receptors on dopaminergic neurons.

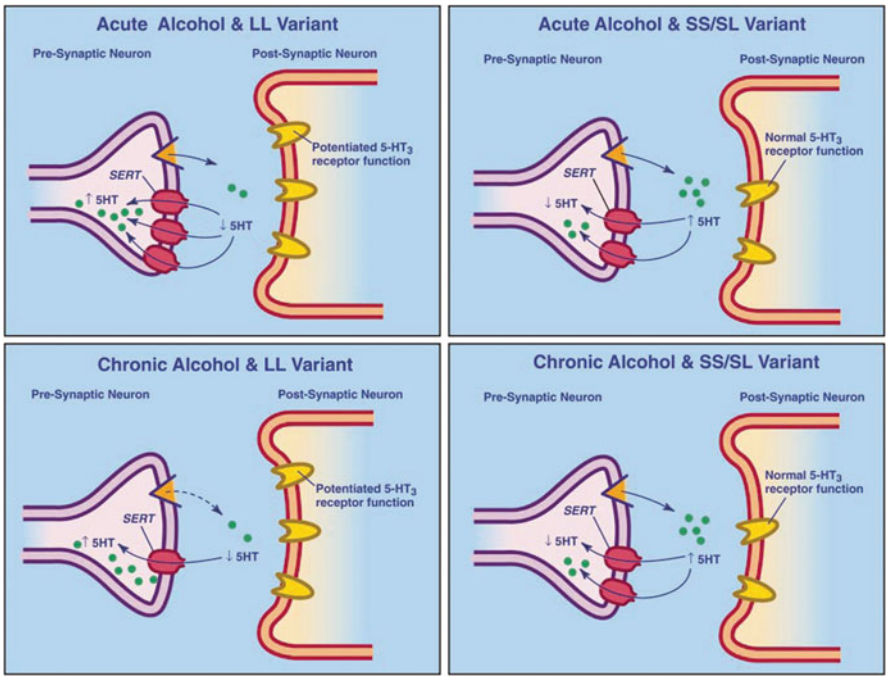

Fig. 1 The Johnson Model is a theoretical model, derived from empirical observations, that hypothesizes the mechanism of how variation in 5-HTTLPR genotype is associated with differences in the effectiveness of selective serotonin reuptake inhibitor and ondansetron alcoholism treatment. The LL genotype of 5-HTTLPR produces a hypodopaminergic state and potentiated serotonin-3 (5-HT_3) receptors on dopaminergic neurons, which results in an enhanced "urge to drink". 5HT, serotonin; SERT, serotonin transporter. (Figure reprinted with kind permission from Springer Science+Business Media: Johnson and Ait-Daoud [14], p. 335.)

Several lines of empirical evidence led to the Johnson Model (see references in Johnson [12] and Johnson and Ait-Daoud [14]):

1. The S allele of the 5-HTTLPR polymorphism is a common variant that is dominant to the L allele and reduces serotonin reuptake by approximately one-third via a reduction in the number of serotonin transporter proteins produced (i.e., it significantly influences serotonin neurotransmission).
2. Selective serotonin reuptake inhibitors bind to the serotonin transporter and block serotonin reuptake, enhancing serotonin neurotransmission.
3. Response to selective serotonin reuptake inhibitor treatment for alcoholism is better for those with late-onset alcoholism than for those with early-onset alcoholism.
4. Serotonin-3 receptors are located on mesocorticolimbic dopamine-containing neurons and are involved in the rewarding effects of alcohol.
5. Ethanol potentiates the activity of serotonin-3 receptors.
6. Response to alcoholism treatment with the serotonin-3 receptor antagonist ondansetron is better for those with early-onset alcoholism than for those with late-onset alcoholism.
7. Acute alcohol exposure increases serotonin function.
8. Chronic alcohol exposure decreases serotonin function.

The primary focus of the Johnson Model was to explain the observation that for individuals with early-onset alcoholism (assumed to be predominantly of the LL genotype), alcoholism pharmacotherapy with ondansetron was more effective than treatment with selective serotonin reuptake inhibitors. The efficacy of ondansetron was hypothesized to be due to its presumed effectiveness at reducing the rewarding effects of alcohol (via a reduction in dopaminergic activation due to serotonin-3 antagonism). The relative effectiveness of selective serotonin reuptake inhibitor pharmacotherapy for individuals with late-onset alcoholism (assumed to be predominantly carrying one or more S alleles) was hypothesized not to be due to serotonin-3 mechanisms. Rather, individuals with late-onset alcoholism and chronic selective serotonin reuptake inhibitor treatment were hypothesized to experience an "anti-rewarding effect" as a result of drinking alcohol because of a long-term inhibition of dopaminergic activity [12].

Because of the large number of components involved in the Johnson Model and the rather complex nature of the interactions among them, a systems-based model provides a platform for systematic testing of the model's hypotheses. In the next section, I use a dynamic systems-based model to examine the Johnson Model.

A Dynamic Systems-Based Model

Although control system modeling has a relatively long history, with Wiener's influential book on cybernetics first published in 1948 [37], it has not been widely used in behavior genetic analysis. However, with an increasing focus on the mechanisms of heredity-behavior relations made possible by advances in molecular genetics and neuroscience, it seems that control system modeling is poised to catalyze significant contributions to our understanding of how genes influence behavior.

The Johnson Model is well suited for implementation as a control system model because it considers the system as a whole that can be described by the levels or rates of specified parameters [9]. Levels are sometimes referred to as "stocks" or "states" and rates as "flows". For example, in the Johnson Model, the level of serotonin in the synapse can be considered a stock and the rate of serotonin reuptake determined by 5-HTTLPR genotype can be considered a flow. Control system models are dynamic models, in that they utilize difference or differential equations to account for change over time, deriving subsequent states of the system from the current state [9]. Control system models are particularly useful for modeling the influence

of genetic differences or of pharmacological intervention on neurotransmitter system function where feedback loops are known to occur and where epistatic interaction plays a role [31, 33]. It is important to keep in mind that these kinds of control system models are not intended to be exact replicas of the system being simulated. These models describe qualitative behavior of the actual system under varied parameter states that can simulate genetic variation or pharmacological manipulation. An important goal of the control system model is to help to identify leverage points—that is, components of the system that are key in controlling system function. Therefore, a complete catalog of every component of the system is not necessary. Similarly, in control system modeling there is little focus on scaling every parameter so that biological realism is obtained. On the contrary, one often works with standardized parameters so that matters of scale are de-emphasized. One is more concerned with the functional relations among the parameters than with the relative lack of biological realism.

One of the most favorable features of control system modeling using systems of differential equations is that when these equations are solvable and produce unique solutions, the toolkit of the mathematician can be brought to bear [33], such as fast, general-purpose differential equation solvers such as Berkeley Madonna [38]. Most importantly in the context of pharmacogenetics, one can examine the controllability of the system under study. That is, it may be possible to adjust the parameters of a system to move its functioning from an undesirable state to a desirable one [33]. In the context of the serotonin system, there is substantial empirical evidence that it is possible to manipulate system parameters either by the use of medications or by genetic techniques (e.g., constructing "knockout" lines of mice) to alter serotonin system function. Although a complete understanding of the dynamics of the serotonin system has not yet been achieved, the use of control system modeling may enable the systematic variation of parameters in silico to achieve empirically based controllability of the system. In other words, dynamic systems models such as this one may provide us with the platform on which we can build an empirically derived understanding of how to adjust system parameters with medication to move an individual's serotonin function into a desired state.

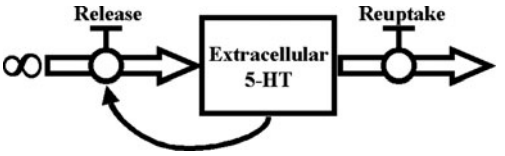

Fig. 2 A "stock and flow" diagram of a control system model of serotonin (5-HT) function. The stock of extracellular serotonin is increased by presynaptic neural activity (i.e., release) and is decreased by serotonin transporter-mediated reuptake. When extracellular levels of serotonin are above some threshold, somatodendritic autoreceptors (serotonin-1A) inhibit neural firing via a feedback mechanism. When presynaptic neural firing is enabled, terminal autoreceptors (serotonin-1B) control the serotonin release amount. The infinity sign represents an infinite reservoir for the production of serotonin

The model to test the Johnson Model [30] arose out of efforts to model presynaptic regulation of the serotonin system [31]. In that base model, presynaptic regulation of serotonin function was hypothesized to be controlled by three components, each of which varied genetically (see Fig. 2). These components included: the serotonin transporter that removes serotonin from the extracellular space via reuptake; the somatodendritic autoreceptor (serotonin-1A) that inhibits neural firing and, therefore, serotonin release, and the terminal autoreceptor (serotonin-1B) that influences the amount of serotonin released. Each of these components was hypothesized to have a "high" and a "low" functioning variant. The main outcome variable for this model of presynaptic regulation is the level of extracellular serotonin. Another outcome that can be considered is the firing rates of serotonin neurons.

As previously mentioned, the gene that codes for the serotonin transporter contains a variant in the upstream regulatory region (5-HTTLPR) that does not affect the structure of the serotonin transporter, but does affect the number of serotonin transporters produced. The S allele acts

in a dominant fashion so that individuals with one or two copies (i.e., SS or SL, the "low" functioning variant in the model) produce fewer serotonin transporters than those homozygous for the L allele (the "high" functioning variant in the model) [20]. The most commonly prescribed class of antidepressants, the selective serotonin reuptake inhibitors, bind to the serotonin transporter and block the transport of serotonin from the extracellular space to the intracellular space, where it can be either repackaged into vesicles for re-release or catabolized by monoamine oxidase. Lines of mice that have the structural gene for the serotonin transporter knocked out have been widely studied and have much to contribute to our understanding of pathways from gene to behavior [7, 23, 24].

The serotonin-1A somatodendritic autoreceptor is a key controller of the firing of serotonin-containing neurons [10]. When levels of extracellular serotonin are elevated, the serotonin-1A receptor inhibits neural firing. This type of feedback inhibition resembles the functioning of a thermostat that sends a signal to the furnace to turn off when the room temperature exceeds some set point. Such feedback mechanisms are well modeled with control system models. A recent study reported that a single nucleotide polymorphism in the serotonin-1A gene may be functional and is associated with the response to selective serotonin reuptake inhibitor treatment for depression [16]. Both agonists and antagonists for the serotonin-1A receptor have been identified and have been widely used to study the function of the receptor. Lines of mice have been developed in which the structural gene for the serotonin-1A receptor has been knocked out. These serotonin-1A knockout mice exhibit elevated anxiety-like behaviors when compared with mice with functioning serotonin-1A genes [26].

The serotonin-1B terminal autoreceptor controls the amount of serotonin released when neural firing occurs [10]. Therefore, the serotonin-1B receptor can be considered a second controller of serotonin release that has its effect only after the primary controller (serotonin-1A) has enabled neural firing (i.e., not inhibited firing). Both agonists and antagonists of the serotonin-1B receptor have been developed and have been used to study the function of the receptor. Lines of mice have been developed with the structural gene for the serotonin-1B receptor knocked out. These serotonin-1B knockout mice drink more alcohol and attack intruders more quickly and vigorously than wild type mice [3]. There is also evidence in human populations that genetic variation in the serotonin-1B gene is associated with early-onset alcoholism [18].

The starting point to simulate the Johnson Model was a relatively simple control system model of presynaptic serotonin function that focused on extracellular serotonin level and rates of serotonin firing [31]. The model included three main components: the serotonin transporter, the somatodendritic autoreceptor (serotonin-1A), and the terminal autoreceptor (serotonin-1B; see Fig. 2). To test the Johnson Model, only the function of the serotonin transporter was varied [30]. The functioning of the two autoreceptors was held constant because these controlling system components were not part of the Johnson Model. The functioning of the serotonin transporter was modeled as having a "high" and a "low" functioning variant to correspond to the LL and S/_ (i.e., SS or SL) genotypes, respectively.

From this basic model, extensions were added to accommodate the Johnson Model (see Fig. 3). Sixteen separate conditions were modeled that consisted of two levels of each of the following parameters: 5-HTTLPR genotype, alcoholism status, acute drinking status, ondansetron treatment status, and selective serotonin reuptake inhibitor treatment status (see Table 1).

In the model, the flow of serotonin into the extracellular space (i.e., release) was primarily influenced by acute drinking status. In the acute drinking conditions, the release of serotonin was doubled.

In the model, reuptake was primarily dependent on serotonin transporter functioning, which was affected by 5-HTTLPR genotype and selective serotonin reuptake inhibitor treatment status and, for the LL genotype condition, chronic alcoholism status. For the LL genotype, the reuptake

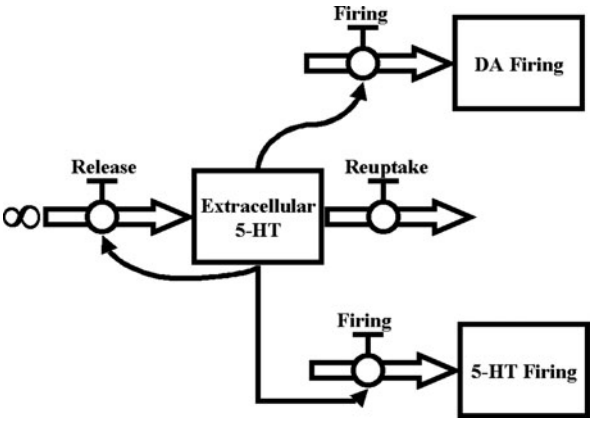

Fig. 3 A "stock and flow" diagram of the Johnson Model. This is an extension to the basic model presented in Fig. 2, with additions of counters to track both dopamine (DA) and serotonin (5-HT) firing rates. Both of these firing rates are dependent on extracellular serotonin level. The infinity sign represents an infinite reservoir for the production of serotonin

Table 1 Parameter values for conditions tested by Stoltenberg [30]

Condition	Genotype	Alcoholism	Drink	Selective serotonin reuptake inhibitor	Ondansetron
L	0.90	1.00	0	1.00	0
LD	0.90	1.00	1	1.00	0
LA	0.90	0.55	0	1.00	0

L LL genotype, *S* S/_ genotype, *D* drink condition, *A* chronic alcoholism, *O* ondansetron treatment, *S** selective serotonin reuptake inhibitor treatment

rate was set at 0.90, whereas for the S/_ genotype, the reuptake rate was set at 0.30. The selective serotonin reuptake inhibitor treatment condition further reduced reuptake by a multiplier, 0.20. Additionally, for those with the LL genotype, chronic alcoholism further reduced the reuptake rate by a multiplier, 0.55. So, for example, the LL, chronic alcoholic on selective serotonin reuptake inhibitor treatment had a reuptake rate of $0.90 \times 0.55 \times 0.20 = 0.099$. That is, 9.90% of the extracellular serotonin was removed at each time step of the model.

A simple counter was implemented to track the serotonin firing rate. The level of extracellular serotonin affected the serotonin firing rate. When the extracellular serotonin level exceeded a dynamic threshold, firing was inhibited (see Stoltenberg [31] for details about firing inhibition mediated by the serotonin-1A autoreceptor).

In general, the firing of dopaminergic neurons mediated by serotonin-3 receptor activation was modeled as a binary variable (i.e., either fire or not fire) with probabilities that were inversely proportional to the level of extracellular serotonin. However, when extracellular serotonin levels were very low, the probability of dopamine firing was increased, to model

the potentiation or upregulation of serotonin-3 receptors. Ondansetron treatment status reduced the probability of dopamine firing by half.

One of the first steps in the modeling process subsequent to model development is model validation. It is important to test whether the model produces output that is consistent with expectations. For example, the LL genotype should produce lower levels of extracellular serotonin than the S/_ genotype because the LL genotype has relatively higher reuptake rates, which should produce a relative reduction in serotonin levels in the synapse. For the Johnson Model simulation, we can identify the S/_ genotype as the standard (i.e., 100%) and the simulation produces extracellular serotonin levels for the LL genotype that are 39% of those produced by the S/_ genotype. Similarly, modeling a selective serotonin reuptake inhibitor should produce increases in extracellular serotonin levels because selective serotonin reuptake inhibitor treatment reduces reuptake rates. In the simulation, selective serotonin reuptake inhibitor treatment for the S/_ condition raised serotonin levels to 283% of baseline. A similar increase was observed in the LL genotype condition. Ondansetron treatment should reduce dopamine firing, which it did by approximately half in both the LL and S/_ genotype conditions. Acute drinking approximately doubled extracellular serotonin levels for both genotypes. In each case, the model provided output that was consistent with expectations, which provides a measure of confidence in the model's face validity.

The Johnson Model was motivated by an interest in improving our understanding of the mechanisms by which the 5-HTTLPR polymorphism may be associated with differential outcome of alcoholism pharmacotherapy with ondansetron and selective serotonin reuptake inhibitors. One of the important results of the simulation is that the LL genotype condition shows a dramatic difference in how reinforcing alcohol drinking is under ondansetron and selective serotonin reuptake inhibitor treatment. Figure 4 presents simulation data showing that under selective serotonin reuptake inhibitor treatment, alcohol drinking is more rewarding in the LL condition than it is under ondansetron treatment. Reward is operationalized as the difference in dopamine firing for the drink and no-drink conditions, such that higher levels of dopamine firing are considered more rewarding. That is, for those with the LL genotype,

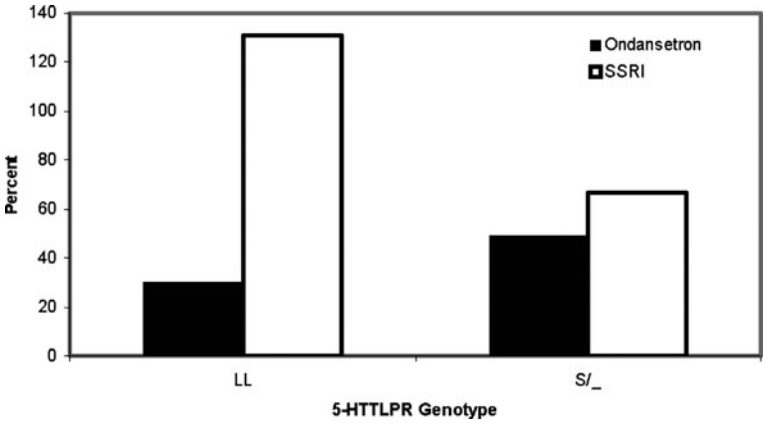

Fig. 4 The positive reinforcing effects of drinking alcohol are presented for groups defined by 5-HTTLPR genotype and treatment condition. The reinforcing effects of drinking alcohol are operationalized as the difference in dopaminergic activation between the drinking and no drinking conditions. For those with the LL genotype, drinking is relatively more rewarding in the selective serotonin reuptake inhibitor (SSRI) treatment condition than in the ondansetron treatment condition. For those with an S allele, little difference in reward is seen between the two treatment conditions

drinking in the selective serotonin reuptake inhibitor treatment condition is relatively more rewarding than drinking in the ondansetron treatment condition (see Fig. 4). It seems a reasonable interpretation that the ineffectiveness of selective serotonin reuptake inhibitor treatment for individuals with the 5-HTTLPR LL genotype is due to the reinforcing properties (i.e., capacity to activate dopaminergic neurons) of drinking. In contrast, under ondansetron treatment, drinking alcohol is not very reinforcing, which may explain the relative effectiveness of ondansetron treatment for those with the LL genotype. For those with the S/_ genotype, there is little difference in the reinforcing properties of drinking for the two treatment conditions. It may be that those with the LL genotype drink alcohol primarily for its rewarding properties, and, because ondansetron reduces the reward of drinking, it can be an effective treatment. Because selective serotonin reuptake inhibitor treatment actually increases the rewarding effects of drinking, for those with the LL genotype, it is ineffective as a treatment. The simulation results are consistent with the Johnson Model predictions regarding ondansetron treatment.

The simulation results for the selective serotonin reuptake inhibitor treatment conditions do not lend themselves to a simple interpretation. Figure 5 presents extracellular serotonin levels in both treatment conditions for both genotypes. The pattern of extracellular serotonin is similar for the LL and S/_ genotypes. Drinking raises serotonin levels across the board and, when coupled with selective serotonin reuptake inhibitor treatment, does so rather dramatically. It is worth noting that acute drinking raised serotonin to about the same level as did selective serotonin reuptake inhibitor treatment. Therefore, if an individual were to drink to raise serotonin into some "target zone", the same result could be accomplished by taking a selective serotonin reuptake inhibitor. The combination of drinking and selective serotonin reuptake inhibitor treatment raises serotonin levels substantially, perhaps to levels that could be considered aversive. For the LL genotype condition, the reinforcing effects due to dopaminergic activation may outweigh such aversive feelings. Because drinking is less reinforcing for the S/_ genotype group, the elevated serotonin levels may be aversive enough so that drinking is reduced under selective serotonin reuptake inhibitor treatment. These data seem to fit with a craving pathway model [36] such that those with the S/_ genotype experience relief craving and those with the LL genotype experience reward craving [30].

Such findings suggest questions that could be addressed empirically. Do individuals with the LL genotype drink primarily for alcohol's positive reinforcing effects? Do individuals with the S/_ genotype drink primarily for alcohol's

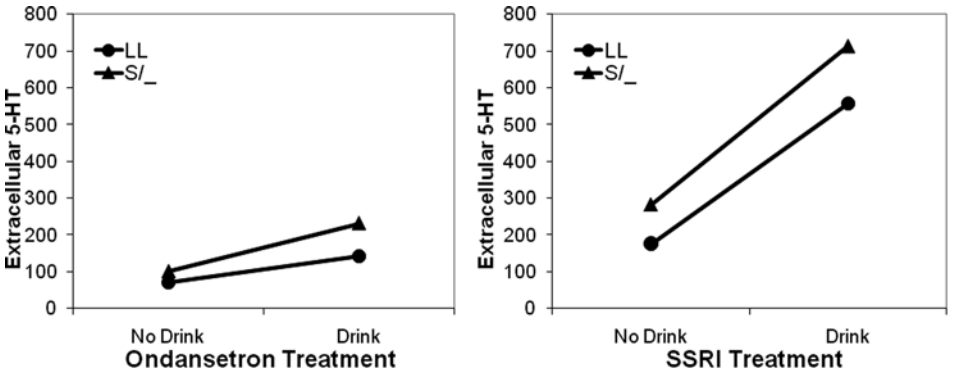

Fig. 5 Levels of extracellular serotonin (5-HT) across treatment and drinking conditions for groups defined by 5-HTTLPR genotype. Drinking raises serotonin levels for both ondansetron and selective serotonin reuptake inhibitor (SSRI) treatment, but the drinking-related increase is greater in the selective serotonin reuptake inhibitor treatment condition

negative reinforcing effects? Do individuals who drink for alcohol's positive reinforcing effects respond well to ondansetron treatment? Do individuals who drink for alcohol's negative reinforcing effects respond well to selective serotonin reuptake inhibitor treatment? Ondansetron does appear to reduce cue-induced alcohol craving [25] as well as other reinforcing effects of alcohol [13], but these effects might be specific to certain genotypes or alcoholism subtypes [13, 30].

In this section, a dynamic systems-based model was described as an example of how to incorporate genetic variation into mechanistic models of alcoholism treatment. The potential for the use of such control system modeling to test and to generate hypotheses regarding alcoholism pharmacogenetics has not yet been fully realized. Models such as these enable the systematic investigation of systems that have many parameters and in which components interact, thereby making predictions difficult. Dynamic control system models are relatively easy to construct using commercially available software such as STELLA (http://www.iseesystems.com/) or Berkeley Madonna (http://www.berkeleymadonna.com/). Both of these systems enable the user to build models with graphic interfaces and do not require the user to write systems of equations. These easy-to-use software packages enable the non-mathematician to engage in theoretically stimulating model building. Increased use of such modeling is likely to catalyze an increase in our understanding of the complex genetic architecture that underlies the etiology of alcoholism and the heterogeneity of alcoholism treatment response.

Modeling and the Personalized Treatment of Alcoholism

It is reasonable to envisage that future treatment of clients who present for alcoholism treatment might benefit directly from a personalized approach that utilizes a dynamic systems-based model. Such a model could make use of data obtained during the intake interview, such as age of onset and measures of severity and comorbidity, together with genetic data obtained from a buccal cell or blood sample, to characterize the specific dysfunction related to their disorder and to determine the most effective course of treatment.

Dynamic system models enable the researcher to utilize the full toolbox developed by mathematicians for solving and manipulating differential and difference equations. One of the most important properties of such equations is that they can often be shown to be controllable. The controllability of such systems of equations is of particular interest in terms of personalized medicine. If the system is controllable, then it may be possible to adjust parameters to move the system's current state into a desirable space. In the context of personalized alcoholism treatment, such controllability suggests that it may be possible to identify a combination of medications at specific doses that have a high probability of altering system function to, for example, reduce or eliminate the urge to drink in a particular individual. Such an approach to alcoholism treatment that is informed by biological mechanism, individual differences, and dynamic system models would be an important advance in personalized medicine.

While the systems involved have not been characterized fully, there is no question that genetic variation plays a significant role in the effectiveness of alcoholism treatments. The use of theoretical models, such as the Johnson Model, is an important first step in an empirically based, mechanistic understanding of the pharmacogenetics of alcoholism treatment. Dynamic systems-based models are important tools for systematically investigating complex systems across levels of analysis such as individual differences in alcoholism treatment response.

Conclusions

Personalized alcoholism treatment, while not yet a reality, is an important goal for researchers and treatment providers. Currently, the focus is

on identifying the relevant personal characteristics that will be of diagnostic and therapeutic utility. It is thought that treatment regimens based on specific characteristics of the individual seeking treatment will result in outcomes that are more rapid, more effective, and more long-lasting than treatment regimens not tailored to the individual. One approach to personalizing alcoholism treatment is to use the client's genotype for information about alcoholism subtype and relevant pharmacokinetic and pharmacodynamic states. Theoretical models that describe the relations between a person's genotype and the action of pharmacological agents are sorely needed to advance the science underlying personalized alcoholism treatment, and the Johnson Model is a step in the right direction. The Johnson Model proposes a mechanistic explanation of differential outcomes of pharmacological alcoholism treatment based on genotype. The simulation described in this chapter advances the study of personalized alcoholism treatment by providing a platform to facilitate systematic hypothesis testing and generation. Because the systems of interest are complex and cross levels of analysis, dynamic and systems-based models are likely to be of great utility in the quest to develop a rational and systematic approach to personalized treatment for alcoholism.

Part XI
Dependence in Specific Populations

Enhancing Positive Outcomes for Children of Substance-Abusing Parents

Karol L. Kumpfer and Jeannette L. Johnson

Contents

Introduction

The misuse of alcohol and other drugs has a significant impact on global health and economy as well as the well-being of children and families. It is estimated that around 48% of adults worldwide use alcohol and 4.5% use illicit drugs, though only about 15% misuse alcohol and drugs [4]. The greater the consumption of alcohol, the greater the harm done [7, 110]. It is of interest that Europeans have the highest amount of yearly alcohol consumption in the world. It is 2.5 times that of the world average

[4]. Despite lower overall consumption levels in Northern European countries compared with Southern European countries where drinking small amounts of wine with meals is common, when Northern Europeans in Nordic counties drink they display more detrimental patterns of excessive use [79]. Alcohol and other drugs misuse has a wide impact on all strata of society, not just in terms of illness and disease, but also on violence and crime rates, workplace injuries and performance, and family stability and relationship breakdown. The cost of addictions in the United States is very high and is estimated at about $2,000 per person in economic costs related to lost revenue, taxes, treatment costs, criminal justice costs, fires, accidents, and other related costs [17].

Prevalence of Children of Substance Abusers

The substance misuse by adults does great harm to both themselves and society in general. Their children are impacted as well, often negatively, because many adult substance abusers are also parents. Substance abuse is a family disease because the addict affects those who live around him or her. Parental substance abuse is a public health concern due to its high prevalence and relationship to many negative child developmental and health outcomes. It is estimated that about 25% of children in the United States (19 million) under the age of 17 are exposed to parental alcoholism [42]. The estimate for the number of children of drug abusers in the United States is about 12.7%, or 9.2 million.

Children's Feelings and Beliefs About Parents' Substance Misuse

Recent studies [9–11] have reported on the child's perspective toward their alcohol or drug-using parents. These studies demonstrate three common themes: family role reversal, keeping the family secret, and coping strategies. These themes demonstrate the need for new approaches and interventions to support the development of children living in families where drug use is a problem. Children can feel confused and insecure when they do not understand their parents' erratic behavior and mood, which can be significantly impacted by the effect of alcohol or other drugs. Parents are often like "Dr. Jekyll and Mr. Hyde"—two different personalities. They tend to be more loving and humorous when using moderately, but can be anxious, paranoid, and use excessive punishment when in withdrawal from their drugs. Of course, the impact on personality of the parent depends on the drug of choice and other mental health problems. Excessive use of stimulants can make parents more agitated and dangerous to children, whereas heroin or depressant users tend to just get sleepy and groggy. Many children take on the parents' role for their younger siblings due to the incapacitating effects of some drugs.

Differences Between Children of Alcoholics and Children of Other Drug Abusers

There are many different combinations of substances that can be abused and patterns of parental chemical dependence that influence the lives of the children growing up in alcoholic or chemically addicted families [51]. First, the behavior surrounding the drug of choice differs. Unlike alcohol, the possession of heroin or cocaine is illegal, as is marijuana in most states. Children exposed to parents who abuse illegal drugs are also exposed to an aspect of life that children of alcoholics are not; using illegal drugs means that it is a criminal offense. The children who know about their parents' drug use must be involved in a shroud of secrecy, giving rise to a home environment that is veiled in fear, lest the cops find out about what their parents do. Unlike alcohol, which can be consumed openly and without fear of legal reprisal (barring certain restrictions), illicit drug use/abuse requires

great secrecy. For this reason, the child of an addicted parent must contend with the secretive illegal drug activity of their parent both at home and in the community. Second, unlike children of alcoholics, the AIDS epidemic directly confronts the children of addicted parents, especially if the parents are intravenous drug users. Loss of significant others due to AIDS-related illness may become more pronounced in the lives of these children. Addicted parents may have AIDS (or be HIV positive); friends of their parents may have AIDS, or babies in the community may be HIV positive. Third, the type of chemical dependence influences the type of childhood home environment, especially if the addicted parent abuses heroin or is involved with an insidious addiction to crack. Parents involved with deviant activities may invite adult friends into the home who are also involved with similar activities. The presence of adult antisocial role models is a strong possibility for children living with addicted parents. Home environment is a critically important variable in shaping cognitive skills, academic achievement, and psychosocial adjustment. Deviant home environments are the source for many childhood behavioral problems [114]. Finally, the effect of the drug on the parents' behavior is profound. Methamphetamine addicts act one way, and heroin addicts another. This affects the parental role and parental behavior profoundly.

Higher Risk for Addictions

Research suggests that children of addicted parents are at 2–9 times greater risk of becoming substance abusers as adolescents or adults [1, 23, 58] despite the positive and adaptive behavioral outcomes of many of these children [50]. Among adolescents, children of substance abusers misuse substances more than children whose parents are not substance abusers and escalate their use more steeply. As young adults they are more likely to be diagnosed with alcohol and drug abuse/dependence [21]. The risk for later substance misuse depends upon their degree of risk factors compared with protective factors including the extent of their family history of alcoholism, which includes whether one or both parents are abusers and the addiction severity, the type of alcoholism that runs in the family [115, 117], and the extent of their parents' antisocial behavior, health, and mental health problems. Gender differences also exist; for example, girls have increased vulnerability to the negative impact on later drug use of family environmental risks, which are high in families with substance-abusing parents [73].

Living with a parent who abuses alcohol or other drugs can have severe effects on every aspect of a child's life, including social acceptance, mental and physical health, and school performance [78]. Most studies find children of substance abusers to have elevated rates of psychological symptoms [26]. Beyond risk for addictive behaviors, children of substance abusers are also at higher risk for developing emotional, behavioral, academic, criminal, and other social problems [80, 101]. They tend to be lower on protective factors and higher on risk factors [97], increasing their risk for depression, suicide, eating disorders, chemical dependency, and teen pregnancy.

They tend to have heightened levels of conduct problems in preschool [37], elementary school [130], and delinquency in adolescence [22, 100], particularly if their parents also show antisocial behavior [108]. Children of substance abusers also demonstrate elevations in impulsivity and activity level [37] as well as behavioral disinhibition [126], leading some researchers to view them as behaviorally undercontrolled. Children of alcoholics have been found in a longitudinal study to age 23 years to employ more of a cognitive coping style and less of a decision-making coping style than children of non-alcoholic parents [46]. Similarly, children of two parents with substance use disorders tend to use aggression as a major coping style, compared with children of only one or no parents with substance abuse disorders, who use a more problem-solving, decision-making style of coping [8]. Earlier studies described children of

substance abusers as higher in "difficult temperament", meaning a relatively stable trait, likely genetically linked, that led to increased emotional and behavioral liability and difficulty with behavioral control [13]. Parental alcoholism has also been linked to anxiety and depression in children [22, 113], and West and Prinz [133] have noted that children of alcoholics had higher levels of anxiety and depression than did controls in 10 of 11 published studies.

Children of substance abusers show lower academic achievement than do children whose parents are not substance abusers [89], even in comparison with depressed children or children of divorce [116], and they have poorer cognitive functioning in the preschool years than do children whose parents are not substance abusers [95]. Casas-Gil and Navarro-Guzman [18] have identified five variables on which school performance by children of alcoholics was poorer: intelligence, repeating a grade, low academic performance, skipping school days, and dropping out of school. Sons of male alcoholics who have many alcoholic relatives across generations have been reported to show deficits in verbal and abstract reasoning and verbal learning [44, 134]. For this subgroup, Pihl and associates [106] suggested that cognitive deficits may be caused by heritable dysfunctions of the prefrontal cortex and limbic systems. However, cognitive impairments may also stem from fetal alcohol exposure [124], high stress levels in pregnant mothers or a lack of environmental stimulation or conversely a chaotic home environment [95].

Genetic Risks

Family, adoption, and twin studies support the heritability of addictions estimated to contribute to about 40–60% of the overall risk for addiction. This heritable influence appears not to be substance specific. For instance, children of alcoholics today are also becoming abusers of illegal and prescription drugs. Children in families with many early-onset alcoholics (beginning use before 15 years of age) are at highest risk for later substance abuse or addiction because this is an indicator of Type II alcoholism. Type II alcoholism is the highly heritable type of alcoholism that appears to have a heavy genetic loading as compared with Type I alcoholism, which is more environmentally caused. Research suggests that about 60% of the variance in risk for an alcohol use disorder is related to genetic factors and the remaining 40% is due to environmental factors in this type of alcoholism in males [117]. However, twin and adoption studies suggest that girls are not at such a high risk. In females, only about 40% of the variance in risk for an alcohol use disorder is related to genetic factors and the remaining 40% is due to environmental factors. However, this risk increases if both biological parents are alcoholics from Type II alcoholism families. Luthar and associates [84] found that similar adverse circumstances are present for children whose parents abuse illegal drugs. They concluded, however, that maternal drug abuse per se is not as damaging to children's resilience as maternal stress, depression, and anxiety disorders [85].

Which Genes are Involved?

Since the completion of the human genome project, there has been considerable interest in the identification of genes involved in this complex disease. Research has identified many genes that contain allelic variants associated with heritable phenotypes or characteristics that enhance vulnerability to addiction [127]. Over 1,500 genes have been implicated in research to increase vulnerability to addiction. However, a meta-analysis of these studies by a Chinese research team found that only five gene pathways were involved in the four major types of drug dependency from a total of 18 statistically significant molecular pathways for single types of addiction [81]. These five pathways may underlie shared rewarding and addictive processes—i.e., neuroactive ligand-signaling interaction, long-term potentiation, and the mitogen-activated protein kinase

signaling pathway linked to memory and learning, and two new ones: (1) the gonadotrophin-releasing hormone signaling pathway involved in gonodrophine secretion, and (2) stress-induced drug seeking and gap junction. They connected the five pathways into one common hypothetical molecular network for addictions. According to Uhl and associates, "The overlapping genetic vulnerability for developing dependence on a variety of addictive substances suggests large roles for 'higher order' pharmacogenomics in addiction molecular genetics" [128]. Discovering the pharmacogenomics of addiction is likely to have broad implications for neurotherapeutics.

Characteristics or Phenotypes of Children of Alcoholics that Increase Their Risk

Because the specific genes for addiction are only now beginning to be discovered, research has focused on identification of the phenotypes or disorders these children could inherit that increase their rates of substance abuse. Actually, genotypes do not always translate directly into phenotypes; hence, predicting later substance abuse is enhanced by monitoring the behaviors of high-risk children with many relatives who began alcohol or drug use before the age of 15 years of age.

These phenotypes or characteristics of children of substance abusers with Type II alcoholism include higher rates of neuropsychological and limbic system deficits that include either: (1) behavioral and emotional self-regulation problems or (2) reduced executive functioning [23]. Research suggests that these two cognitive deficits are primary factors leading to reduced resilience and increase risk for addiction [40, 43].

Children of substance abusers have been reported to be genetically vulnerable to two major syndromes: (1) the overstressed youth syndrome (e.g., poor emotional regulation, difficult temperament, autonomic hyper-reactivity, and rapid brain waves) and (2) prefrontal cognitive deficits in verbal and abstract reasoning and verbal learning. These cognitive deficits reduce their ability to understand that their parents' erratic behaviors are caused by drugs and not by the child's own behaviors [87]. Schuckit [115] found that alcohol smoothes out the overactive autonomic nervous system stress response in children of alcoholics so that they report feeling normal for the first time in their lives. Alcohol and drugs also increase essential neurotransmitters such as dopamine, serotonin, and noradrenalin, which reduce their depression and anxiety.

Diversity of Outcomes in Children of Substance Abusers

Although having a substance-abusing parent affects many aspects of a child's life, the degree of impact on children of substance abusers varies considerably. Although they are at higher risk, most children of substance abusers manifest few developmental and psychological problems and do *not* develop substance use disorders [119]. The great difference in later substance use disorder rates among children of substance abusers appears related to the number of inherited phenotype risks from Type II alcoholism family history and the number of Type I alcoholism environmentally caused risks. Also, girls appear to have less genetic risk than boys, but girls can have higher sensitivity to family environmental risks.

The impact of parental addiction on children of substance abusers varies with degree of severity, developmental timing, and length of parental substance misuse. For example, children of active alcoholics have greater psychological distress than children of parents in recovery [91], particularly if the parents' abuse ended early in the child's development before 6 years of age [92]. A longitudinal study by Andreas and O'Farrell [5] suggested that periods of fathers' heavier drinking patterns lead to increased children's psychosocial problems. O'Farrell and

Feehan [102] found that remission after alcoholism treatment was associated with reduced family stressors, domestic violence and conflict, separation, and divorce, as well as improvement in family cohesion and caring. Also, children were less affected by parental substance abuse if their parents had no other mental disorders [48].

The Family

Environmental Impacts: Global Negative Impact of Childhood Adverse Experiences on Children of Substance Abusers

There has been considerable interest recently in the negative impact of early childhood adverse experiences on children's neurodevelopment and health outcomes leading to increased health care costs [3]. Parental drug abuse and alcoholism has been found, in a decade-long study by the Centers for Disease Control and Prevention of health management organization members, to be associated with multiple adverse early childhood circumstances [31]. This same research group found that parental alcoholism and multiple childhood adverse experiences increased the risk for later adult alcoholism [32]. However, multiple childhood adverse experiences increased the risk 2- to 4-fold for later self-reported alcoholism, heavy drinking, and marrying an alcoholic even without parental alcoholism. In this retrospective self-report study of over 8,500 individuals, those who grew up with *both* an alcohol-abusing mother and father had the highest likelihood of childhood adverse experiences. The mean number of childhood adverse experiences for persons with no parental alcohol abuse was only 1.4, compared with about twice as many for those with an alcohol-abusing father only (2.6) or mother only (3.2). Having both parents abusing alcohol increased the risk of childhood adverse experiences almost 3-fold for a mean of 3.8 childhood adverse experiences. Of interest is the lack of protection from adverse experiences in the family if the mother was an alcohol abuser.

Similar adverse circumstances are present for children whose parents abuse illegal drugs [84]. These childhood adverse experiences can include exposure to frequent stressful and traumatic experiences such as abuse (emotional, physical, and sexual), neglect (emotional and physical), witnessing family violence and criminal behavior, parental divorce and separation, and parental incarceration. Hence, parental substance abuse or a family history of early-onset alcoholism or drug abuse is a potent risk factor for later addiction in children.

Family Environmental Risk and Protective Factors

A number of family risk and protective factors contribute to the high rates in youth today. Worldwide, parents are spending less time parenting and supporting their children. Few parents in the United States still have a meal each day with their children, although two-thirds of children in other countries still have the main meal with their parents. However, fewer children than that talk with their parents on a regular basis [129]. Living with drug-addicted caretakers, who spend about half as much time with their children as the average parents spend, increases children's stress levels.

Other research suggests that positive family functioning can reduce genetic predispositions [49]. Having a mother who is an addict or two parents who are addicted increases their risk for later developmental problems [31]. Without extended family protection and family or agency support, many children of substance abusers live in disruptive family environments. These environments are frequently characterized by family conflict, disorganization or disrupted family rituals (meals together, bedtime rituals, holidays, etc.). The environment contributes to an already elevated sense of anxiety and stress in the children.

In families where alcohol or other drugs are being abused, behavior is frequently unpredictable and communication is unclear. Family

life is characterized by chaos and unpredictability. Behavior can range from loving to withdrawn to crazy. Structure and rules may be either nonexistent or inconsistent. Adult children of alcoholics report more parentification, instrumental caregiving, emotional caregiving, and past unfairness in their families of origin [56].

Not every family is affected identically. Research has shown that families that maintain certain "rituals", such as holiday traditions or a Friday night pizza and movie, can help mediate the chaos of addiction. Sober parents who are able to provide stability, support, and nurturing also help to minimize confusion and strengthen children. Sometimes family life is less damaging because children rely on "adaptive distancing", a technique in which the child separates from the "centrifugal pull" of family problems in order to maintain pursuits and seek fulfillment in life, school, and friendships [62].

Finally, in addition to adverse circumstances within the family, parental alcoholism is also associated with elevated levels of more general negative uncontrollable life events [22, 113, 120]. In particular, because alcoholics are likely to have less education and lower income [93], children of alcoholics may have fewer economic resources available to them. Consistent with their lowered socioeconomic status, children of alcoholics are more likely to report that a parent was fired from a job and that their families suffered from financial problems [120]. Although little is known about the exposure of children of alcoholics to adverse neighborhood or school environments, their lowered socioeconomic status raises the possibility that their broader social environments may also be less than ideal.

Substance Abuse Impact on Parenting

An important, yet poorly understood, feature of drug overuse is the potential impact on parenting capacity and child health outcomes. It is known that parents who are substance users become more aggressive and/or abusive toward their child when under the influence of drugs [137]. It is estimated that 40–80% of child abuse reports concern families with substance abuse issues [24, 99]. Parents who use alcohol and drugs tend to be poor role models for their children, often exposing them to drug use and illegal behaviors, which may increase the risk of the children being recruited into drug use as they get older [20]. Thus, parents who use alcohol or drugs have greater risk of influencing children's developmental outcomes.

Although not all children are negatively impacted by their parents' use of alcohol or drugs, the task of raising a child is undoubtedly made more difficult when a parent is regularly affected by alcohol or drug use [9]. Despite federal funding and Medicaid funding for mothers' and children's residential or outpatient treatment facilities, there are still not enough treatment facilities that accept children; when they do, programming for the children is frequently neglected. Unfortunately, there is a common notion among many treatment programs that the parent should focus on his or her own recovery; the children are kept separated from the treatment process. This ignores the fact that improving parenting significantly reduces the parent's guilt and depression and reduces relapse.

Child Abuse Potential

The comprehensive national survey conducted by the National Center on Child Abuse and Neglect [98] found that 80% of surveyed states reported that parental substance abuse and poverty are the two major problems among child protective caseloads. Children of substance-abusing parents are 3 times more likely to be abused and 4 times more likely to be neglected than children from families where parents do not abuse alcohol and/or other drugs [66]. Other national studies also support these findings; between 40% and 80% of all child maltreatment cases involve parental misuse of alcohol or drugs [24].

Compared with non-addicted parents, addicted parents tend to neglect their children, spend about half as much time with them, and use more of a punitive and authoritarian parenting style with higher levels of corporal punishment [67]. However, these children are more often neglected rather than emotionally or physically abused. Suomi's [125] research with peer-raised monkeys suggests that neglect may be more devastating to children's brain and social/emotional development than physical punishment because neglected children feel unprotected by caring adults. Their levels of stress and anxiety are raised, resulting in insecurity, lack of parental bonding, and stronger peer cluster bonding; in turn, exploratory behaviors are reduced. Exploratory behaviors are needed in the development of self-control and executive functioning, but since they are reduced in stressful and anxiety-producing environments, the developmental process is perturbed.

The less-than-optimal parenting and family environments that children of alcoholics experience extend beyond the relationship between the alcoholic parent and the child. Even in infancy, deficits in mother-infant attachment have been found in families with problem-drinking fathers [33]. Moreover, parental alcoholism is associated with higher levels of parent-adolescent conflict [12]. Parental alcoholism is also associated with higher levels of exposure to family conflict and violence [90, 120], although parents are not necessarily the perpetrators of the violence [90].

Protective and Resilience Factors in Children of Substance Abusers

Resilience has been defined as the achievement of competence or positive developmental outcomes under conditions that are adverse or that challenge adaptation [88]. The Resilience Framework [61] suggests that the development of resilience in high-risk children, such as children of substance abusers, is a complex transactional process between the child, his or her parents or caretakers, and their environment.

Not enough research has been conducted to understand these resilience processes. In contrast to the substantial literature on the relationship between parental alcoholism and children's psychological problems, studies have generally failed to examine the development of resilience and competent performance or positive outcomes in children of alcoholics, although some relevant work has been done on the absence of negative outcomes. Generally, these studies have sought to specify factors that protect children of alcoholics from the negative outcomes associated with parental alcoholism. For example, Werner [131] followed children of alcoholics from birth to age 18, and reported that those who did not develop serious problems had experienced fewer negative stress events, had more cuddly and affectionate infant temperaments, and had higher self-esteem and better communication skills. In a 32-year longitudinal study, Werner and Johnson [132] found that one caring adult in the child's life is a significant protective factor.

Several studies have focused on positive family environment factors and have discovered a few protective factors or processes. Wolin and colleagues [136] found that alcoholic families who maintained consistent rituals (e.g., vacations, birthday celebrations) had children who were less likely to develop alcohol problems. Similarly, children of alcoholics whose families had higher levels of organization were less likely to initiate illegal drug use [45].

Higher levels of family cohesion and support have also been shown to enhance outcomes for children of alcoholics. Farrell et al. [36] found that children of alcoholics showed high levels of adolescent deviance and distress when family cohesion was low, but that these effects were reduced when family cohesion was higher. Similarly, Barrera and associates [12] found that children of alcoholics in low-conflict families resembled children whose parents were not alcoholics, whereas children of alcoholics who experienced high levels of family conflict showed elevated levels of psychological distress. The notion that family cohesion and support are associated with better outcomes among children of

alcoholics is consistent with Moos and Billings' [91] finding that families in which paternal alcoholism had remitted after treatment had both higher levels of family cohesion and lower levels of psychological distress among their children. These data suggest that parental recovery may promote resilience for children of alcoholics, perhaps because the family environment also recovers. However, because these findings are from a sample of fathers who received alcohol treatment, they may not generalize to untreated families [21].

Research has also suggested that parental supervision is an important protective factor for children of alcoholics. Curran and Chassin [27] found that consistent discipline and monitoring of their adolescents' behavior by mothers were associated with better outcomes among both children of alcoholics and children whose parents were not alcoholics. However, consistency of discipline includes monitoring and positive reinforcement and should not be taken as synonymous with punishment, which has been associated with poorer outcomes among children of alcoholics [130].

Finally, some data point to the importance of extra-familial influences. Ohannessian and Hesselbrock [103] found that children of alcoholics with high levels of support from friends closely resembled children whose parents were not alcoholics, whereas children of alcoholics with less peer support consumed more alcohol and had more alcohol-related problems. Thus, a supportive relationship with someone outside of the family may be protective. Moreover, Jordan and Chassin [52] found that adolescent children of alcoholics who had greater involvement in positive activities outside the home were less likely to develop a substance use disorder in young adulthood. In the case of parental alcoholism, where adverse circumstances exist within the family environment, extra-familial influences may be particularly important.

A significant protective factor to build the resiliency of children is to bolster social support networks and to increase autonomy and sense of safety. For children growing up in an unpredictable environment with parental substance abuse, improving resilience and enhancing protective factors is valuable. It seems clear that educational health care interventions presented in a supportive social environment are a useful and effective strategy for improving outcomes and enhancing health behaviors.

In summary, although research has not focused specifically on positive outcomes and competent performance among children of alcoholics, some work has been done to identify factors that predict lower levels of negative outcomes. These studies suggest that parental support and control, and family environments that are characterized by stability, cohesion, organization, and preservation of routines and rituals are associated with better outcomes. These critical family protective processes (e.g., family attachment, parental supervision and monitoring, and organization and communication) were found to be the most important protective factors of later substance use in a major cross-site study of 8,500 high-risk youth funded by the Center for Substance Abuse Prevention [123]. In addition, high levels of friend support and involvement in positive activities outside the home reduce negative outcomes for children of alcoholics. Finally, it has been suggested that parental recovery from alcoholism is itself protective.

Prevention Programs Specifically for Children of Alcoholics

School-Based Primary Prevention Programs

Very few prevention programs have been developed specifically for children of alcoholics [59, 135]. Most prevention programs specifically for children of alcoholics are limited to school-based education programs that are relatively short in duration and conducted with small groups of students who self-identify as children of alcohol or drug abusers [107]. Although there may be many such school-based programs for children of alcoholics, according to Price and Emshoff [107], very few of them are

even described in the prevention literature and even fewer have outcome evaluations. Because of the positive research results for behavioral training models, programs for children of alcoholics are including more social competency skills training. In one of the few research-based models, Roosa and colleagues [112] found positive changes in knowledge, social support, and emotion-focused coping behavior in their 8-week, school-based program for children of alcoholics. Emshoff's [34] Students Together And Resourceful program teaches students social competency skills, and provides accurate information about alcoholism and its effects on the family. Participants reported more friends and stronger social relations, increased sense of control, and improved self-concept with less depression.

Family-Focused Prevention Programs for Children of Alcoholics and Substance Abusers

Several prevention programs for children of alcoholics and substance abusers that include a family-strengthening approach to increasing resiliency through family skills training have been developed and tested in federally funded prevention research—namely, the Strengthening Families Program [60, 72] and Focus on Families [19]. Positive results have been found for the Strengthening Families Program in improving social competencies and family relationships and in reducing later tobacco, alcohol, and drug use in children of addicted parents in treatment. Moreover, this program has been modified and evaluated for rural and urban African/American, Latino, Asian and Pacific Islander, and, recently, American Indian families.

Community-Based Prevention Programs for Children of Alcoholics

There are very few community-based programs for children of alcoholics, but one popular one is Alateen. This self-help support program for children of alcoholics is implemented in the community through Alcoholics Anonymous. This program provides a safe environment in which children can share their feelings, experiences, and tips for surviving their parents' addictions and negative behaviors. The Cambridge and Somerville Program for Alcoholism Rehabilitation program [28] offered junior-high-aged children of alcoholics or children whose parents were not alcoholics a range of after-school services at schools or in community settings. DiCicco et al. [30] found that mixing children of alcoholics and children whose parents were not alcoholics in alcohol education groups, compared with groups specifically for children of alcoholics, resulted in reduced drinking among children of alcoholics and reductions in the intention to drink in the future. Moreover, because of stigmatization issues, recruitment of children of alcoholics was easier for the basic education group than for the group that was specifically for children of alcoholics. These results suggest that prevention programs not specifically for children of alcoholics may be a valuable option for recruiting and delivering services to children of addicted or substance-abusing parents.

Family-Based Prevention and Treatment

Developmental theories support the critical role of families in child raising and suggest that supportive families are key to raising healthy children and preventing later adolescent problems. Our consumer-oriented, fast-paced society appears to have forgotten this important role for parents. Longitudinal research suggests that parents substantially impact their teens' health behaviors [111]. Although peer influence is a major reason why adolescents initiate negative behaviors, a positive family environment (e.g., family bonding, parental supervision, and communication of pro-social family values) protects youth from engaging in unhealthy behaviors, such as substance abuse, delinquency, and

early or unprotected sex. These protective family factors have even a stronger influence on girls [71].

What can be done to reduce unacceptably high levels of harmful behaviors in adolescents? Evidence-based family intervention approaches that have been found to be effective include [65]: (1) behavioral parent training (primarily cognitive/behavioral parent training); (2) family skills training (including parent training, children's skills training, and family practice time together); (3) family therapy (structural, functional, or behavioral family therapy), and (4) in-home family support. The most recent review [2, 63] identified 35 family interventions. Information on these specific family interventions including program descriptions, Web sites, and contact information can be found at www.strengtheningfamilies.org.

Only seven family interventions of these 35 programs met the highest level of evidence of effectiveness, or Exemplary I, which required a minimum of two randomized controlled trials with positive results implemented by at least two independent research teams with different populations [70]. These Exemplary I family programs included: Helping the Noncompliant Child, The Incredible Years, the Strengthening Families Program, Functional Family Therapy, Multisystemic Family Therapy, Preparing for the Drug Free Years, and Treatment Foster Care. Seven programs were classified into the Exemplary II Level because they had at least one randomized controlled trial with positive prevention results. The other programs were classified primarily into the Model Level because they had only quasi-experimental research results. Some Promising Level programs were added to the list because they were programs that were based on existing proven programs, but did not yet have outcome results. Since the last expert review in 1999, additional randomized controlled trials have been conducted on existing and new family interventions; hence, this list is not complete.

The senior author is currently developing a Web site for the United Nations Office of Drugs and Crime with program descriptions and contact information of all the best parenting and family programs in the world for dissemination to developing countries. So far, at least 50 high level evidence-based programs have been identified, with over 500 programs located. A protocol for culturally adapting evidence-based family strengthening interventions has already been published from this United Nations Expert Group's work [77].

Family-Focused Prevention Programs for Children of Alcoholics and Substance Abusers

While a number of effective family-based approaches to substance abuse prevention have been found through expert reviews of the literature [71, 83], only a few were designed specifically for children of substance abusers and only two have been tested in randomized controlled trials—The Strengthening Families Program and Focus on Families.

The Strengthening Families Program [29, 67, 69] was designed by Kumpfer and colleagues in 1982 and tested specifically for children of substance abusers in outpatient methadone maintenance and mental health drug treatment centers in a National Institute on Drug Abuse randomized controlled trial testing the three different components. The resulting Strengthening Families Program includes three 14-week sessions in parent training, children's social skills, and family relationship enhancement, followed by booster sessions every 6 months. Specific program results included improved parenting skills, confidence, and parenting efficacy, which led to a reduction in children's overt and covert aggression, hyperactivity, depression, conduct disorders, and improved social competencies. Family relationships (organization, cohesion, communication, conflict) were significantly improved. Decreases in substance use in both the parents and older children were also revealed. Moreover, this program has been modified and evaluated by independent researchers for rural and urban African/American, Latino, Asian and

Pacific Islander, and American Indian families with positive program outcomes that include a 40% improvement in recruitment and retention for culturally tailored programs [74]. Other randomized controlled trials have reported positive program results in elementary school-aged rural children [75, 76], junior high school rural children [122], and inner-city 7–11 year olds [41]. One 10-year study followed participants to the age of 22 and found a 2- to 3-fold reduction in lifetime diagnosis of anxiety, social phobia, depression, and personality disorders when compared with their no-treatment controls [122].

Recently, a Cochrane Collaboration and World Health Organization meta-analysis of universal alcohol prevention programs in schools [39] found that a 7-session Strengthening Families Program for 10–14 Year Olds [72] was twice as effective in reducing alcohol use as any other school-based intervention having at least 2 years of follow-up data. A cost-benefit analysis showed a return of $9.60 for every dollar spent by the school when they implemented the Strengthening Families Program for 10–14 Year Olds [121]. Because of these positive results, the Strengthening Families Program has been adopted for replication and evaluation in seven countries in Europe, including four that have 1–2 years of pre- to post-test outcome results—Spain [105], Netherlands [104], Sweden [57], and the United Kingdom [38].

The second program, Focus on Families [19], was also developed for children of parents in methadone maintenance treatment. This program found reductions in relapse for the parents but no significant improvement in the children [20]. Zucker and associates [86] found positive results on children's prosocial skills at a 6-month follow-up after the fathers or both parents participated in a 12-session behavioral parenting program tested with fathers arrested for drunk driving.

Two other programs have been designed for children of substance abusers and show promising preliminary non-experimental research results—Celebrating Families and Nurturing Program for Families in Substance Abuse Treatment and Recovery. Designed to prevent child maltreatment in children of alcoholics, the 15-session Celebrating Families has been found to improve family reunification rates from 37 to 72% for children of alcoholics removed by child protective services [109] as well as to reduce the number of days to reunification. Positive changes in knowledge, coping skills, decision-making, and feelings expression were also reported for the program [53]. Using the same evaluation instruments as those used for the Strengthening Families Program, Celebrating Families reported similarly positive effects at post-test on several outcome measures: improving parenting skills, family organization, communication, and cohesion. The child outcomes were mixed, however, and only two positive child outcomes were reported (reduced depression and concentration problems). The study also reported a non-significant positive trend for social skills, and three negative iatrogenic effects, namely for overt and covert aggression, and hyperactivity [64]. A longitudinal study is necessary, as children of substance abusers have been observed to increase their negative acting-out behaviors when their parents enter treatment. Some suggest that these children act out because they feel safer to do so. Finally, research on 170 mothers participating in the Nurturing Program [16] suggested improved parenting attitudes at post-test on the Adult-Adolescent Parenting Inventory and reduced relapse [96].

Prevention programs not specifically designed for children of substance abusers may also be effective if they have core content demonstrated to be effective in reducing mediating factors for later substance abuse in children of substance abusers. For example, Chassin and associates [23] have discussed necessary core content for children of alcoholics that includes content that increases children's alcohol and drug awareness, social competencies, awareness of feelings, emotional and behavioral control, and reducing depression. With the exception of Zucker's intervention [86], most family-based programs for children of substance abusers are family skills training programs that typically include the parent training component and not

children's skills training or family skills training utilizing a standard dosage between 14 and 17 sessions. Shorter programs are not as effective in attaining behavioral changes in addicted families.

Reviews of prevention programs for children of alcoholics and substance abusers [23, 25, 107] have expressed the need for additional research on etiology and effective prevention programming as available outcome studies are dated. Ethical and practical issues in designing, implementing, and evaluating programs for children of substance users are discussed in several publications [25, 35, 50, 55, 61, 87, 107].

Core Content of Effective Family Programs

Effective family programs involve the whole family (rather than just the parents or children) in interactive, skills, or behavior change processes, rather than involving them in didactic educational lessons. The underlying psychological theories include behavioral psychology and/or family systems theory [82] which stress the importance of the engagement process and reducing barriers to attendance through relationship building, personal invitations, provision of meals, childcare and transportation, and sometimes, paying families for their time. Most effective programs begin with sessions designed to improve positive feelings in the family through positive reframing or skills exercises stressing family strengths. Engagement in structured methods for communication and discipline techniques are also practiced once positive family feelings are increased. O'Farrell and Fals-Stewart [101] have found that behavioral couples therapy reduces domestic violence, which indirectly benefits the couple's children. Hence, behavioral couples therapy should be expanded to include children of substance abusers to improve outcomes. An affectionate parent-child bond has a protective effect on later drug use [15]; hence, therapeutic interventions that strengthen parent and child bonding are recommended, particularly when there is already stress from the "generation gap" or differential generational acculturation in immigrant families.

Kaminski and associates [54] at the Centers for Disease Control and Prevention have analyzed the critical core components of evidence-based family intervention programs from 77 studies of programs for 0–7 year olds. Since the presence of conduct disorders in early life often precedes later delinquent, aggressive, and risky behaviors in adolescence, they reasoned that effective parenting could reverse this trend. The core components of effective parenting and family interventions are: (1) the format should include practice time for the parents with their children in the sessions with the therapists or group leaders available for coaching; (2) during family sessions, parents should be taught to interact positively with children (such as showing enthusiasm and attention for good behavior and letting the child take the lead in play activities); (3) parenting content should include increasing attention and praise for positive children's behaviors, children's normal development to make expectations realistic for children's behaviors, positive family communication including active listening and reducing criticism and sarcasm, and effective and consistent discipline including time-outs; (4) children's content should include teaching children social skills for how to get along better with parents, peers, and teachers in a more respectful manner, and (5) home practice assignments should be assigned and encouraged in order to improve generalization of new behaviors at home. Additional reviews of the literature on effective family strengthening approaches have also supported these findings [65, 77] (Office of Juvenile Justice & Delinquency Prevention, Strengthening America's Families Web site, www.strengtheningfamilies.org; United Nations Office of Drugs and Crime Web site, www.unodc.org/unodc/en/prevention/index.html).

Effective Prevention Programs

Kumpfer and Hopkins [68] have stressed preventive approaches for prevention programs for

children of alcoholics and substance abusers that include: emphasizing the negative consequences of alcohol; developing in youth an increased sense of responsibility for their own success; helping them to identify their talents; motivating them to dedicate their lives to helping society rather than feeling that their only purpose in life is to be consumers; providing realistic appraisals and feedback for youth rather than graciously building up their self-esteem; stressing multicultural competence in an ever-shrinking world; encouraging and valuing education and skills training; increasing cooperative solutions to problems rather than competitive or aggressive solutions, and increasing a sense of responsibility for others and caring for others.

Research-based prevention interventions developed for other high-risk youth can also be very effective for children of alcoholics if they address risk factors for children of alcoholics (described earlier) including externalizing problems, internalizing problems, and cognitive deficits or delays. Here we summarize prevention interventions not specifically for children of alcoholics that may be capable of strengthening resilience to later alcohol and drug use among children of alcoholics, organized by their targeted risk factors.

Programs that Increase Behavioral Control and Social Competency

A number of preventive interventions have been developed that are helpful in increasing social competencies, emotional management, and behavioral control, and these may be useful for children of alcoholics who manifest conduct disorders and aggression. When applied universally in classrooms [14, 47], these programs can reduce conduct problems, promote healthier friendships with prosocial children, and hence prevent substance abuse and violence. They are effective without the children having to be identified as children of alcoholics or drug abusers. Some of the indicated prevention programs, however, do require that the teacher refer children with aggressive tendencies and conduct disorders to a pull-out group. Because of possible negative contagion and labeling effects, it is best also to include socially skilled youth in the group.

Programs to Increase Emotional Resilience, Happiness, Self-Esteem, and Humor

Research on resilience in children of alcoholics [131, 132, 136] suggests that hopefulness, happiness, and emotional management increase positive outcomes in children of alcoholics. Universal prevention programs that support improved mental health and resilience also help children of alcoholics. One universal, school-based resilience program is the Strengthening Families Program for 10–14 Year Olds [72], which was first developed in Iowa with National Institute on Drug Abuse and National Institute of Mental Health funds. It is a 7-session parent, child, and family intervention for middle school students. Because resilience studies with adult children of alcoholics (Walker R, Kumpfer K, Neiger B, Richardson G (1997) Resilience in adult children of alcoholics, Department of Health Promotion and Education, University of Utah, "Unpublished doctoral dissertation") have found that meaning or purpose in life is the most critical resilience factor in positive life adaptation, this new Strengthening Families Program focused the first sessions on parents supporting children in developing dreams and goals. Depression is reduced by having children and their parents focus on hopefulness and positive dreams for the future. Youth are encouraged to think about their talents and ways they can use these talents to help others through kind acts and a productive and successful career. Positive psychology [118] suggests that feelings of well-being are more enhanced by doing kindness to others than by doing nice things for oneself. Children of alcoholics who are resilient are youth who have meaningful roles in

their families to help others, or the characteristic of required helpfulness, found in resilience research. Hence, parenting and family skills training programs that teach parents to negotiate chores, create chore charts, and monitor and reward completion of chores help to increase positive self-concept and increase happiness.

Programs for Emotional Management and the Awareness of Feelings

Because children of alcoholics have a higher likelihood of having alexithymia, an inability to identify feelings, most programs for children of alcoholics focus on feelings identification training and on training parents to label feelings that the child appears to be having. This intervention may also help to promote stronger parent-child attachments [33]. Anxiety in children of alcoholics can be reduced through increased predictability of the family environment as well as the school and community environment through family strengthening prevention programs that increase family organization, family management, and expression of supportiveness and love. Children of alcoholics often do have realistic reasons to be worried about their parents' welfare, their welfare, and the stability of the family, because child abuse and neglect [66], job loss and poverty, divorce, and parent deaths are more common [120]. Emotion-focused and problem-focused coping skills training within prevention programs for children of alcoholics [94] can help children to talk through feelings, reframe the negative aspects of the situations, create emotional distance from their fears, and develop other emotional supportive relationships with other adults. Mentoring and after-school programs can be very helpful to children of alcoholics in developing these needed supportive relationships with other caring adults. As found by Jordan and Chassin [52], involvement in positive activities outside the home by young children of alcoholics tends to reduce the likelihood of a substance use disorder in young adults.

Programs to Increase Cognitive Resilience Characteristics

Research with children of alcoholics [131, 50] found that cognitive resilience characteristics include a conceptual understanding of the parents' disease and relationships, the capability to distance oneself from the alcoholic parents in terms of identification, humor, and academic skills and mastery. Both traditional educational programs for children of alcoholics and community media campaigns can be used to promote these resilience factors.

Programs for Educational Interventions, Screening, and Referral

Children of substance abusers, as well as their parents, should know the results of the risk and resilience research on children of alcoholics. They need to know what signs and symptoms to watch for that might indicate that they or their children are high or low in resilience or in risk factors. Research demonstrates that children of substance abusers who are aware of their risk status drink significantly less than those who are unaware of their risk status [59]. Public media and education campaigns could be developed that will disseminate this research and allow children of substance abusers to conduct risk and resilience assessments for themselves. They need to know that a high tolerance for alcohol and being able "to drink others under the table" is not a good sign. Public education campaigns are also needed to reduce stigma and provide additional legal, social, educational, and academic supports for children of alcoholics in a non-stigmatizing environment. Parents and youth should be informed that living with an alcoholic parent can, in fact, lead to increased cognitive, behavioral, and emotional management. Increased stress-coping competencies can improve the ability of children of alcoholics to function in very stressful careers and in

times of distress, thereby improving pride and self-confidence and reducing the fear of a self-fulfilling prophecy.

Summary of Recommendations for Future Research and Policy Improvements

The most obvious implication from this review points toward the need for better longitudinal research. Most studies on children of alcoholics or other drug abusers are not longitudinal; that is, they examine behavior at one point in time. From these studies, it is unclear whether we see true deficits or merely developmental delay. Longitudinal studies allow us to predict when early disorders and behavioral deviations will be transient or when they will be precursors to more severe types of maladaptive behavior. Longitudinal research would also enable us to explain specific childhood outcomes. Differences in outcome could be studied simultaneously to understand whether antecedents discovered for one outcome are specific to it or are general antecedents leading to a broad variety of outcomes. The second implication from this review is the need also to understand the characteristics of resilient children in order to apply these protective factors in our campaign messages. Researchers and helping professionals have long identified a subgroup of children who grow up in homes with alcoholic parents and who seem to grow up relatively "invulnerable" to the detrimental effects of familial alcoholism. The research focusing on this subgroup is scarce. Anthony [6] suggested that there may be subgroups of children of substance abusers who, despite all odds, do, in fact, enjoy good health from birth, experience a positive environment at home, and develop rather normally into socialized, competent, and self-confident individuals. Certain individuals may be more competent in adapting to stressful living environments than others. These children are somehow able to compensate and cope with the various negative biological or environmental influences in their lives. Certain individuals may be able to manipulate their environment by choosing roles and goals in life that stabilize their developmental process and bring them the positive reinforcement they need to develop a positive self-image and, eventually, a relatively healthy life. Other individuals may be able to master the processing of incoming data and to conceptualize these data in such a way as to choose positive behaviors in life that compensate for whatever problems present. Finally, a list of policy recommendations, modified from a more extensive discussion by Chassin and associates [23], point the way toward future social responsibility:

1. International and local national agencies and institutes should develop research programs and support the implementation of evidence-based and family-focused prevention programs for children of substance abusers.
2. Policy makers within international, federal, state, and local governments should provide adequate funds for research, field tests, and wide-scale dissemination of effective prevention approaches for children of alcohol and drug abusers.
3. National surveys should include information that assesses and evaluates precursors of substance abuse such as risk and protective factors including strength-based behaviors.
4. Legislation affecting agencies providing services to children of substance abusers should include language that specifically stipulates the importance of funding effective and evidence-based prevention approaches that include parenting and family skills training programs.
5. Future research should maintain the privacy and confidentiality of children of addicted parents enrolled in prevention, education, and intervention programs.
6. Interagency collaboration is essential if public policy related to children of substance abusers is going to shift.

Overview of the Chapter

Adolescents and young adults make choices that set the course for much of their adult lives. While adolescence is not as chaotic as some may believe, substance use and abuse occurring during this critical period may have a continuing influence on emerging adulthood and beyond. For some, early experimentation with drug and alcohol use leads to a series of increasingly aberrant behaviors with social, legal, and educational consequences. Following experimentation, others age out of problems with the onset of adult responsibilities such as full time employment, marriage, and parenthood. In this chapter, we explore the scope of addictive disorders and substance abuse in adolescents and emerging adults, consider the impact of substance use and disorders on later development of addictive and other life problems, and review the potential for prevention or early intervention to reduce the consequences, including lifelong harm, of drug and alcohol use during these vulnerable periods.

Adolescence: Epidemiology and Risk Factors

Exploration and development of identity, autonomy, sexuality, academic functioning, and peer relationships are important age-appropriate tasks of adolescence [6, 15, 41]. Specifically, this developmental stage may manifest as adolescents question prior beliefs and assumptions and

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_66,

explore new philosophies and behaviors [96]. In addition, during this stage, adolescents are likely to try out behaviors that they believe characterize different facets of adult life. Some of this exploration and experimentation may include substance use and related risk-behavior, including normative and non-pathological experimentation with alcohol, cigarettes, and marijuana [4–6]. For those who are curious, high school provides many opportunities to experiment, as social events often include alcohol and other substances.

Across the nation, experimentation with substances has been starting progressively earlier; by age 13th (8th grade), 26% of surveyed students reported trying alcohol, 16% had smoked a cigarette and 9% had tried marijuana [10]. The rate of substance use and abuse increases throughout the high school years, with high school seniors showing the highest rates of alcohol and other substance abuse [10, 17, 63]. Throughout adolescence, many factors, including environmental characteristics, such as the availability of substances, the level of actual and perceived parental monitoring, and peer group behavior, play a strong role in determining level of substance experimentation and abuse [17].

Risk Behaviors During Adolescence

Binge Drinking During Adolescence

In a recent survey, 74% of adolescents reported having at least one drink in their lifetime [10]. Just under half of these students (43%) stated that they currently use alcohol (defined as at least one time of use during the past month), with that number rising to 51% for high school seniors [10]. More concerning, however, is the rate of binge drinking among adolescents. Specifically, approximately a quarter of adolescents (26%), and 32% of high school seniors reported recently engage in binge drinking [10]. For adolescents, binge drinking is defined more conservatively than for adults; the current definition is three drinks or more per drinking episode for adolescent girls and four drinks or more per drinking episode for adolescent boys. Binge drinking is considered one of the more problematic consumption styles [43].

Rather than causing harm through consistent, steady rates of excess, these single occasions of excessive consumption are harmful because binge drinkers may make poor choices that can lead to sadly irrevocable outcomes, such as the accidents, injuries, and fatalities that may result from drinking and driving [18]. The focus on the harms related to binge drinking are salient, as the current rates of alcohol-related risk behavior that occur among today's high school students is stunning. For example, 30% of American high school seniors reported having ridden in a car driven by a drunk driver, parallel to the percentage of high school seniors who smoke cigarettes [10]. In addition, just a slightly lower percentage (17%) stated that they had driven a car while intoxicated [10].

The demographic factors correlated with binge drinking have been consistent over the last few decades [9]. Specifically, being male, Caucasian, doing poorly in school (in terms of low grade point average and high truancy), having disposable income, and frequently socializing in the evenings correlate with higher levels of binge drinking.

Manifestations of Alcohol Abuse and Dependence in Adolescents Versus Adults

While alcohol use disorders (abuse and dependence) are relatively rare during early or middle adolescence, toward late adolescence, the rates begin to approximate those of adults [17]. Yet, distinct differences remain between adolescent and adult drinking [17, 22]. In a comparison of a adolescent drinkers and adults with alcohol dependence, it was found that while adolescents drink less frequently than adults (adolescents = 13.8 days per month; adults = 21.0 days

per month), the quantity of alcohol consumed per occasion was equivalent between the age groups [29]. Once adolescents commenced regular drinking, defined as drinking at least once a month for 6 months or more, adolescents displayed dependence symptoms including tolerance, withdrawal, and continued alcohol use despite related problems around month seven, while adults did not show these symptoms until year three [22]. After the first year and a half of drinking, many of the adolescent drinkers met criteria for a diagnosis of alcohol dependence whereas the adults did not meet criteria for dependence until year eight [22], indicating the possibility of a "telescoped" progression [62] for adolescents. Together, these data suggest that adolescents with alcohol use disorders may display an absence of traditional dependence symptoms [54].

Marijuana Use During Adolescence

Almost paralleling rates of binge drinking, 38% of American high school students have used marijuana in their lifetime, and 20% report current use [10]. Similar to the predictors of alcohol use, adolescents who use marijuana tend to be male, Anglo, performing poorly in school (in terms of low grade point average and high truancy), have higher income, and frequently socialize during weeknights [18]. While some posit that adolescent marijuana use is not risky and is potentially adaptive for adolescents [98], current concerns about the potential harms of marijuana use have resulted in several National Institutes of Health-based initiatives to intervene with adolescent marijuana use and related risk behavior. Specifically, the literature indicates that adolescent marijuana use has been linked to academic difficulties, other risk taking behavior, delinquency, legal consequences, and health consequences, particularly as related to sexual risk-taking [12]. Moreover, 40% of an adolescent sample identified their marijuana use as contributing to problems involving interactions with others [75]. In addition, this sample of adolescent marijuana users were so dissatisfied with the effects that marijuana had been having upon their lives, that 55% indicated having made a past decision to decrease their marijuana use and 20% stated that they intended to stop using marijuana within the following year.

Tobacco Use During Adolescence

Approximately one quarter (23%) of high school students currently smoke tobacco [10]. The prevalence of tobacco use has been found to vary by several factors, including educational level, income, gender, and culture [118]. Among adolescents, across cultures, Caucasian adolescents evidence the highest rates of current smoking and tobacco use [10]. Also, in terms of gender, smoking has been found to be greater among boys than girls [10]. The most notable aspect about adolescent tobacco use, however, is the high proportion of adolescents who are currently dissatisfied with their smoking. Specifically, over half (55%) of the current adolescent smokers report that they are actively trying to quit smoking [10]. However, tobacco use has been found to be fairly intractable, and reducing use has been found to be quite difficult [58, 59]. There are serious health implications for failed cessation attempts. Specifically, cigarette smoke contains thousands of substances, of which a substantial proportion is carcinogenic [111]. In addition, annually, the number of deaths caused by smoking surpasses the sum of deaths caused by HIV, alcohol and other drug use, motor vehicle accidents, suicides, and murders combined [29, 80]. Smoking has been linked to cancer, cardiovascular disease, pulmonary disease, reproductive health problems, and a number of health problems in nonsmokers [111]. In the United States, smoking peaks around late adolescence (ages 18–24; 24%), and decreases with age, with only 10% of people aged 65 and older smoking [11], highlighting the importance of determining and conducting efficacious tobacco prevention interventions for adolescents.

Alcohol- and Other Substance-Related Sexual Risk Behavior

Like substance use, sexual experimentation during adolescence is normative and has been argued to be developmentally appropriate [97]. While not inherently dangerous, high risk sexual behaviors, such as sexual intercourse without the use of a condom, or sexual intercourse with multiple partners, increase an adolescent's risk of unplanned pregnancy, contraction of sexually transmitted infections including HIV. Among adolescents, alcohol, marijuana, and tobacco use have been highly correlated with sexual activity [90, 104]. Specifically, 23% of sexually active adolescents have used alcohol or drugs before their sexual intercourse [10]. Unfortunately, the relationship between sexual activity and substance abuse is quite risky, as for many adolescents, adverse sexual consequences occur while using alcohol and marijuana, including unplanned sexual intercourse, intercourse with multiple partners, and inconsistent condom use [8, 90]. These risks are heightened for adolescents with comorbid psychopathology, who are two to four times more likely to engage in high-risk sexual behavior while drinking [8].

Adolescence as a Salient Developmental Period for Prevention/Intervention Efforts

Adolescent substance abuse patterns, particularly adolescent drinking behaviors, do not often predict later life patterns of use [25]. In fact, regardless of their substance use patterns, many adolescents continue into their adult lives without experiencing adverse effects [96]. However, the substance use and related risk behavior of some adolescents will interfere with their health and development [96]. The inherently transitional nature of adolescence presents a natural turning point for adolescents [94]. Specifically, the flux inherent in the adolescent lifestyle offers an outstanding opportunity to intercept maladaptive lifestyle choices, such as unhealthy drinking patterns and substance use, and re-route adolescents toward healthy life choices and skills [96].

Alcohol abuse and addiction in adulthood typically originate in drinking problems that begin in the adolescent and early adult years, a period termed "emerging adulthood." Patterns of drinking during this period may influence the onset or avoidance of alcohol abuse or dependence, and associated health, legal, and social problems related to excessive drinking.

Emerging Adulthood

Emerging adulthood is a developmental stage occurring in the late teens into the late twenties distinct from adolescence and young adulthood that is common in industrialized nations, during which individuals' demographics, subjective perceptions, and identity explorations are highly volatile [2, 3]. Emerging adulthood is characterized by a prolonged period of volitional activities, identity formation, seeking novel experiences, taking risks, and ultimately, achieving a defined sense of the self as an adult [41]. Attainment of adulthood is related to young people's subjective sense of attaining adult competencies, such as accepting responsibility for themselves, making independent decisions, becoming financially independent, and becoming a parent, and less related to status markers such as stable residence, school completion, career selection, or marriage/romantic commitment [21]. Emerging adults between the ages of 17 and 27 as a group show changes consistent with increasingly adult status markers; part time employment declines, full time employment increases, living with family declines, and being financially supported by family declines each year. However, status markers are highly volatile during this age period. Emerging adults show reversibility in status regarding residence, romantic attachments, and work life, and make

frequent transitions from one status to another, with periods of great independence sometimes followed by childlike levels of functioning in at least two domains [21]. Gender differences are strong during this period, with women achieving a stable residence status earlier, but achieving financial independence from families later [21]. Participation in higher education does not mediate demographic differences in the trajectories from childlike to adult status, with patterns similar among emerging adults who are in college and those who are not; thus, emerging adulthood is now viewed as a true developmental stage with distinct developmental challenges [12, 21, 41, 99].

Risk Behaviors Peak in Emerging Adulthood

Several types of risk behaviors peak between the ages of 18 and 25, indicating a strong relationship between risk behaviors and emerging adulthood [61]. While drinking, smoking, drug use, and sexual behavior are often initiated in adolescence, these behaviors increase in frequency and risk level during the emerging adulthood developmental phase, with risk behaviors such as binge drinking peaking at ages 21–22 according to the Monitoring the Future Survey [5]. The risk behaviors that peak during emerging adulthood and are of great public health concern include unprotected sex, substance use, and risky driving including high speeds and driving while intoxicated [5, 15]. Increased drinking is associated with leaving the parental home after high school and reduced adult supervision, and declining drinking is associated with marriage and parenthood [5]. Because of the strong relationship between age and substance abuse, problem drinking and other substance abuse has been labeled as a developmental disorder by some researchers [107, 108]. These increases in risk taking may be reflections of identity exploration, the desire for novelty and sensation seeking that is common among this age group, and the relative freedom from parental and role constraints [2]. Unfortunately, alcohol use can result in serious consequences, including injuries and death, most often from driving while intoxicated. College students are more likely to delay marriage and parenthood than other emerging adults and may drink at higher levels of risk for a prolonged period during emerging adulthood [2]. Binge drinking is particularly prevalent among college students with heavy episodic drinking higher among college than non-college youth ages 18–29 [28].

There may be long-term negative health consequences of binge drinking even among those who avoid injuries. Those who increase binge drinking between ages 18 and 24 are more likely to progress to alcohol abuse or dependence diagnoses [87, 120]. Although college students may be at particularly high risk, they did not differ from non-college students on criteria for alcohol dependence [28, 101]. While some researchers found a higher rate of clinically significant alcohol-related problems in the past year among college students vs. non-college peers [101], along with a higher rate of alcohol abuse and higher overall rate of drinking, others found no difference between college and non-college youth in rates of alcohol abuse [28]. Because heavy episodic drinking and alcohol use disorders are common among emerging adults and college students, research on college students may generalize to other emerging adults. However, residence status does relate to risk for diagnosis, with more alcohol abuse occurring among students living off campus, and the highest prevalence of alcohol dependence occurring among students living on campus [28].

Binge Drinking and Health Risks in Emerging Adults

Alcohol use in emerging adulthood is prevalent [63], and much of the drinking that occurs during this age period occurs in a binge pattern. Binge drinking is currently defined as drinking

that results in a peak blood alcohol concentration of .08 or greater, typically means consuming 5 (for males) or 4 (for females) standard drinks in about 2 h [88]. Binge drinking is persistently frequent among college students despite increased prevention efforts over the past decade [115]. Forty percent of college students have binged in the past two weeks, according to the College Alcohol Survey [115].

There are distinct developmental trajectories of binge drinking and associated health risks among emerging adults. In a prospective study of binge drinking trajectories and their correlates, investigators identified 4 distinct groups among a sample of high risk (children of alcoholics) and unknown risk (general sample) adolescents, with a college attendance rate of about 75% [12]. Nearly 40% of the sample was classified as non-bingers, having no evidence of binge drinking over a 5–7 year period with observations typically beginning at age 13. Those with an early onset of binge drinking (at 13–14 years old) reached a peak of binge drinking (weekly or more) at ages 19–20, had the greatest risk of short-term negative consequences of drinking, and were at the highest risk to develop alcohol abuse and dependence; this group represented 21% of the sample. A late-moderate group had an onset of binge drinking at ages 16–17, but binged less than monthly and represented 30% of the sample. The infrequent group had an early age of onset, but binged only a few times per year, and represented 9.6% of the sample. Consistent with other studies, this study found gender differences and negative health consequences of binge drinking. Males in any binge group showed increased risk for alcohol use disorder diagnoses by age 23, with 44% of the late-moderate group, 69% of the infrequent, and 84% of the early-heavy group carrying an alcohol abuse or dependence diagnosis by age 23. Females in the early-heavy group were at higher risk than those in other categories, with 73% becoming diagnosed with alcohol abuse or dependence by age 23. However, girls in the infrequent group were at the highest risk for elevated depression and were more likely to be children of alcoholics. Across genders, those in any of the binge drinking trajectory groups compared with non-bingers were more likely to be diagnosed with drug abuse and dependence. Across genders, non-bingers were more likely to be in college full time than those in any binge group. This study provided a promising roadmap for further examination of the impact of binge drinking on subsequent alcohol problems. While the authors found that the age on onset of binge drinking and the severity of drinking could generate risk trajectories, there are many possible factors that may determine the impact of risk drinking during emerging adulthood. These may include developmental processes such as individuation and identity formation and milestones such as coupling, educational achievement, and other risk behaviors such as smoking, drug use, unprotected sex, driving while intoxicated, etc.

Other Drug Use Among Emerging Adults

New evidence shows that marijuana use, binge drinking, and smoking often co-occur for college students. The Robert Wood Johnson foundation funded the Tobacco Etiology Research Network, tasked with identifying the trajectory of use of nicotine to dependence among college freshmen. The University Project Tobacco Etiology Research Network was a year-long study of freshmen at Purdue University and included screening assessment, baseline assessment, and weekly assessments, as well as twice-yearly cotinine and body weight measurements, on 912 university freshmen who had smoked 1 or more cigarettes in their lifetimes or had smoked 1 puff or more within the past year. Forty-six percent were female, 45% had smoked in the last month, and most had smoked fewer than 100 lifetime cigarettes. The University Project Tobacco Etiology Research Network utilized a Web-based application into which students entered weekly data. One advantage of the Web-based weekly survey methodology was the generation of a continuous stream of data that

could be queried for a large number of research questions, and that can identify patterns of risk and lower risk periods. For example, in the University Project Tobacco Etiology Research Network, most students smoked an average of 4 cigarettes per day, but this average could obscure the finding that cigarettes per day varied by day of the week, with most smoking occurring on the Thursday/Friday/Saturday weekend. Smoking occurred in a pattern consistent with weekend social events. Moreover, alcohol consumption, especially binge drinking, showed the same pattern, as did marijuana use [110]. These data clearly show that smoking, binge drinking, and marijuana use co-occur among large groups of college students, and that college students are willing and able to provide usable weekly data on their risk behaviors through a Web-based survey method. Unfortunately, because Tobacco Etiology Research Network studies are highly focused on smoking, the data they generated on drinking was relatively limited.

Consequences of Binge Drinking in Emerging Adulthood

Approximately 1500–1700 deaths and 599,000 injuries, and 200,000 serious injuries occur in the United States each year among college students [43, 44]. While some students may escape any problems related to binge drinking during college, others experience negative short-term problems and long-term health problems from drinking. Drinking among emerging adults can cause a range of health risks and psychosocial consequences including motor vehicle accidents, legal problems, personal injuries including date rape or other types of violence, blackouts, missing classes, unwanted or unprotected sex, and sexually transmitted diseases [56, 66]. Rates of these problems are high. Nearly 700,000 students are assaulted by another college student who has been drinking [56]. The 400,000 students ages 18–24 had unprotected sex and 100,000 students reported being too intoxicated to know if they consented to sex [56]. In the short term, other problems associated with drug and alcohol use in emerging adulthood include violence, depression, unprotected sex with risk for pregnancy and sexually transmitted diseases [9, 48, 49]. Twenty-five percent of college students report academic problems related to drinking such as missing classes, falling behind, doing poorly on exams and papers, or getting lower grades [48, 49, 91, 120]. Consequences are most likely among those students classified as frequent binge drinkers (defined in these older studies as 5+ drinks per occasion) vs. less frequent binge drinking [52].

While a minority of students becomes addicted to alcohol, 31% endorsed criteria for an alcohol abuse diagnosis and 6% met criteria for alcohol dependence during college [65]. When an adolescent or emerging adult evidences an alcohol use disorder, they generally have additional problems. Alcohol-related blackouts, craving, and risky sexual behavior are common among adolescents with alcohol use disorders [74]. Rates of disorders vary by gender and by binge drinking. Among household survey respondents ages 18–23, rates for men who had not binged (had not had 5 or more standard drinks on one occasion) in the past month for alcohol abuse were 13.3% and for dependence were 6.7% [116]. Among men who had binged, rates were much higher, 23.8 for alcohol abuse, and 13.0 for alcohol dependence. Among women 18–23 without recent binge drinking, 6.5% met criteria for alcohol abuse and 3.8% met criteria for alcohol dependence. Among women who had binged, the rates were 15.5% for alcohol abuse and 10.6% for alcohol dependence. Long-term effects can be quite serious; heavy drinking during the college years predicts alcohol-use disorders up to 10 years later [89, 120]. Binge drinking during college was also related to academic attrition, early departure from college, and less favorable job outcomes [60]. The use of illicit drugs in adolescence and emerging adulthood is the strongest predictor of life-time dependence [46].

Binge drinking is a prominent correlate of sexual risk among emerging adults, and this relationship is found across diverse studies.

A study using the 1993–1999 Youth Risk Behavior Survey found that binge drinking was a better predictor of adolescent sexual activity than lifetime and current use of alcohol [36]. Early binge drinkers had significantly more sex partners, while later onset binge drinkers and marijuana users had more sexual partners and were less likely to use condoms [47]. Binge drinkers were twice as likely as non-binge drinkers to have participated in unplanned or regretted sex. The use of other drugs in adolescence did not predict risky sexual behavior at age 21, suggesting a unique role for binge drinking and marijuana. Gender differences exist in risk-taking; for women, there is a risk profile with both high alcohol use and sexual activity, while for men, marijuana may be a marker for other risk behaviors [60].

Other Health Risk Behaviors and Consequences in Emerging Adults

Emerging adults are at risk for sexually transmitted diseases/HIV transmission due to multiple sex partners, unprotected sex, and substance use combined with sexual activity, and that these health risk behaviors were particularly problematic during "spring break" [1]. During spring break, prior casual sex, alcohol use prior to sex, and impulsivity significantly predicted casual sex, while condom availability and impulsivity predicted whether students used condoms. Unsafe sex could lead sexually transmitted diseases including HIV/AIDS or pregnancy. The consequences of infection with some sexually transmitted diseases include lifetime chronic illness in the case of herpes and a progressive fatal illness in the case of HIV/AIDS. The Youth Risk Behavior Surveillance System is an annual survey of health risk behaviors that contribute either to unintentional injury, illness, or death, and is administered in school to 9th–12th graders in the United States. The Youth Risk Behavior Surveillance System collects demographic information and covers a broad range of health risk behaviors including bicycle helmet use, seatbelt use, weapon carrying, school safety concerns, theft, property damage, fighting, date violence, depression, suicidal feelings, tobacco use, alcohol and drug use, sexual behaviors, weight, diet, exercise, riding with an intoxicated driver, driving while intoxicated, HIV knowledge, and asthma. The most recent analyses of the Youth Risk Behavior Surveillance System show that during the past 30 days, many high school students engaged in behaviors dangerous enough to increase their likelihood of death, including driving after drinking, drinking, and using marijuana. More than a third of the high school students who were sexually active reported using no condom during the last intercourse. The implications of the survey are that priority health risk behaviors such as drinking, unprotected sexual intercourse, and drug use are well established during adolescence, extend into adulthood, are interrelated, and are preventable [37].

Summary of the Literature on Drinking and Drug Use in the Emerging Adult Period

Data on emerging adulthood clearly points to a constellation of risk-taking behaviors centered around binge drinking, with an increasing risk of severe consequences with more frequent drinking. Emerging adults in college are at particular risk for frequent binge drinking and associated risk behaviors, including other drug use, smoking, unprotected sex, driving while intoxicated, and academic problems. The consequences of binge drinking and other risk behaviors are potentially lethal or lifelong, in the cases of motor vehicle accidents and sexually transmitted disease exposure including exposure to HIV. Most studies to date have provided a snapshot of emerging adults' behavior at one time point. Such studies do not allow a characterization of how binge drinking and other risk behaviors change as the emerging adult moves from adolescence to adulthood, how drinking may covary with other risk behaviors, and the likelihood of

alcohol use disorders and other alcohol problems due to patterns of risk drinking. What is needed is a longitudinal, real-time approach that could capture the ongoing drinking and other risk behaviors of a cohort of college students whose outcomes can be studied over time. That type of study would lead to the identification of students at greater risk of problematic outcomes and thereby identify the most fruitful targets for preventive interventions.

Prevention

Delay of Drinking and Substance Use

Preventing the initiation of substance use behaviors clearly has beneficial outcomes, in terms of adolescents' mental and physical health and development. Generally, the literature indicates that the earlier substance use begins, the more likely it is that the person will have problems such as a greater risk of substance use disorders, and other health problems [38]. Additionally, some adolescent boys who exhibit harmful drinking at younger ages have been found to persist in harmful drinking into their early 30s, while a percentage of both adolescent boys and girls who binge drink continue to binge drink into their early 30s [78]. As such, this has been an area of much interest, but research in this area has been more controversial, as many common educational approaches have not gained much empirical support for effectively preventing alcohol and other substance use [100]. However, while there is still much work to be done in this area, recent research has indicated that certain approaches may be better able to delay the onset of substance use and related risk behaviors.

Settings for Prevention Efforts

Media-Based Programs

Adolescents are reliable media consumers; 37% of adolescents watch more than 3 h of television a day [10]. Studies from the tobacco and alcohol advertising literature have indicated that adolescents' decisions to use tobacco and alcohol are influenced by media messages promoting their use [39]. Following these findings, several alcohol and substance abuse prevention programs have organized around helping adolescents develop media resistance and substance refusal skills (e.g., [40, 53]). Specifically, research has supported that the development of skills in these areas has predicted with lower levels of alcohol abuse up to two years following the prevention program [40].

School-Based Programs

Several school-based prevention programs have gained empirical support in intervening with substance use behaviors. Three of these approaches, while slightly different in content or construction, occur in school settings. When compared with control groups who receive education only or no intervention, many of these programs evidence support for interrupting the trajectory toward increased substance use. First, Project ALERT [73] and Project CHOICE [27], two relatively brief prevention programs that included several components common to many effective intervention strategies. Examples of those components include the provision of normative feedback, evaluating substance use expectancies, substance refusal skills, developing alternative coping strategies, planning, and problem solving options for potential settings where there is likely to be substance use. Second, although containing a slightly longer curriculum (18 sessions), the Positive Youth Development Program [109] was developed with a focus on strengthening adolescents' skills in problem solving and decision making. This prevention program has also gained support for interrupting the increasing progression of substance use among participating adolescents. Third, with components that integrate both effective prevention as well as effective family intervention strategies, Spoth and colleagues have found empirical support for their prevention approach [102, 103], which actively involves family members in their substance abuse prevention programs. After provision of this brief family-based prevention

intervention, this program significantly interrupted the rate of adolescents' substance use initiation [103].

Prevention for Emerging Adults

Much less has been published about prevention of substance use sequelae among emerging adults with the exception of interventions delivered in college settings. College prevention and intervention programs have included social marketing campaigns that attempt to set a new (more accurate) norm of lower levels of drinking or rates of binge drinking, or of drug use [16, 22, 69]. In addition, a variety of interventions for college drinkers have been tested, and generally include a non-confrontational approach, provision of personalized feedback of risk, raising awareness of potential negative consequences, education about specific dangers such as health risks of very high blood alcohol content, and referral to treatment when needed [22, 67, 82]. In addition, innovations such as Web-based programming are now gaining popularity; these interventions are generally based on evidence and can be completed in private at the student's convenience [34, 92, 93]. These interventions can be cost-effective and may reduce any potential for aberrant renorming by peers as might occur in an assessment plus feedback group [113, 114].

Early work settings have been overlooked as potential forums for dissemination of substance misuse prevention programming for emerging adults. The early work setting has been targeted for health behavior improvements for diet and exercise, thought to reduce later costs associated with heart disease and diabetes [92]. One study evaluated the effect of a Web-based normative feedback program designed for the prevention of high risk drinking among emerging adults in the workplace [35]. Compared with controls, intervention participants drank significantly less at the 30 day follow-up. Such studies, while rare, point to innovative solutions that may hold special appeal for today's emerging adults.

Treatment

The majority of adolescents and emerging adults who use substances do not face future substance dependence during their lives [4, 19, 96, 98]. For many, substance abuse and related problems naturally remit [9], leaving only a minority, who tend to be heavier or binge users, on the trajectory toward chronic and severe substance dependence [13, 14, 17, 20, 30, 89]. While treatment goals for adolescent interventions vary (i.e. some emphasize the importance of abstinence, while others strive for harm reduction), it is clear that most of the interventions aimed at adolescents do not result in long-term sustained abstinence [17, 55, 119]. The same is true for emerging adults, where most intervention programs target reducing harm related to drinking and drug use, rather than achieving abstinence [22]. The data suggest that interventions based on information and awareness models do not decrease substance use, while skills-based and cognitive-behavioral interventions show greater promise in decreasing substance use or related harms [69]. The interventions that have gained empirical support with adolescent substance abuse primarily fall between two categories: individual interventions and family-based interventions. Because many emerging adults no longer live with their families of origin, most treatment interventions for them have focused on them as individuals or as members of a specific peer group, such as college students who violated underage drinking policies.

Treatment for Substance Use Problems Among Adolescents and Emerging Adults

While the social nature of adolescent behavior, and the predominance of peer-based settings (i.e., schools, after school programs) make group interventions for adolescents appear to be a natural (as well as cost-effective) fit, the use

of group approaches to intervene with adolescent substance use has been quite contentious. Specifically, many argue that group-based interventions pose a high risk for iatrogenic effects with substance abusing adolescents [33]. Others posit that adolescent group-interventions lead to improved substance use and related health outcomes [64], and some group interventions for college emerging adults with drinking problems have been successful [68, 73, 82, 109].

In terms of individual interventions, two intervention approaches have gained substantial empirical support for reducing adolescent substance abuse: cognitive-behavior therapy [117] and motivational interviewing [83]/motivational enhancement therapy [84]. The skills-based and behavioral nature of individual cognitive-behavior therapy may assist adolescents in specifically developing skills and actively implementing strategies to reduce adolescent substance use [31, 96]. Often used in conjunction with cognitive-behavior therapy, the non-judgmental, open, and guiding approach of motivational interviewing and motivational enhancement therapy, focus on adolescents' ambivalence around their substance use and related risk behaviors. Both motivational interviewing and motivational enhancement therapy have led to reductions in alcohol use, related risk behaviors [17, 42, 85, 86], marijuana use [54, 112], and poly-substance use [76, 77]. However, the efficacy of motivational interviewing and motivational enhancement therapy with adolescent tobacco use has yielded mixed results [23, 24, 100].

One intervention finds itself between individual and family interventions: the adolescent community reinforcement approach [45]. Drawing on the community reinforcement approach [81] and effective parent-training programs, this intervention style includes both individual and family sessions dedicated to components including skill building, relapse prevention, increasing prosocial behaviors, positive communication, and effective parenting. The adolescent community reinforcement approach has gained empirical support in intervening with adolescent marijuana abuse [31].

As adolescents function within multiple systems, several empirically supported interventions have indicated that effective interventions for adolescent substance use should include a systems or multiple-level approach [7, 79]. Three types of family interventions have gained support in reducing adolescent substance abuse behavior [103]: brief strategic family therapy [105], multidimensional family therapy [70, 71], and multisystemic therapy [49, 50].

Developed for Hispanic and African-American youth with unremitting conduct, substance abuse, and related problems, brief strategic family therapy focuses on the behaviors and interactions of the family, culture, and critical social systems [106]. Notably, this intervention was one of the first to emphasize and integrate the role of culture into an adolescent substance abuse intervention. During the last two decades, Szapocznik and colleagues have found that families receiving brief strategic family therapy evidenced reduced adolescent substance use and improved family functioning [106]. In addition, when compared with adolescents who received group therapy, adolescents who received brief strategic family therapy demonstrated significantly reduced conduct problems, delinquency, substance use, and significantly improved family cohesion and interactions [95].

Like brief strategic family therapy, multidimensional family therapy was created as a developmentally-conscious intervention for adolescent substance abuse [103]. Like brief strategic family therapy, multidimensional family therapy is focused on enhancing positive family interactions [71, 71]. In addition, multidimensional family therapy also operates at a larger systems level to enhance the relationships between the family and relevant social systems [71]. Adolescents receiving multidimensional family therapy have displayed sustained reductions in substance use at 6 and 12 month follow-ups as well as improvements in externalizing symptoms, family cohesion, and school behavior [70, 72].

Like brief strategic family therapy, multisystemic therapy is a strength-based approach, aiming to empower families of adolescents engaged

in substance use and delinquency [26]. Like multidimensional family therapy, multisystemic therapy focuses on the interface between the adolescent, family, peer, school, and social networks [51]. Across evaluations, multisystemic therapy has gained support with adolescent offenders, showing improved caregiver functioning, family cohesion, caregiver supervision of the adolescent [26], reduced adolescent criminality [52], and more mixed outcomes for substance abuse, likely due to confounds in study design and treatment fidelity [52].

Many questions remain regarding driving factors behind efficacious interventions [32, 57]. Also, research is only beginning to explore the factors that moderate and mediate the efficacy of adolescent and emerging adult substance abuse interventions. However, it appears that some common factors, such as the emphasis on alliance, strength-based, and non- confrontational approaches may play an important role in the positive outcomes in these adolescent interventions. Medication-based interventions for addiction have yet to be widely tested in adolescents or emerging adults. The possibility of using a combination of psychotherapeutic and pharmacologic treatments to interrupt progression to dependence among early heavy drinkers or drug users remains intriguing and understudied.

Conclusions

Many factors lead to adolescent and emerging adult experimentation with alcohol and drugs, and for the majority of people, experimentation is a rite of passage that does not lead to irrevocable harm. Increasingly, preventive interventions strive to delay the initiation of use, and then to minimize any consequences or harms of drinking or drug use. For a minority with heavier patterns of drinking, binge drinking, or early onset of drug use, more selected interventions may be needed to alter a course toward aberrant, hazardous, and health-harming substance use. Studies that have examined the trajectory of risk over long periods of time have begun to identify those adolescents and young adults who may be at greatest risk. New directions that will further develop our understanding of adolescent and emerging adult substance abuse risks will include genetic evaluation of those with heavier patterns of use and abuse that may lead to highly specific pharmacotherapy treatment for those with highest risk and highest potential treatment response. In addition, new behavioral interventions that include delivery in non-traditional formats such as over the internet or via cell phones may have enhanced, specific appeal to adolescents and young adults.

Alcohol and Substance Abuse in African Americans

William B. Lawson, Robert G. Lawson, Jessica Herrera, Bikash Sharma, and Akbar Broadway

Contents

Introduction

The problem of health disparities for Africans Americans is well documented. The Surgeon General's Report noted that mental health and substance abuse disorders were common, and contributed significantly to morbidity and mortality [57]. In a subsequent supplement, it was concluded that racial and ethnic disparities existed in mental health and substance abuse for racial and ethnic minorities. The report found that mental disorders, including substance abuse, were not more common in African Americans than in other ethnic groups [58]. The problem was not one of differing prevalence. Rather, ethnic minorities had a greater illness burden. Clearly, socioeconomic factors are important. African–American families are more likely to have incomes below the poverty level, and they are more likely to be uninsured. Moreover, they are often the first or second generation able to accumulate wealth. As a result, family wealth among African Americans is only a fraction of that of their White counterparts [38]. However, the Surgeon General's Report showed that disparities in outcome persisted even when income or insurance status was controlled.

The reason for concern about substance abuse is its pervasive impact. The direct effects of substance abuse cost the country over $100 billion per year [55]. The African–American community probably is affected differentially because their median income is lower than that of Caucasians and their family wealth is substantially lower. Drug abuse contributes to the health disparities seen in ethnic minorities, and these disparities persist even when income is controlled [58].

Epidemiology

Although African Americans are often stigmatized as being at greater risk of becoming substance abusers, the evidence shows otherwise. Prevalence of overall substance abuse disorders is indeed greater [31]. However, these global statistics often hide trends that suggest the opposite, depending on age of use, gender, and type of

drug. For example, among teenagers, Caucasians are more likely to drink or use some drugs than African–American youth [27, 63]. African Americans tend to begin drinking at an older age than other ethnic groups. African Americans have lower levels of alcohol use in both adolescence and young adulthood, develop fewer alcohol-related problems, and are less likely to smoke. Crack cocaine, on the other hand, is more commonly used than powdered cocaine and may be related to income since it is much cheaper [59]. Marijuana use may be greater later in life, but African Americans start using at a later age [31]. Compared with other ethnic groups, however, African–American youth are significantly more likely to initiate marijuana use before cigarette use [60].

The peak age for injected heroin use is higher for African Americans than for Caucasians [10]. This is a consequence of African Americans resisting the use of injected heroin and preferring non-injected heroin. Such a finding has obvious implications for the AIDS epidemic and mode of the spread of HIV. Overall, these findings show the importance of examining the patterns of usage rather than the volume or quantity of use to better understand ethnic differences.

Preventive and Risk Factors

Multiple factors contribute to the ethnic differences in use patterns. As noted above, socioeconomic factors are important, not only because the cost of a drug may determine use but also because income can determine where one resides. Drugs of abuse may be more easily accessible in inner-city and marginalized areas [25]. Also, residents in many of these areas consider themselves trapped and unable to move due to poverty and other social factors such as redlining [66].

Dealing drugs of abuse, while risky, is also potentially lucrative. For a low-income individual, the benefits may outweigh the risks and have the added value of giving the dealer status [19]. Such an individual would have the power to distribute wealth and paradoxically appear altruistic to the community as one who has the resources to make things better for everyone.

Place of residence is also important. African Americans who live in the same locations as Caucasians and who, therefore, have the same access to drugs tend to show the same abuse pattern in both the type of drug used and the prevalence of abuse [58]. The type of neighborhood clearly impacts use. However, geographical location is important as well [35].

The type of neighborhood also can determine the risk of exposure to trauma. Traumatic experiences are a risk factor for substance abuse even when it does not lead to post-traumatic stress disorder [48]. It is well documented that individuals in inner-city neighborhoods are more likely to be exposed to traumatic events [3]. African Americans are especially at risk given their residence pattern, which is often not because of choice [66].

Media exposure and advertisement also are factors. Advertisement, either directly or indirectly, can certainly influence drug use. Some in the African–American community have contended that their drug use is a result of targeted advertisement [58]. However, other ethnic differences probably contribute to differential exposure. African Americans spend more time watching television than do other groups. Recent studies have shown that African–American women exposed to alcohol ads are more likely to drink [34]. Manipulation of this factor could both explain use and provide a way of reducing abuse.

Education and positive role models are associated with drug use. Academic achievement and peer drug use have consistently been shown to have protective effects. In a recent study, they were shown to be significant predictors of alcohol and marijuana use among high-risk African–American youth [17]. Religiosity and spirituality have been proposed as protective factors [63]. One way in which these factors may work in inner-city youth may be through preventing post-traumatic stress disorder or other complications of trauma exposure [4].

It has been reported that African–American youth are significantly more religious than White and Hispanic youth, which could explain the lower rates of drug use for this group [64]. However, more recent studies have found that religion does, in fact, "protect" Black and Hispanic youth from substance abuse, but the strength of this relationship is greater for White than for non-White youth. The reasons for racial and ethnic differences in the strength of the relationship between religiosity and substance abuse are not clear. One possibility is that religiosity may be more of a cultural or group phenomenon among non-White youth, while among White youth it may be more of an individual factor affecting individual behavior such as substance use. Understanding the mechanisms by which religion might influence substance use and the reasons why these mechanisms may vary by race and ethnicity may provide clues to implementing effective prevention programs.

Impact on the Individual

Alcohol- or substance-abusing African Americans compared with other ethnic groups have worse mental health outcomes, physical health outcomes, and social outcomes when socioeconomic factors are controlled [58]. These agents adversely affect health outcome irrespective of race. African Americans, however, seem to be more adversely affected.

In one report in a cross-sectional study among mostly African–American alcohol-, heroin-, or cocaine-dependent persons without primary medical care admitted to an urban inpatient detoxification unit, 45% reported being diagnosed with a chronic illness, and 80% had prior medical hospitalizations. The mean age-adjusted SF-36 Physical Component Summary score was significantly lower than in the general United States population [21]. The impact of drug abuse is, therefore, pervasive and can be shown to impact broad measures of health outcomes.

In yet another study of substance abusers, African Americans averaged more emergency department visits than Whites and higher average yearly emergency department charges than Hispanics ($1,991 vs. $1,603). Charges over 2 years totaled $6,111,660. The high charges were no surprise since Blacks were most likely to be diagnosed with injury, hypertension, cardiac disease, alcohol abuse/dependency, and sexually transmitted diseases. Only 34% of this group of drug users was identified with a diagnosis of drug abuse or dependency [7]. These findings emphasize the high cost of substance dependence to a community that can ill afford it, as well as the problem of lack of access to services, since emergency department visits can be considered a proxy for limited access to treatment programs.

Substance abuse also contributes to mortality. The Surgeon General's Report and other previous reports have noted the consistently lower life expectancy in African Americans in comparison with other racial and ethnic groups. While there have been improvements, the trend has been a maintenance of that gap [57]. The lesser use of alcohol has, however, meant lower rates of death from alcohol-related diseases [45].

General medical conditions show poorer outcomes in substance abusers, which may help explain the mortality gap. One of the most important is HIV/AIDS, which the National Institute on Drug Abuse has concluded has now become a pandemic. The National Institute on Drug Abuse has established that drug abuse treatment is essential to HIV prevention [43]. Due to a number of complex and interacting biological, social, and economic factors, there are some populations that are at increased risk for HIV/AIDS. African Americans experience striking disparities in HIV-infection rates compared with other populations, and they are at particularly high risk for developing AIDS. African Americans make up just 13% of the U.S. population but more than half of the total AIDS cases diagnosed in 2004. Moreover, African–American females accounted for 68% of the female HIV/AIDS diagnoses from 2001 to 2004 while White females accounted for 16% and Hispanic females 15%. Although African Americans aged 13–19 represent only 15% of

U.S. teenagers, they accounted for 66% of new AIDS cases reported among teens in 2003 [14]. Not only is AIDS more common in African Americans, but African Americans tend to seek treatment later and do not survive as long after diagnosis. As a result, HIV infection has become the leading cause of death for African–American women aged 25–34 and for African–American men of all ages [43].

Drug abuse and addiction have been inextricably linked with HIV/AIDS since the start of the epidemic. While intravenous drug use is well known in this regard, less recognized is the role that drug abuse plays more generally in the spread of HIV by increasing the likelihood of high-risk sex with infected partners [49]. As a consequence, while the use of illicit substances by injecting abused drugs has featured prominently in the epidemic, the recent tendency to use agents such as opiates intranasally has not diminished the risk. Non-injected abused drugs such as cocaine, marijuana, methamphetamine, and even alcohol are also significant cofactors that affect HIV transmission as well as the course and outcome of the disease. Continued drug use contributes to the poor outcome seen in African Americans. These findings are consistent with others in showing that drug abuse is a major contributor to the health disparities and higher mortality rate in African Americans.

Drug abuse is known to be associated with family and personal violence. Adults who were abused were often abused by an intoxicated parent, leading to increased risk of drug abuse and abusive behavior [67]. The increased risk of child abuse in African–American communities can be attributed to the interaction of drug abuse with other risk factors in inner-city settings. Drug abuse contributes to behaviors such as personal conflicts, poverty, poor maternal care, and other factors that increase the risk of abusive behavior. Minority women are more likely to be assaulted or raped [1]. Additional to factors such as poverty and living in the inner city, drug abuse carries an increased risk of being victimized. Incapacitated/drug-alcohol-facilitated sexual assault is rapidly gaining recognition as a distinct form of assault with unique public health implications. Incapacitated/drug-alcohol-facilitated sexual assault accounted for 18% of all reported sexual assaults, with a prevalence of 4.0% among girls 15–17 years of age and 0.7% among girls 12–14 years of age. Girls with a history of incapacitated/drug-alcohol-facilitated sexual assault were significantly more likely than girls with other sexual assault histories to report past-year substance abuse [40].

The problem of gang violence is well known as a risk factor for the high rate of adolescent assaults and the extremely high homicide rate in African Americans, making communities unsafe and worsening poverty by making such areas unattractive to businesses. Drug abuse is clearly a factor. Drug abuse provides economic benefit for crime, but it also can lead to violent turf wars and be a justification for violent crime [8]. Even illicit but less lucrative drugs such as marijuana can contribute to gang formation and criminal activity in African–American youth. In fact, alcohol and marijuana are often the most commonly used drugs [39].

One of the consequences of drug abuse is involvement with the criminal justice system. African–American substance abusers are far more likely to be referred to the correctional system rather than for treatment. Moreover, African Americans arrested for possession are more likely to be incarcerated than their White counterparts [29]. These observations are significant because 40% of those in the correctional system have alcohol abuse and 20% have substance abuse at the time of offense, with two-thirds actively involved with drugs prior to admission to jail [22]. Incarceration means that as many as 14% of African–American males can no longer vote as a result of criminal conviction. Those who have served time can be excluded from public assistance, subsidized housing programs, and college financial aid. Many are also barred from employment in certain professions, including education, childcare, and nursing home service provision [15]. As a consequence, factors that contribute to drug abuse are exacerbated. In an effort to remedy the negative consequences of drug abuse, legislatures across the country passed harsh penalties including mandatory

minimum sentences targeting the derivative crack cocaine drug while users and distributors of the parent drug cocaine were able to escape with less punishment. This legislation had the consequence of further exacerbating the disparity in incarceration seen for African Americans since they and others in poverty settings were far more likely to use crack cocaine [23].

Thus, while many drugs of abuse are used less by African Americans compared with other ethnic groups, drug use itself interacts with other risk factors that contribute to violence and other risky behaviors. African Americans are more likely to be exposed to factors that contribute to drug abuse. African Americans may, in fact, be at lower risk of drug abuse if all other factors are kept equal [24]. Nevertheless, a legacy of discrimination, poverty, and social adversity contribute to a drug abuse problem that, in turn, worsens the impact of the drug use.

Comorbidity

Substance abuse is often comorbid with mental disorders. People diagnosed with mood or anxiety disorders are about twice as likely to suffer also from a drug use disorder (abuse or dependence) compared with respondents in general. Similarly, people diagnosed with drug disorders are roughly twice as likely to suffer also from mood and anxiety disorders [18]. This observation has important implications for African Americans.

First, comorbidity may contribute to the misdiagnosis of mental disorders. It has been established in multiple studies that African Americans with mental disorders are often misdiagnosed or never diagnosed [2, 53]. As a consequence, they are often never treated, overmedicated, or not offered treatment by mental health professionals [36, 46].

Because drugs of abuse affect similar brain circuits or receptor mechanisms proposed for mental disorders, drugs of abuse can cause abusers to experience one or more symptoms of mental illness. The result is misdiagnosis and inappropriate treatment of those without a mental disorder. Second, mental illnesses can lead to drug abuse [18, 32]. Additionally, individuals with overt, mild, or even subclinical mental disorders may abuse drugs as a form of self-medication. As a result, the mental disorder is ignored or considered yet another symptom of substance abuse. Treatment for the mental disorder is delayed or never provided. This treatment deferral or delay is often seen in African Americans with mental disorders [58]. Drug use disorders and other mental illnesses are caused by overlapping factors such as underlying brain deficits, genetic vulnerabilities, and/or early exposure to stress or trauma [12, 20]. The very factors that we described earlier as risk factors for substance abuse also increase the risk of mental disorders. To the extent that African Americans may be exposed to risks for substance abuse, similar factors may contribute to mental disorders. Finally, the combination of substance abuse and mental disorders adds greatly to the burden of illness [47, 62]. Treatment is more difficult. Services are less available, and the burden on the individual, family, and community is far greater. The increased burden of disease in African Americans is exacerbated.

Often African Americans face a triple burden as both disorders are important risk factors for general medical conditions such as HIV. In a recent study, individuals were assessed for psychiatric diagnoses, substance abuse, and HIV risk behavior using structured clinical interviews and self-report questionnaires. The majority (75%) were sexually active in the past 6 months and reported high rates of sexual risk behaviors, including unprotected intercourse (69%), multiple partners (39%), sex with prostitutes (24%, men only), and sex trading (10%). Recent manic episodes and greater drug severity were independent predictors of total HIV risk. Cocaine dependence was associated with increased risk of sex trading [42]. Mental disorders and substance abuse can, therefore, interact to increase the risk for HIV.

To conclude, comorbidity is yet another complication of substance abuse in African Americans. The co-occurrence may be yet

another factor that contributes to health disparities. In addition to the problem of misdiagnosis and undertreatment, the co-occurring disorders may further increase the risk of suicide, homicide, and chronic diseases.

Prevention

As noted above, protective and risk factors can be identified that may impact on drug use. Such a strategy can be used to develop prevention interventions for high-risk youth. Prevention strategies work. These can include parental monitoring and supervision [33]. They also may include drug education and information for parents or caregivers [6]. Additionally, brief family-focused interventions for the general population can positively change specific parenting behavior and reduce later risks of drug abuse [50]. These programs are particularly effective when culture is taken into account [26, 44]. Often, however, prevention programs to the African–American community are limited in scope or given low priority in funding compared with interdiction and law enforcement programs [46, 68].

Treatment

There is now little doubt that treatment can work, and it works for a variety of substances, across ethnicity groups, and in a variety of settings [28, 41]. Treatment programs, especially if they address cultural needs, are effective and have strong participation by ethnic minorities [51]. Effective treatment also can mean reductions in behaviors that increase the risk of HIV [52].

Racial disparities in treatment participation and access are well documented [58, 65]. Income and poverty are certainly a factor. As a result, African Americans have to depend on the availability of public facilities, which are sensitive to the political climate and willingness to provide funding for treatment versus the correctional system. However, differences persist even when income is controlled [65]. Part of the disparity may be related to the unwillingness of African Americans to accept treatment. In fact, African Americans may discontinue treatment sooner, leading to a poorer outcome [30]. This finding is complicated by the fact that African Americans are less likely to receive outpatient care. When access to outpatient care was controlled for statistically, racial differences in residential care and overall treatment retention disappeared [9].

The problem of access to service is complicated further by the type of services available. In one study, a city's racial composition was found to influence treatment center characteristics and services available, but the pattern is complex in that there are inequalities in treatment for certain types of services but not others. For instance, cities with high percentages of Latino Americans and African Americans provide more treatment options, such as employment and domestic violence counseling or programs for gay/lesbian clients. However, such cities have fewer integrated treatment centers that provide comprehensive assessment for substance abuse and mental health problems [61]. Thus, the problem is not simply the quantity of services but the quality of services that may greatly impact the poor and the underserved.

African Americans with substance abuse problems are more likely to be incarcerated [29]. However, many substance abusers in jail have received treatment or participated in a substance abuse program [22]. Correctional settings for African Americans are more likely to be punitive rather than rehabilitative. Moreover, the limitations in personal freedom after incarceration further limit access to treatment [15].

African Americans have been found to have less access to newer, more effective treatment approaches in mental health services [37]. Similar findings have been made in substance abuse. For example, buprenorphine is a long-acting partial agonist that acts on the same receptors as heroin and morphine, relieving drug cravings without producing the same intense "high"

or dangerous side effects. Congress passed the Drug Addiction Treatment Act, permitting qualified physicians to prescribe Schedule III–V narcotic medications for the treatment of opioid addiction. This legislation created a major paradigm shift by allowing access to opiate treatment in a medical setting rather than limiting it to federally approved opioid treatment programs. Buprenorphine was found to be effective in reducing opiate abuse and is an effective tool in AIDS prevention [54]. Moreover, African Americans were as accepting of this treatment as other ethnic groups [5]. Yet the vast majority of those who have access to buprenorphine are non-White males [16].

Clearly a number of socio-cultural factors exist that would prevent access to treatment and reduce disparities. However, some approaches have worked very well. As noted above, African Americans are more likely to be incarcerated. Untreated substance-abusing offenders are more likely to relapse to drug abuse and return to criminal behavior. This can bring about re-arrest and re-incarceration, jeopardizing public health and public safety and taxing criminal justice system resources. Successful drug abuse treatment in the criminal justice system can help reduce crime as well as the spread of HIV/AIDS, hepatitis, and other infectious diseases. Recent findings show that drug treatment works very effectively in the correctional system [11, 56]. Studies show that treatment can cut drug abuse in half, reduce criminal activity up to 80%, and reduce arrests up to 64% [13]. The result has been that more Africans Americans can have treatment available and avoid the revolving door of re-incarceration. Moreover, such treatment also reduces the spread of HIV, which has been associated with individuals in corrections returning to the community. Additional efforts, such as drug courts to avoid incarceration and legislative changes making it easier for inmates to expunge a criminal record if substance use or possession is the only crime, would go a long way to reduce the factors that contribute to involvement in the correctional system. Most importantly, it would move the focus of African–American drug users from punishment to treatment.

Conclusion

Addressing the problem of drug use and abuse in the African–American community has special challenges. Yet the problem must be addressed if there is going to be a genuine effort to reduce racial disparities in health. Drug abuse is clearly a problem that exacerbates the consequences of discrimination and poverty. The good news is that advances have been made in understanding the behavior and neurobiology of addiction, which has led to effective methods of detection, prevention, and treatment. These interventions work for African Americans. The challenge is to create the public and political will to shift the addiction focus to prevention and treatment, and to reduce disparities and improve treatment accessibility.

Sexual Orientation: An Overview

Often the expression "sexual orientation" is used as though it were a simple concept with a clear meaning. To the contrary, "sexual orientation" is a complex concept that is often misunderstood. As an umbrella term, it replaced "sexual preference," which was more or less discarded as the ongoing discussion escalated regarding whether one's sexual orientation is really a choice, or "preference," or whether it is innate, something we are born with. We still do not have an answer to that question [104] nor do we need one to address the issues covered in this chapter. Sexual orientation has been defined as "the preponderance of erotic feelings, thoughts, and fantasies one has for members of a particular sex, both sexes, or neither sex" ([104], p. 28). Everyone has a sexual orientation.

The expression is sometimes used interchangeably with "sexual identity" although they are not the same. Sexual identity generally refers to a label one uses to describe oneself, usually incorporating a number of elements, including behavior, feelings, attractions, and fantasies [104]. Sometimes others, such as clinicians or researchers, might apply a sexual identity label that is incongruent with how the individual labels himself or herself. Likewise, the meaning of a label may change depending on who is applying it. For example, the young college student who proudly proclaims herself or himself to be "queer" likely has a different frame of reference for the term compared with the bully who calls a classmate "queer" in an attempt to intimidate.

It is also important to distinguish sexual behavior from sexual orientation or sexual identity [104]. Sexual behavior can be more confusing than it sounds as we debate about which acts constitute sexual behavior. A person's self-labeling and the behavior in which he or she engages often are consistent but sometimes are not. This distinction can become critical as we make assessments in both research and clinical practice.

Despite these complexities, it is helpful to have some sense of what terms generally mean (while being open to the possibility that any given client or research participant might have

a different perspective). "Gay" can mean a man or woman whose sexual and affectional involvements are exclusively, or almost exclusively, with someone of the same sex, although "lesbian" is often used when referring to women. People who are "bisexual" are sexually and affectionally drawn to both women and men, sometimes sequentially and sometimes simultaneously, more often the former [63]. It is important not to confuse bisexuality with promiscuity because one does not imply the other. "Heterosexual" generally refers to someone whose sexual and affectional interest is exclusively, or almost exclusively, with persons of the opposite sex. Historically, we have tended to view sexual orientation and sexual identity as static, something we have for life. Recent research has shown that this is not always accurate, especially among young people [32, 33, 104]. Sexual identity in particular and sometimes sexual orientation can be quite fluid over time. Also, many people are reluctant to label themselves at all when it comes to sexual orientation. Thus, simple questions on research surveys or intake forms might not always be sufficient to gather the complex information needed to understand fully a person's experience.

Importantly, society does not, on the whole, portray a range of options when it comes to sexual orientation or sexual identity. Rather, heterosexuality is considered the norm, with anything else portrayed as some sort of lesser option if it is portrayed at all. As a result, most people are raised believing that they are heterosexual unless and until they realize that this does not fit with their experience and identity. If and when this occurs, there is often a transition process as one becomes more aware of oneself and of new ways of understanding and defining oneself. There are currently more models of lesbian and gay identity development (e.g., [15–17, 28, 42, 84, 107, 113] than there are of bisexual identity development (e.g., [11]), although work continues in both areas. Part of the process of developing a gay, lesbian, or bisexual identity involves moving away from a majority identity toward a minority identity [75], which is critical in fully understanding the scope of what occurs. It is important for researchers and clinicians to have a working knowledge of gay, lesbian, and/or bisexual identity development or the coming-out process.

Part of moving from a majority identity to a minority identity involves facing the stigma and oppression that confront minorities in a culture that values conformity. The victimization that gay, lesbian, and bisexual people face through harassment, verbal, sexual, and physical assaults, including murder, and continuing discrimination in housing, employment, and custody rights has been well-documented [7, 51, 55–57, 59, 60, 66, 67]. In addition, lesbian, gay, and bisexual people face less overt but still serious social experiences wherein they are marginalized or stigmatized as "other" [34, 44, 99]. A discussion about the mental health consequences of this minority stress follows later in this chapter.

"Heterosexism," defined by Herek ([58], p. 158) as "an ideological system that casts homosexuality as inferior to heterosexuality," is present whenever heterosexuality is seen as the standard and any other sexual orientation or identity is seen as "something else" or "other" rather than simply having a range of options—for example, when intake forms provide options related to marital status that do not include one pertaining to a same-sex life partner. Heterosexism also applies to the privileges that one enjoys when one is part of the majority—for example, the right to inherit jointly owned property without being taxed or to bring a partner to a company social event without fear of being fired. Likewise, heterosexism is present when we assume that all clients or research participants are heterosexual unless they make a point of telling us otherwise. Heterosexism also can pertain to bisexuality or any other non-heterosexual orientation besides homosexuality, although one's experience of it might look different depending on whether one is currently with a same-sex or other-sex partner.

A related expression is "internalized heterosexism," which refers to "the internalization by lesbian, gay, and bisexual ... individuals of negative attitudes and assumptions about

homosexuality that are prevalent in society" ([111], p. 510). Simply put, it is difficult to live in a heterosexist society without coming to believe some of what one hears and observes, or at least wonder what is true and what is not true. Thus, it is not uncommon for gay, lesbian, and bisexual individuals to develop self-hatred or self-questioning to accompany the social negativity that they experience on a regular basis. "Internalized heterosexism" has tended to replace the expression "internalized homophobia" in the literature as a more accurate description [111]; however, the expression "internalized homophobia" still continues to appear. Those familiar with addiction know that alcoholics and addicts often must overcome the stigma and accompanying shame that can arise from society's attitudes toward alcoholism and addiction. Hopefully that awareness can be helpful in understanding the complexities of heterosexism and internalized heterosexism. People who are gay, lesbian, or bisexual and addicted must face both sets of struggles simultaneously.

Prevalence of Substance Use and Abuse and Related Problems

The gay, lesbian, and bisexual population has long been considered an at-risk population with respect to alcohol and other drug addiction; however, it is difficult to assess exactly what this means. Early studies suggested rates of addiction, particularly alcoholism, that were far greater than those among the general population, with perhaps as much as 30% of the gay and lesbian population experiencing problems (bisexual men and women were not considered in these earlier studies) (e.g., [43, 71, 103]). Although these studies were important in bringing attention to the issue of substance abuse in the gay, lesbian, and bisexual population, they have since been criticized for their methodological problems (e.g., [6, 13, 95]), such as inconsistent definitions of both substance abuse and sexual orientation, convenience sampling drawn largely from gay bars, and lack of heterosexual comparison groups [23, 25, 30, 46, 63].

Despite the methodological concerns and resultant inflation of the problem, these early studies were helpful in bringing the gay, lesbian, and bisexual population to the attention of the addiction field and awareness of addiction to the gay, lesbian, and bisexual community. A number of studies followed in the late 1980s and early 1990s that attempted to address some of the concerns in the earlier studies, especially by recruiting larger, more representative populations from sources other than bars and making some attempt at having comparison groups of heterosexuals. Stall and Wiley [108] conducted a prospective study of single men living in and around the Castro district of San Francisco, which is known for having a heavy concentration of gay males. This allowed them to draw not only a pool of gay men, but also a comparison group, which had been lacking in previous studies. Bloomfield [8] studied lesbian/bisexual women and heterosexual women living in San Francisco using a random sample from a household directory. McKirnan and Peterson [86, 87] examined gay men and lesbians in and around Chicago, recruited through a variety of connections with the Chicago gay and lesbian community; they used results from a 1979 national survey as a comparison group. Skinner [105] and Skinner and Otis [106] conducted a longitudinal study of lesbian and gay men in two unidentified small cities in a southern state, recruited through mailing lists of gay and lesbian organizations, through snowball sampling, and at a gay pride celebration. They used the 1988 National Household Survey on Drug Abuse as a comparison group.

These studies helped to enhance our understanding of substance use in the gay, lesbian, and bisexual population although there were still methodological problems. They provided a more complex look at the issue, or at least helped point out the complexities that needed to be explored further. They did not offer consistent results; indeed, they sometimes contradicted each other. They were, however, consistent in suggesting that the early research likely

presented an exaggerated picture of substance use and abuse, especially alcohol use, in the gay and lesbian community. Nonetheless, this did not mean that the community should no longer be considered an at-risk population.

Contrary to the earlier studies, several of these studies found few differences in overall alcohol use between gay, lesbian, and bisexual populations and heterosexual comparison groups [8, 86, 108]. Still, they all found differences in patterns and outcomes of use that were important at the time and helped to shape future research. Among the more consistent results with respect to alcohol were fewer declines in use with age among the gay, lesbian, and bisexual samples compared with the heterosexual comparison groups [86, 106, 108]. Although Bloomfield [8] found very few differences between lesbian or bisexual women and heterosexual women in her study, those looking at both men and women [86, 106] found gender differences in results such that lesbians showed patterns of alcohol use more similar to their gay male counterparts than to heterosexual women. McKirnan and Peterson [86] and Skinner and Otis [106] found gay men and/or lesbians to be less likely to abstain from alcohol use; however, Stall and Wiley [108] found gay men to be more likely to abstain. McKirnan and Peterson [86] observed that their gay, lesbian, and bisexual sample was more likely to experience a variety of problems related to alcohol use than their comparison group despite a lack of differences in heavy use. Bloomfield [8] found that a larger percentage of lesbians than heterosexual women in her study were in recovery from alcoholism.

Another advance during this period was the examination of drug use beyond alcohol [86, 106, 108]. Patterns of other drug use for gay men and lesbians did show significant and sometimes substantial differences from comparison groups, although there are variations between studies in terms of which drugs are more prevalent and how this is broken down in terms of frequency, timeline, and demographics. Marijuana use was consistently found to be higher among the gay, lesbian, and bisexual samples [86, 106, 108]. McKirnan and Peterson [86] also found cocaine use to be higher among the gay, lesbian, and bisexual sample, although neither Stall and Wiley [108] nor Skinner and Otis [106] observed this to the same extent. Gender differences were also apparent with drug use, as with alcohol use, with lesbians tending to use at rates more comparable to gay men than to heterosexual women, although there were variations by drug and by study. Skinner and Otis [106] looked at cigarette use as well and found that lesbians were smoking at rates not only higher than those reported in national studies, but also higher than gay men in their own study. Another drug found to be related to both sexual orientation and gender was "poppers," the inhalants amyl nitrate and butyl nitrate sometimes used during sexual activity, especially among gay men [86, 106, 108]. Indeed, the use of poppers was so strongly associated with gay men that Stall and Wiley ([106], p. 68) commented, "If there is a distinctive 'gay drug,' that drug is poppers." Stall and Wiley [108] also found that gay men used a larger number of different drugs than their heterosexual comparison group, although this was not associated with the use of particular drugs more frequently.

Although these studies were an improvement over the very early ones and they did help to advance the field, there were nonetheless still numerous methodological problems. Some of the comparison groups were not true comparison groups, but rather attempts to compare data collected in a study narrowly defined by population and location with national data [86, 105, 106]. All of the studies were done in urban areas with a definable gay, lesbian, and bisexual community, which is not always the case in many areas. Having the availability of an identifiable community, even if somewhat hidden from the general population, has the potential to make the experience of being gay, lesbian, or bisexual different from that in locations lacking such a community. Likewise, recruiting from gay, lesbian, and bisexual organizations and gay pride events likely attracts a particular segment of the community that might not be representative of other segments of the community. Furthermore, although an improvement over recruiting

from gay bars, they are still convenience samples.

The reliance on local samples, whether prospective or convenience, was necessary due to the fact that none of the larger national studies asked questions about sexual orientation. By the late 1990s, some of these larger, national, random studies did add a question or questions that attempted to tap into sexual orientation. This change allowed researchers not only to assess gay, lesbian, and bisexual people's patterns of use with more confidence in the methodology, but also to get better comparisons with the heterosexual population.

Several large population-based studies asked participants about the sex of their sexual partners in the past year, over their lifetime, or both. This question was used to examine differences between heterosexual participants and participants with any same-sex sexual activity during the time period being considered. National surveys used have included the 1996 National Household Survey on Drug Abuse [23, 24] and the National Comorbidity Survey [47]. Although a detailed description of each study is beyond the scope of this chapter, there were some themes worth noting. No differences were found among men with respect to consumption of alcohol or meeting criteria for alcohol or drug disorders, although there were some differences between exclusively heterosexual men and men with any same-sex experience with respect to mood or anxiety disorders, with the latter more likely to meet criteria for disorders. Among women, those with same-sex sexual experience had higher consumption rates than those who were exclusively heterosexual, and were more likely to meet criteria for an alcohol use disorder. Women with same-sex sexual experience were also more likely to report having received treatment related to their alcohol use. Unlike some studies that have found lesbian or bisexual women to have consumption patterns similar to gay and bisexual men, the National Household Survey on Drug Abuse found gender differences such that women's consumption patterns were lower than men's regardless of sexual behavior or orientation [23].

Regional studies have included The California Women's Health Survey [12], the Los Angeles County Health Survey [31], and a survey of members of a large health maintenance organization [49]. These studies have looked exclusively at women and focused primarily on alcohol. In these studies, which compared exclusively heterosexual women with women who either self-identified or behaviorally were identified as lesbian or bisexual, the non-exclusively heterosexual women reported higher rates of consumption than the exclusively heterosexual women for both tobacco and alcohol [12, 31, 49]. There were some interesting age-related patterns. Unlike other research that has suggested that lesbian and bisexual women's use does not tend to decline with age, as is the case with the general population, these studies did find decreases over time. One study [49] found that differences in heavy drinking at younger ages between lesbian or bisexual women and exclusively heterosexual women disappeared over time and were not present in older age groups. Another study [12] found that there were declines with age for all women, although the declines were not as large for the lesbian and bisexual women.

Several studies examined the 2000 National Alcohol Survey, a population-based survey of more than 7,000 adults in the United States [35, 36, 112]. Two questions addressed sexual orientation—one asking participants to self-identify and one that asked about sexual behavior—and were combined in the analyses differently from other studies. Four rather than two sexual orientation categories were determined, with self-identification and sexual behavior matched as homosexual, bisexual, heterosexual, or a fourth category for both males and females wherein participants self-identified as heterosexual but also had some same-sex behavior in the past five years.

Breaking out self-identification and behavior, as well as gender, allowed for examining some finer distinctions among non-heterosexual participants than had been done previously. For example, heterosexual men and women were significantly more likely to abstain from using

alcohol than any of the other groups; however, lesbians were more likely to abstain than bisexual women or women who identified as heterosexual but had some same-sex partners, although these latter differences were not significant. Controlling for other variables removed most of the differences among groups with respect to consumption, although there were a few significant differences that put bisexual women and heterosexual women reporting some same-sex sexual activity at higher levels than exclusively heterosexual women. The only significant difference among men was that homosexual men reported more incidents of drunkenness than exclusively heterosexual men. Lesbians and bisexual women were more likely to report problems related to alcohol and to report past treatment than exclusively heterosexual women. Lesbians were about eight times more likely and bisexual women were more than five times more likely than exclusively heterosexual women to have been in treatment. At the same time, they were less likely than heterosexual women to report being satisfied with their treatment experience. There were no significant differences among men with respect to having been in treatment. These higher rates of treatment involvement for lesbians are important to note as they suggest that treatment facilities are likely to have lesbian and bisexual women among their women clients, whether they publicly identify as such or not, and that they might not be adequately meeting their needs.

It has not been until very recently that researchers began considering bisexual individuals and/or people who self-identify as heterosexual but report same-sex sexual activity separately from gay men and lesbians. Early indications seem to suggest that bisexual people may experience greater and perhaps unique risks with respect to the use and misuse of addictive substances. When researchers using the California Women's Health Survey [12] broke out lesbian and bisexual participants, they found that, although exclusively homosexual women did report higher rates of alcohol consumption than exclusively heterosexual women, those differences were not significant. The most prevalent and significant differences were between bisexual women and exclusively heterosexual women, leading the authors to conclude that the bisexual women were most at risk. Other studies [36, 112] found bisexual women more likely to drink heavily in bar and party contexts, more likely to use tobacco, and more likely to use tetrahydrocannabinol. An Australian community survey found that bisexual participants displayed poorer mental health than either heterosexual or homosexual participants across a range of problem areas, including alcohol misuse [69]. In contrast to these results, one of the studies based on the National Household Survey on Drug Abuse [24] did not find differences in prevalence of psychiatric syndromes between gay/lesbian participants and bisexual participants. Clearly this is an area ripe for more extensive and sophisticated research. In the meantime, however, it does show the importance of recognizing differences in non-heterosexual sexual experiences rather than simply referring to "gay/lesbian/bisexual" as if it was one all-encompassing description. This is vital in both research and clinical work.

Unfortunately, there has not been much research examining the influences of race or ethnicity on substance use and misuse or recovery. One recent study that drew data from the National Latino and Asian American study [26] found that, as has been the case in general population studies, lesbian and bisexual women showed greater likelihood than heterosexual women of recent substance use disorders, although gay and bisexual men showed lower likelihood than heterosexual men. The authors also compared prevalence rates with published general population studies and suggested that rates among the Latino and Asian American population seem to be less than what is reported in the general population studies. In a couple of studies in which the samples included half to two-thirds ethnic minority participants [62, 65], the researchers found lesbians reporting high rates of problem drinking, having been treated for addiction, and being in recovery. These results are consistent with other research. The one study that looked at racial differences found very few [65]. Clearly, more work needs

to be done in this area before we can draw any conclusions. Such research needs to address not just prevalence rates but also the ways in which sexual orientation and race interact, as well as the ways in which both interact with substance use and misuse.

Much of the research pertaining to substance use and misuse in the gay, lesbian, and bisexual population has focused on alcohol, perhaps because the earliest studies showed such high rates of alcoholism and perhaps because the role of the gay bar suggests that this is an area of particular vulnerability. This has produced some valuable information that had been lacking, and as research methods improve we gain a better understanding of the role of alcohol in the gay, lesbian, and bisexual community, as well as some of the outcomes of alcohol use in this population. In addition, as in the general population, alcohol use is more prevalent, thus affecting more people, than the use of other drugs. At the same time, the limited research that has examined the use of other drugs in the gay, lesbian, and bisexual community has found rates to be higher in this population than in the general population [64]. The use of stimulants, especially methamphetamine, among gay men is particularly problematic, especially among those involved with circuit parties (see discussion below). In fact, the Gay and Lesbian Medical Association recently undertook a project to increase the understanding of the problem of methamphetamine use among gay and bisexual men with the aim of better addressing it [45]. They reported that 10–20% of gay men had used methamphetamine in the 6 months prior to the publication of their report, with considerably larger percentages among some subpopulations. These rates are quite a bit larger than rates in the general population. The report addressed challenges in terms of treatment and encouraged health care providers to take a proactive role in screening and referral to treatment. In addition to the problems that methamphetamine creates on its own, its use in conjunction with sexual activity can put users at increased risk of HIV [52]. Another recent study reported higher rates of tetrahydrocannabinol use (e.g., marijuana, hashish) among lesbian and bisexual women than among heterosexual women [36]. More research is needed to gain a better understanding of drug use as well as alcohol use in the gay, lesbian, and bisexual population.

The large population-based studies have primarily sampled adults; however, there is evidence that gay, lesbian, and bisexual youth are also at increased risk for substance use and misuse. A study in New York City found adolescent gay males and females using alcohol at higher rates than their heterosexual counterparts, with differences between lesbian/bisexual and heterosexual young women being greater than differences between gay/bisexual and heterosexual young men [100]. Another study that used behavioral indicators to determine sexual orientation found similar results [94]. Lesbian, gay, and bisexual adolescents have also been found to use illicit drugs, including marijuana and cocaine, at higher rates than heterosexual adolescents [4]. Thus, adolescent treatment programs also must be prepared to address the specific needs of gay, lesbian, and bisexual youth.

Why Might Gay, Lesbian, and Bisexual People be More at Risk?

Although there continue to be more questions than answers regarding the increased risk that gay men, lesbians, and bisexual individuals face with respect to substance abuse, there are two reasons that seem to be consistently offered, both linked to their sexual minority status. One has to do with gay culture and the role that alcohol and other drugs have played over time. The other pertains to the stress created by living constantly in a society that oppresses them.

Although there are a greater range of options available now, historically gay, lesbian, and bisexual people have had limited avenues available for finding each other and gathering where they could be open about and accepted for who they are. Traditionally, the gay bar has played a

central role in bringing gay, lesbian, and bisexual people together. These places were far from paradise, and patrons frequently faced raids by police and harassment as they entered or left, but nonetheless they were all that was available that provided any type of refuge or sense of community. Indeed, the modern gay rights movement is generally traced to a police raid on a bar in New York City when patrons fought back rather than passively submitting to being rounded up and harassed. The pride celebrations that many communities still hold in the month of June originally began to commemorate the riots at the Stonewall Inn.

It is difficult to have a bar be a central gathering place without having alcohol (and often tobacco and other drugs) come to be a large part of social interactions. This raises the question of whether greater prevalence of drinking, heavy drinking, or problem drinking might be a function of contextual factors that create greater access [25]. The research on this is extremely limited. One early study found that the use of alcohol in recreational settings by homosexual men and women correlated significantly with alcohol problems, although this was mediated considerably by consumption [87]. A more recent study found that gay men, lesbians, and bisexual individuals do seem to frequent bars more often than their heterosexual counterparts, but do not uniformly drink more when they are there [112]. There were no significant differences in number of drinks among men or between lesbians and exclusively heterosexual women; however, bisexual women and women who identified as heterosexual but had same-sex partners did drink more in bars than other women. There is a need for more research in this area before any conclusions can be drawn about the role of bars in contributing to prevalence rates for the gay, lesbian, and/or bisexual population.

Still, for the gay, lesbian, and bisexual population, the bar has always represented more than a place to go for a drink; it has represented community [18, 115]. This has implications when attempting to intervene in problem drinking. The traditional approach of urging recovering alcoholics to refrain from going to bars might be less realistic when working with this population. Many will continue to go anyway [115]. Thus, harm reduction approaches may, where appropriate, be more pragmatic than abstinence-only approaches. In addition, relapse prevention work might need to focus more on abstaining in situations where alcohol is present than on avoiding alcohol-related events. With a wider variety of options now available for the gay, lesbian, and bisexual community, it is also vital that treatment providers familiarize themselves with what is available locally to help clients make connections with activities and groups in the gay, lesbian, and bisexual community that are less alcohol and drug oriented.

Another more recent cultural phenomenon that pertains primarily, although not exclusively, to gay men is the circuit party. These are dance parties, often private, but sometimes sponsored by commercial establishments, that can last for several days and attract large numbers of men [85]. They tend to occur in larger cities, with various cities holding annual events. Many participants make the circuit of numerous such parties—hence the name "circuit party" [82]. Men who attend these parties tend to be well educated and financially well off [82]. Circuit parties can sometimes be fundraisers for services in the gay community, frequently related to HIV/AIDS, although often they are not. They involve dancing, music, and light shows, as well as extensive drug use and sexual activity. Although a variety of drugs, including alcohol, are used heavily, the most popular drugs used at these events tend to be stimulants, including methamphetamine, gamma-hydroxybutyric acid, ecstasy, ketamine, cocaine, and amyl nitrite or poppers, with many participants using multiple drugs [74, 82, 85]. Some of these drugs are particularly risky for potential overdose. In a study of men who had attended at least one circuit party in the past year, 25% of the sample indicated at least one instance of overuse during that time [74].

Gay men attend circuit parties for a variety of reasons. For the majority, the reasons are primarily social. As with the gay bar, these

parties provide an opportunity for socializing and meeting people in a gay-friendly environment. For some, however, the reasons are primarily sensation-seeking [82, 101]. Not surprisingly, there is greater risk for problematic substance use and/or sexual behavior among those who attend for sensation-seeking reasons. Likewise, drug use, especially the use of multiple drugs, increases the likelihood of risky sexual behavior [74, 82, 101]. For those seeking the sensation of combined drug, especially stimulant, use and intense sexual activity, the two behaviors can become associated in ways that must be considered in treatment [50]. Just as the drug use can enhance the sexual experience, so too can the sexual activity become a trigger for relapse. Although it is not uncommon to include sexual abstinence as part of a treatment plan, this must be done in ways that do not exacerbate any psychological struggles with minority sexual orientation.

Another reason often associated with the gay, lesbian, and bisexual population's special risk with respect to substance use and abuse is the stress of living in a society in which they are marginalized as "other" and face prejudice, discrimination, and oppression. Minority stress has been defined as "a state intervening between sequential antecedent stressors of culturally sanctioned, categorically ascribed inferior status, resultant prejudice and discrimination, the impact of these forces on the cognitive structure of the individual, and consequent readjustment or adaptational failure" ([10], p. 84). It has been used to describe the physical and psychological fallout of discrimination and oppression related to racism, sexism, and classism. More recently, the concept of minority stress has been applied to the mental health consequences of heterosexism experienced by lesbians and gay men [10, 34, 88, 89]. We are beginning to see consistent evidence that lesbian, gay, and bisexual people are experiencing harmful effects that go beyond the harassment—even violence—that they experience because they violate society's norms of heterosexuality. Further, research is also beginning to show that such experiences have negative ramifications for both physical and mental health, even if one is not open about one's sexual orientation (e.g., [34, 44, 102]).

Some researchers have operationalized minority stress as it pertains to sexual orientation through measures assessing such things as internalized homophobia, stigma or stigma-consciousness, and experiences of prejudice and/or discrimination related to sexual orientation [27, 60, 72, 73, 83, 88, 92]. They have found that these factors contribute to elevated levels of psychological problems such as demoralization, guilt, thoughts of suicide, depressive symptoms, depressive disorder, traumatic stress symptoms, anxiety, anger, panic disorder, and meeting criteria for more than one disorder, as well as physical problems.

To date, the empirical research examining substance abuse in conjunction with minority stress has been quite limited, most of it not addressing minority stress theory per se. The results have been mixed and somewhat weak. An early study [87] found the use of alcohol to reduce tension to be related to the prevalence of alcohol use and alcohol problems among gay men and lesbians. The same study found that external stress due to discrimination had a greater influence than internal turmoil related to sexual orientation, although this effect was more pronounced among men than among women. Another study [83] that examined the relationship of perceived discrimination to a variety of mental health problems, including alcohol and drug abuse, found that gay men, lesbians, and bisexual individuals experienced more discrimination than their heterosexual counterparts and that those experiences correlated with greater psychiatric morbidity, even when controlling for other factors. A more recent study [114] also found that gay, lesbian, and bisexual individuals whose responses indicated a substance use disorder had significantly higher scores on a measure of discrimination due to sexual orientation; however, the effect size was small. Studies looking at internalized homophobia in relation to substance use and misuse have found less consistent and weaker relationships with indicators of excessive or problematic use of substances, as well as some inconsistent gender differences

[1, 2, 114]. One study even found a negative relationship between internalized homophobia and lifetime use of tobacco, alcohol, and marijuana, as well as past-month use of marijuana, among lesbian and bisexual women. There is a need for more research in this area, perhaps enhanced by stronger measures of internalized homophobia [2], which is a concept still being refined empirically, as is sexual orientation-based discrimination. The existing literature suggests that minority stress might contribute to increased levels and more problematic use of substances among the gay, lesbian, and bisexual population; however, that relationship is likely more complex than our current understanding reveals. It is also worth remembering that, given the high rates at which substance use disorders coexist with other mental health disorders [40], the effects of minority stress as evidenced in other psychiatric problems will likely have ramifications for many individuals in treatment for addiction.

It is important to keep in mind several things when considering explanations for elevated and sometimes unique risks for substance use and misuse among the gay, lesbian, and bisexual population. Perhaps the most important is the fact that, even though there might be particular risks for gay, lesbian, and bisexual individuals, the majority of them do not experience substance abuse or other psychiatric disorders [25]. Thus, it would be wrong to operate on the premise that addiction is rampant in the gay, lesbian, and bisexual population or that this population is somehow sicker than the heterosexual population. Recognizing some potential aspects of gay, lesbian, and bisexual culture or experience that might put them at risk does not mean pathologizing them as a group, especially since some of those factors are socially imposed. Likewise, it would be short-sighted not to consider the elements that help the majority of gay, lesbian, and bisexual people to be resilient in the face of these unique risk factors [25]. It is important not just that we affirmatively treat those who do misuse substances, but that we work to strengthen the resiliency factors in those who do not but might eventually misuse them without intervention. It is likewise critical that we as a profession work to reduce the risk factors that come from social structures that oppress minority groups, including those who are gay, lesbian, or bisexual.

Affirmative Treatment with Gay, Lesbian, and Bisexual Clients

The State of the Field

Despite the fact that earlier methodological problems might have accentuated the risk for addiction among the gay, lesbian, and bisexual community, this population nonetheless continues to be considered a high-risk group. Furthermore, there are particular issues facing gay, lesbian, and bisexual people, which seem to influence how they use addictive substances and what they must face in recovery. Likewise, there is evidence to suggest that gay, lesbian, and bisexual clients are less likely to be compliant with medical and therapeutic recommendations when providers behave in ways that are insensitive or hostile with respect to sexual orientation [92, 95, 97]. Thus, treatment services that recognize and address these concerns are essential (e.g., [5, 29, 37, 61, 70, 109]). This includes programs that target gay, lesbian, and bisexual clients or have specific components geared for them, as well as counselors in all treatment facilities who are culturally competent in working with this population. Although only a few studies to date have directly queried gay, lesbian, and bisexual people in recovery about their treatment experiences, their message is consistent regarding the importance of counselors, programs, and 12-step meetings that are affirmative [9, 70, 78, 79, 80].

Unfortunately, such cultural competence with respect to the treatment and recovery needs of lesbians, gay men, and bisexual individuals who misuse alcohol and other drugs may be hard to find, especially in less urban areas. Each year, the Substance Abuse and Mental Health Services Administration collects self-reported

information about specialized services offered by substance abuse treatment facilities through the National Survey of Substance Abuse Treatment Services. Although 854 of 7,691 treatment facilities responding in a recent year indicated that they provided specialized services for gay, lesbian, and bisexual clients, when researchers [22] followed up to determine what services these facilities provided, almost three-quarters of them indicated that they did not provide any specialized services. For some facilities, specialized services were described simply as not discriminating against or being accepting of gay, lesbian, bisexual, and transgender clients, although it was not clear exactly what this meant. Only 62 agencies actually provided services specifically directed to gay, lesbian, and bisexual clients, and half of those were located in California and New York. Not only did these researchers find a serious lack of services for an at-risk population, but they also found a considerable amount of inaccurate information that could lead clients to facilities that profess expertise they do not have.

Studies of addiction counselors have likewise found many of them to be insufficiently prepared to work with gay, lesbian, and bisexual clients. Although the research is scant, the results consistently show a lack of knowledge and understanding of both gay, lesbian, and bisexual culture and the particular challenges facing this population in treatment and recovery [29, 38, 39, 54, 68, 80]. Attitudes among addiction counselors toward gay, lesbian, and bisexual clients seem mixed, with some counselors showing fairly positive attitudes, even if they lack the knowledge and skills to be fully effective, while many others display insensitivity and bias that is likely detrimental to clients [38, 39, 79–81]. Interestingly, both attitudes and knowledge seem to be lower, or more negative, with respect to bisexual and transgender clients than to lesbian and gay clients [38, 39]. Given that the limited research considering bisexual individuals separately from gay men and lesbians suggests that bisexuals might be at greater risk, this finding is particularly concerning.

There is some evidence to suggest that counselors who are themselves gay, lesbian, or bisexual are more likely to engage in affirmative practice [39, 78–80]. Caution must be used here because this does not mean that any given gay, lesbian, or bisexual counselor will be more affirmative or more skilled in working with sexual minority clients than any given heterosexual counselor. Nor does it suggest that only sexual minority counselors can be effective with sexual minority clients. Still, addiction treatment facilities would likely benefit from having counselors who are openly gay, lesbian, or bisexual on staff. Such facilities have long recognized the value of having staff members who are in healthy recovery themselves to serve as role models. It seems possible that openly gay, lesbian, and bisexual counselors who are comfortable with their sexual orientation could similarly serve as role models for clients who might be struggling with this aspect of their lives.

There is a need for both systemic and individual efforts in providing affirmative treatment for gay, lesbian, and bisexual substance users and abusers. In the National Survey of Substance Abuse Treatment Services study, some of the agencies reported previously having specialized services that were no longer available after a particular counselor left [26]. Affirmative treatment for gay, lesbian, and bisexual clients cannot be dependent on one counselor. A commitment to sensitive programming must go beyond the term of employment of particular counselors or the length of a grant. Although counselors may specialize, it is important that all counselors have a basic level of attitudes, knowledge, and skills that allows them to work affirmatively and effectively with lesbian, gay, and bisexual clients. Agencies can and must establish a climate that is non-heterosexist. When such a climate exists, individual counselors are more likely to have affirmative attitudes and behavior toward lesbian, gay, and bisexual clients [78]. Such a climate includes, but is not limited to, adding sexual orientation and gender identity to the agency's non-discrimination policy. This lets clients know up front that the agency has

considered their needs [79]. At the same time, such a statement must be backed up by practice.

Affirmative Practice

Because acknowledging one's sexual orientation can often lead to negative or even harsh ramifications, many gay, lesbian, and bisexual people are reluctant to offer this information until they have assessed the climate. Gay, lesbian, and bisexual clients often watch for signs that a facility or a counselor will be affirmative, or at least not discriminatory [79, 81, 109]. Including sexual orientation and gender identity in an agency's non-discrimination policy and publishing it in promotional material is an important way to let potential clients know that an agency has thought about gay, lesbian, and bisexual clients and taken a position that such clients will not face bias or discrimination in treatment. Such a statement must be supported by mechanisms to ensure that it is unequivocally enforced, not only by staff but by other clients as well [109].

Although they provide a critical foundation, non-discrimination policies are not sufficient for creating an affirmative climate. It is important to provide other visible indications that agencies and counselors are aware that some of their clients are likely to be gay, lesbian, or bisexual and actively seek to be inclusive [79–81, 109]. Periodicals and other information in waiting rooms or resource rooms ought to include materials that specifically address the gay, lesbian, and bisexual population. Videos or other materials used in educational programming should be screened to ensure that they are not heterosexist and that gay men, lesbians, and bisexual individuals see themselves portrayed as well as others. Likewise, to the extent that there is artwork or other decorative displays, it should be reflective of the diversity of clients the agency serves. It is also important to remember that the gay, lesbian, and bisexual population reflects the diversity of the general population and is not all White, young, able-bodied, or middle-class.

Another critical piece of affirmative practice involves recognizing that gay men, lesbians, and bisexual individuals represent a hidden minority (e.g., [41]). Thus, a client's status as a sexual minority is not immediately evident. We cannot simply assume that all clients are heterosexual unless they tell us otherwise; we must ask [6, 21, 37, 75, 78]. Likewise, we cannot draw conclusions based on other demographic information. For example, someone who reports being married might be heterosexual, but he or she could be bisexual or even gay or lesbian (married in a state where same-sex marriage is legal, or coming out later in life). Making assumptions can mean missing vital information about a client. Furthermore, making assumptions about heterosexuality can communicate to clients, correctly or incorrectly, that a treatment facility or counselor has not considered their needs. Putting the burden of disclosing sexual orientation on clients serves to marginalize them [98], forcing them into a role of someone who is different from what is expected. Asking all clients about sexual orientation helps to normalize all potential responses. It is important to remember from the discussion earlier that sexual orientation can be fluid and multidimensional, so inquiries must reflect the complexity of the concept. Such questioning also helps counselors to get a clearer understanding of individual clients, regardless of how they identify themselves.

Proper assessment goes beyond just adding a few questions about sexual orientation. Most treatment facilities have extensive assessment procedures that address a wide range of biopsychosocial issues. It is important to ensure that such assessment takes into account concerns related to sexual orientation. There are a number of ways in which assessment procedures might be biased [19]. Omission bias occurs when instruments assume heterosexuality. As important as it is to ask questions about sexual orientation during intake, it is also important to use assessment tools that take a range of sexualities into account. It is especially important to avoid using instruments that pathologize non-heterosexual orientations. Connotation bias occurs when negative concepts are associated

with being gay, lesbian, or bisexual. Likewise, it is important when selecting and interpreting testing instruments to be careful with instruments that have not been normed on the lesbian, gay, and bisexual population [37]. It would be preferable to use only instruments that have been properly standardized with this group, but since so few exist, it is critical to consider whether sexual orientation might influence responses and take this into account when making interpretations. Also important to remember when making interpretations is that scores considered "normal" usually fall within a range. Thus, when gay, lesbian, and bisexual clients score lower than heterosexual clients, but still within the normal range, they are not less psychologically healthy [48].

It is also vital during assessment to examine the interplay between sexual orientation and addiction in a sensitive and informed way [5, 6, 14, 37]. Both addiction and sexual minority status have a history of being linked through shame and pathology in ways that have been inaccurate at best and often more destructive than helpful [9, 14]. Being a sexual minority does not make one a sicker addict; nor does being an addict provide support for pathologizing sexual minorities. Nonetheless, internal struggles around accepting one's sexuality can exacerbate an addiction, and problematic use of substances can make it more difficult to work through conflicts related to sexual orientation. It is important to assess how the two concerns interact with each other in an individual client [5, 6, 14] in ways that empower rather than diminish the client. Included in such an assessment is evaluating a client's stage of development in terms of both addiction and sexual orientation [6, 14, 37, 109]. Assessing the level of addiction and readiness for change is a standard element in treatment facilities and, thus, is familiar to most addiction professionals. Assessing development with respect to sexual orientation is more difficult because theory and research regarding gay, lesbian, and especially bisexual identity development are still considered works in progress; hence, standardized instruments appropriate for clinical use have yet to be developed. Thus, such exploration is best accomplished through the clinical interview, and there are some informal protocols available for guidance in doing this affirmatively (e.g., [76, 109]).

Treatment Issues Specific to Gay, Lesbian, and Bisexual Clients

In addition to the general guidelines for affirmative practice, there are some specific issues that are important to address in addictions work with gay, lesbian, and bisexual clients. Perhaps the most critical issue involves self-acceptance. This was the overarching theme expressed in a qualitative study of lesbians in recovery [79] and is repeated throughout the literature in both empirical and anecdotal work (e.g., [5, 6, 14, 61, 78, 90, 97]). Shame has long been recognized as an element of addiction to be addressed in treatment [96]. Gay, lesbian, and bisexual clients experience this as well. At the same time, they often experience internalized heterosexism, which can interact with the shame around addiction. Participants in qualitative studies stress that both of these issues must be addressed [78, 79] and that the interaction can be tricky. Consistent with common practice in the addiction field, they report that being clean and sober must come first. Without that, it is difficult to tackle the issues related to sexual orientation. At the same time, self-acceptance as a gay man, lesbian, or bisexual person is critical to long-term sobriety. Thus, programs that address only the addiction might help gay, lesbian, and bisexual clients initially to get clean and sober, but are likely to fail them in terms of long-term success. Indeed, one inpatient treatment center specifically for gay men and lesbians has found that over half of the clients who entered had been through inpatient treatment at least once prior to entering that facility, often without ever addressing sexual orientation [97].

Helping lesbian, gay, and bisexual clients develop self-acceptance involves two critical elements for counselors. In keeping with standards for multicultural practice, the first step is an

assessment of the practitioner's own attitudes and beliefs about non-heterosexual orientations [21, 37, 110]. It is a challenge to help a client accept an aspect of himself or herself that the counselor or physician finds unacceptable. Even for the practitioner who wishes to be accepting and affirmative, the effects of societal heterosexism can easily creep into treatment. This applies to practitioners who are themselves gay, lesbian, or bisexual as well as to those who are heterosexual. The next step involves being knowledgeable enough about sexual orientation identity development and the coming-out process to be able to recognize where a client is in that process [5, 6, 14, 18, 61]. Responses that can be very facilitative at one phase of the process can be limiting or even frightening at other points. Just as addiction counselors must assess and work with alcoholics and addicts at their current stage of readiness for change, so too must they assess and work with gay, lesbian, and bisexual clients at their current stage of identity development. This can be further complicated if the gay, lesbian, or bisexual client also happens to be a racial or ethnic minority because that involves negotiating at least two interacting trajectories, sexual orientation and racial identity development [20, 93], along with the addiction.

The coming-out process has some unique implications for gay, lesbian, and bisexual people with respect to recovery from addiction [3, 5, 6, 61, 79]. Although the expression "coming out" can sometimes mean recognizing one's minority sexual orientation and coming to terms with it, "coming out" also means acknowledging this status to other people. Hence, it is an ongoing and lifelong process. Coming out can often bring positive results as one shares important aspects of oneself with important people in one's life. Sometimes, however, the results can be devastating and can include being fired from a job, kicked out of a home, or ostracized by friends or family. Thus, the gay, lesbian, or bisexual person must constantly assess the environment, and interpersonal relationships, to determine whether or not it feels safe to come out in a given context. There are very real reasons for choosing not to do so. This need for caution can sometimes conflict with treatment prescriptions about the importance of honesty over keeping secrets. Because denial and secrecy are often considered unhealthy remnants of addiction, clients are taught the importance of honesty.

Counselors and health care providers must be able to help clients learn to negotiate this tricky process. This begins by creating an environment where clients can feel free to be open with the counselor. It also involves establishing parameters that make it clear that discrimination, bias, or harmful comments from other clients will not be tolerated, thus making it safer for gay, lesbian, and bisexual clients to be open throughout the treatment program. At the same time, it is important to leave decisions about when and to whom to come out up to the client. Confidentiality is a hallmark of most addiction treatment programs; it is even more vital when it comes to disclosing a client's sexual orientation. This should never be done without the client's consent, and clients should never be coerced into giving consent against their better judgment, even if their judgment in many other areas might be questionable, as it often is for people early in recovery. Part of the treatment plan might include learning to distinguish between healthy caution about coming out and unhealthy denial that can threaten long-term sobriety. Some clients might also need help in learning how to assess situations to determine safety for coming out, as this is not a skill that people inherently have. This is an area where it can be very helpful to have gay, lesbian, or bisexual counselors and others who can serve as role models.

Closely related to self-acceptance is helping clients address both heterosexism in society and internalized heterosexism [3, 5, 37]. The stigma, oppression, and perhaps even victimization that existed before a gay, lesbian, or bisexual client entered treatment will not disappear just because he or she gets clean and sober. It is critical that treatment programs help their gay, lesbian, and bisexual clients learn first how to understand the concept of heterosexism and how it works and then how to confront it without using substances to escape it. Intentionally creating a non-heterosexist program helps clients to

experience a healthier environment and also hopefully to better realize that heterosexism is socially created and can be changed. This in turn can help clients to address internalized heterosexism. As they learn new messages about sexual orientation, they can replace the old messages that condemned them for being who they are. Finally, it is sometimes important to act as an advocate in working to change some of the social structures that victimize clients. This does not take responsibility for addiction away from the client but can help facilitate recovery for all gay, lesbian, and bisexual clients. Indeed, part of the process of addressing heterosexism and internalized heterosexism is helping the client to better recognize those forces that are operating from without and those that are operating from within.

In recognizing and addressing heterosexism, it is critical that addiction treatment programs be very familiar with all of the people and places to which they refer clients. This, of course, should be standard procedure across a range of issues, but it has a particular function with respect to gay, lesbian, and bisexual clients. Helping clients to address heterosexism and internalized heterosexism can be undone by referring to programs or people who are likely to further stigmatize or victimize clients. It is critical that treatment staff become familiar with 12-step programs that are affirming of their gay, lesbian, and bisexual members. Some communities have gay meetings, but many do not. Sometimes women's meetings can be helpful to lesbians, although sometimes particular meetings can promote traditional gender roles in ways that might not be a good fit for all lesbians. Gay people have a mixed history with Alcoholics Anonymous, some of it incredibly helpful and some of it dangerously destructive [9]. Treatment programs must know which is which locally. Likewise, just as treatment programs develop a familiarity with respect to which health care providers understand addiction and which ones are likely to feed an addiction through over-prescribing, so too must they become familiar with those who understand the needs of their lesbian, gay, and bisexual clients and are affirming.

Spirituality is another issue that is often a mainstay of addiction treatment and has particular relevance for gay, lesbian, and bisexual clients [61, 78]. Because many of society's views about homosexuality and bisexuality stem from religious teachings, many gay, lesbian, and bisexual people have an understandably ambivalent view toward traditional religion. This can then create a delicate balancing act in treatment programs and especially in 12-step programs that promote dependence on a higher power as a means to ongoing sobriety. Participants in a qualitative study about lesbians' recovery from addiction [78] reported that finding ways to renew a sense of faith while letting go of the aspects of religion that they found hurtful was an important piece of their ongoing sobriety. In general, participants suggested that counselors, sponsors, and others who were less tied to traditional Christianity and more open to faith and spirituality that was not necessarily linked to a particular religious tradition were more helpful. This then becomes another factor when referring clients to 12-step programs. Those that have a more open understanding of "higher power" might be a better fit for some gay, lesbian, and bisexual clients than those that connect "higher power" more directly to religion or religious teachings. Other clients might need assistance in maintaining a church community that is important to them while letting go of the messages that oppress them.

Family programs have become an important piece of many treatment programs. This might involve working through family-of-origin issues or working with current family members to address problems that might have developed due to addiction. Family issues are critical for gay, lesbian, and bisexual people to address as well; however, there are some specific concerns that must be kept in mind [5, 37, 78, 79]. First and foremost, it is important to recognize gay, lesbian, and bisexual people's families [77, 79], which might not always look like traditional families. Same-sex couples are not allowed to marry in most states, but they do nonetheless have long-term relationships, many of which include children. These families must

be included in family programs just as are families recognized through marriage. In addition, many gay, lesbian, and bisexual people form kinship networks among friends, which become families of choice. There might be times when it is important to include members of these kinship networks as extended family in the same way that aunts, uncles, or cousins might be included. Gay, lesbian, and bisexual people are likely to have family-of-origin issues around addiction, just as other clients do; however, they might also have concerns or tensions around sexual orientation. Treatment providers need to be prepared to help clients deal with these issues. They also have to be able to help gay, lesbian, and sometimes bisexual clients address relationship issues in ways that recognize and are sensitive to the fact that the client's primary relationship is with someone of the same sex. Thus, knowledge of same-sex relationships is important so that nuances that might be reflective of a different type of relationship are not pathologized.

All of the above issues that are unique and specific concerns for gay, lesbian, and bisexual clients must be addressed in an atmosphere of safety from oppression, marginalization, and discrimination. This was one of the themes that gay men and lesbians in recovery presented in a qualitative study [79]. Treatment worked better when it was free from the heterosexism that pervades society. When clients felt safe in addressing sexual orientation, they were better able to attend to the tasks of recovery, some of which involved sexual orientation and sexual identity. With this in mind, treatment approaches that are more client-centered or developmentally oriented might work better with this population than more confrontational approaches [37, 53]. To date, there has been very little empirical work on treatment outcomes with gay, lesbian, and bisexual clients. One randomized controlled study did find that motivational interviewing alone had significantly better drinking outcomes than motivational interviewing with a cognitive behavioral component added [91], but this was just one study. There is a need for more such studies examining different approaches specifically with the gay, lesbian, and bisexual population. Given the variety of issues that this population faces, in addition to the concerns common to all clients struggling with addiction, we cannot assume that approaches that are successful with a general population will be successful with this population.

In addressing some of the particular challenges facing them, it is important to remember that gay men, lesbians, and bisexual individuals *do* recover from addiction and experience long-term sobriety. In the United States, gay men, lesbians, and bisexual individuals gather in about 1,800 gay Alcoholics Anonymous meetings per week [9], and that likely taps into a small fraction of the recovering gay, lesbian, and bisexual community. They struggle with many of the same issues with which all recovering people struggle, and some additional ones besides, yet like others they find ways to be successful. It is important to be aware of some of the particular challenges facing this community, but it is equally important to remember that there are strengths as well. Despite living in a culture where heterosexism is pervasive and where oppression is real, the large majority of gay, lesbian, and bisexual people do not fall into addiction [25]. We must learn from their resiliency and find ways to help our gay, lesbian, and bisexual clients develop it as well. Openness and affirmation are a place to start.

Substance Use Disorders in Health Care Professionals

George A. Kenna, Jeffrey N. Baldwin, Alison M. Trinkoff, and David C. Lewis

Contents

Introduction

The impact of licit (i.e., alcohol and nicotine used legally) and illicit (including non-medical prescription) drug use, abuse, and dependence in the United States is well documented in the general population. Overall, a 2006 survey reported that an estimated 20.4 million Americans aged 12 or older were current illicit drug users, meaning they had used an illicit drug—defined as "marijuana/hashish, cocaine (all forms), heroin, methamphetamine, hallucinogens, inhalants or psychotherapeutics used nonmedically"—during the month prior to the survey interview [86]. This estimate represents 8.3% of the population aged 12 years old or older. More specifically, an estimated 5.2 million persons were current non-medical users of prescription pain relievers, up from an estimated 4.7 million in 2005.

A recent report of abuse of prescription medication in the United States reported that many health care professionals are poorly trained to deal with alcohol or drug abuse [84]. A substantial number of patients served daily by health care professionals in various health care facilities are abusing or dependent on alcohol and or other drugs. On the other hand, the public expects health care professionals to understand the proper use of the medicines they prescribe, dispense or administer to their patients. Just as in their patients, though, alcohol or drug use also affects the lives of a number of health care professionals [23].

Starting in college, some health care students develop an attitude of invulnerability and immunity to addiction, fueled by their advanced understanding of the mechanisms of drug action. What begins as recreational college alcohol or drug use [73] may, for some, develop into a

complicated pattern of alcohol or drug abuse or dependence intended to attain a "sense of well-being" ([77] p. 17) without an overt manifestation of intoxication or side effects. This concept of balancing drug effects, also called "titration", or "walking a chemical tightrope" [23] refers to a practice whereby students or health care professionals use their pharmacological knowledge to balance positive and negative drug actions and reactions by "enhancing, neutralizing or counteracting specific drug effects through ingesting multiple types of drugs" [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"].

Health care professionals have a significant responsibility that comes with the privilege of using medications to treat patients [11, 56, 59, 71]. While most health care professionals engage in appropriate prescribing, dispensing and administration of medication, reports of exceptional cases often receive public attention. A North Hollywood, California physician, for example, was charged with conspiring to distribute 406 prescriptions of hydrocodone and oxycodone over two months after he surrendered his license to the Drug Enforcement Administration in May 2008. This pain management specialist was also being investigated regarding a role that his prescriptions might have played in the deaths of six patients over the past 3 years [121]. A Virginia pharmacist was caught with hundreds of phentermine capsules when apprehended by law enforcement authorities [90], and a Maryland pharmacist was trading sex for drugs [90]. Medication errors caused by substance-impaired pharmacists have been cited as posing a direct and serious threat to the public [78]. Moreover, nurses were reported to be alcohol or drug impaired while committing "dozens of errors leading to patient deaths in Illinois" ([9], p. A1).

Whether by virtue of their drug access [72] or socioeconomic status [48], most evidence supports the notion that a small but significant proportion of health care professionals do experience personal problems with the use of alcohol and other drugs which can result in serious consequences to themselves and to the public [Valentine N (1991) Stress, alcohol and psychoactive drug use among nurses in Massachusetts. Brandeis University, Boston, MA, "An Unpublished Dissertation"] [73, 83]. Not only can the economic costs of substance use disorders [27] in health care professionals be considerable [67], early identification is essential as patient and provider well-being may be at risk [23]. Given the increasingly stressful environment due to manpower shortages in the health care system in general [91], alcohol or drug use and misuse among health care professionals has been projected to grow [89]. Treatment of alcohol or drug disorders by health care workers was a policy issue recognized years ago by the professional organizations [2, 5], and the Joint Commission requires hospitals to monitor and identify matters of health [52] including substance use and abuse by physicians and other health care professionals.

The aim of this chapter is to provide perhaps the most comprehensive review of the problem of drug abuse by health care professionals to date. Additionally, while covered in greater detail in other chapters in this book, we will also briefly discuss the behavioral signs and symptoms of addiction in health care professionals, the treatment of substance use disorders in this special subpopulation and the prognosis of sustained recovery and efforts needed to enlighten the various health care professional programs and groups.

Epidemiology of Alcohol and Other Drug Use by Health Care Professionals

The current literature regarding the prevalence of substance use and dependence in health care professionals is limited in both its scope of generalizability and methodological rigor [13, 60]. Lack of empirical data have contributed to an air of skepticism regarding the actual prevalence of substance abuse (abuse as referred to

colloquially, not *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition [27] diagnosis) and dependence by health care professionals. In fact, evidence of the extent of medication diversion, considered to be the major source of non-prescribed drug abuse by health care professionals is based primarily on retrospective accounts [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] [10, 70, 111], though the actual size of the diversion problem is largely unknown [36]. As a result, the prevalence of inappropriate substance abuse and chemical dependency among health care professionals is inconclusive [16, 72] and, like the extent of prescription opioid drug diversion in the United States, for example, is impossible to estimate at the present time [54]. The fact that the behaviors being measured represent illegal or inappropriate behaviors compounds the problem, as it is difficult to obtain accurate estimates of sensitive variables such as substance use [117].

Providing a glimpse of the lack of epidemiological knowledge in the field is best illustrated by contradictory prevalence estimates found in the literature. For example, reports [20, 107] suggested that narcotic addiction in United States physicians was as much as 30–100 times the rate found in the general population, but these data were based on data from Germany in the 1950s [13, 31]. Additionally, the lifetime estimate of combined substance abuse and dependence among health care professionals was reported by Kessler et al. [65] to be at a rate nearly equal to that of the general population, or 26%. Similarly, estimates from other studies of health care professionals have reported a lifetime prevalence of substance dependence ranging from 3 to 20% [11, 42, 95, 114, 116]. While the literature provides limited studies of substance use by dentists, Hedge [46] estimated that as many as 15–18% of dentists could be addicted to drugs and alcohol. In contrast to these rates, however, another report concluded that physicians were at a "greater lifetime probability of developing a substance-related disorder than the general population" ([30], p. 7).

Such statements clearly demonstrate the confusion and misinformation surrounding a meaningful discussion of alcohol or drug use by health care professionals. These generalizations have not only contributed to the uncertainty about the prevalence of substance use, but also to the confusion with regard to risk factors that contribute to substance use among health care professionals [13]. For example, while referring to pharmacists as "drugged experts" ([26] p. 102), Dabney [24] used a measure of questionable reliability and validity to assess substance use in a nationwide sample of pharmacists. Specifically, the measure assessed redundant drug use items, categorized unauthorized use of non-narcotic medications as addictive drug use and provided no directions to participants regarding exactly which drugs were included in each drug category [55]. Moreover, as also noted by Baldwin [7], the frequency data reported by Dabney [24] contained no time frame for reported substance use and were, therefore, not useful in estimating the prevalence of substance use. Though Dabney [24] claimed that the onset of potentially addictive drug use in pharmacists occurred upon becoming a professional, such a conclusion was essentially impossible without longitudinal data or some specific items assessing age of onset of regular use. Though the methods were strongly defended by the author [25], these issues contribute to a suspect interpretation of the data.

Overgeneralizations from methodologically questionable data also exist in the limited amount of literature describing substance use by the dental profession. Except for reporting the number of disciplinary actions taken against Oregon dentists from 1979 to 1984 [18], no known empirical prevalence data for substance use had ever been reported for practicing dentists until recently [62]. However, Chiodo and Tolle [17], drawing on non-representative disciplinary action data, inaccurately concluded that dentists, like physicians, were at higher risk for substance use and abuse than the general population, and also concluded the literature had consistently reported higher rates of chemical dependency in health care professionals, a notion unsupported by quantitative self-reported data [62].

In a series of important analyses, McAuliffe et al. [71–75] assessed alcohol or drug use by both physicians and pharmacists, and Valentine [Valentine N (1991) Stress, alcohol and psychoactive drug use among nurses in Massachusetts. Brandeis University, Boston, MA, "An Unpublished Dissertation"] assessed alcohol or drug use by nurses. Lack of generalizability to other practitioners outside these two disciplines was a major limitation of these studies. Additionally, these studies were conducted in the northeast where past-year alcohol or drug use has been reported to be higher than in other areas of the United States [86]. Subsequently, to address some of the "methodological shortcomings" of these studies, Hughes and colleagues ([48], p. 2333) compared a national sample of physician use of alcohol or drugs with the general population. They reported that when compared with the general population, physicians were more likely to use alcohol, benzodiazepines and minor opioids but less likely to use street drugs such as marijuana and cocaine. Furthermore, contrary to the suggestion made by Chiodo and Tolle [17] that the literature consistently reported disproportionately higher rates of chemical dependency in health care professionals, Hughes et al. reported that only 7.9% of physicians identified themselves as substance abusers, while the corresponding rate for the general population at that time was 15–18% [98]. Hughes et al. also noted, however, that physicians were as likely as their age and gender peers to have experimented with illicit substances in their lifetime, an observation also affirmed more recently [59]. Although methodologically rigorous, Hughes et al. acknowledged the narrow focus of their study to physicians alone that subsequently limited their findings due to the lack of comparable national data across other similar professions. In recognition of this limitation, the authors concluded that any comparisons between physicians and other health care professionals in "similar socioeconomic strata may have yielded different results" ([48], p. 2337). Complicating these issues is stigma that accompanies alcohol or drug use in any population, which leads to underestimates of problem use [88].

Etiology of Substance Use Disorders in Health Care Professionals

Many etiologic factors have been reported to contribute to substance use in health care professionals such as a family history for drug or alcohol use [21, 76, 104], college substance use [6, 19] or age at first alcohol or drug use [66], psychological factors such as "pharmacological optimism" [23, 34, 42, 119], access to prescription medications [42, 69], self-prescribing [19, 48, 72], socioeconomic status [48] and additional factors such as gender (male), lack of religious practices [72, 123] and social influences [66, 92].

Drug Access

Drug access, and in particular easy drug access [118], is generally recognized as a principal factor contributing to substance use by health care professionals. Certainly, studies show, access to prescription medications would explain the higher rates of use of these drugs than the general population [48, 60]. While research on drug use in the working population in general has been inconclusive, Mensch and Kandel [81] suggested that drug use by workers was due less to the workplace than to the workers themselves. Clearly, however a substantial foundation of research indicates that health care professionals are at considerable risk due to their working environment [23, 114, 118]. Drug access is directly related to the job of being a health care professional. As such, the working condition related to medical practice is an important contributing factor enhancing one's exposure to addicting drugs.

To illustrate this point, dentists have historically had easy access to nitrous oxide, an inhalant commonly kept in dental offices, and a known drug of abuse for dentists. Though the data are now dated (1979–1984), 7.1% of 109 impaired dentists in a study that took place in Oregon were sanctioned for abusing nitrous oxide [18]. The authors concluded that nitrous

oxide in particular posed a serious hazard for dentists. While dentists have access to nitrous oxide for procedures, access to other drugs such as minor opioids and anxiolytic drugs is limited. For example, dentists were the only health care professional group who did not report personal use of samples; the study, nonetheless, indicated that they found other sources for addicting prescription medications [63].

Different researchers have developed measures to assess the impact of drug access by health care professionals on drug use [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] [75, 118]. A pilot study by Trinkoff and Storr [117] suggested that easy access to drugs contributed to misuse. This was more firmly supported in a later, more extensive study of nurses (n=3,917) wherein the ease of access positively correlated with past-year misuse [118]. Three workplace dimensions were measured (availability, frequency of administration and workplace controls), and, summed as an index, nurses with easy access on all dimensions were most likely to have misused prescription-type drugs (odds ratio = 4.18; 95% CI: 1.70–10.30). Furthermore, access continued to show the same correlation to misuse, when knowledge of substances was also controlled in the analysis, showing that access was not explained by nurses' knowledge of substances used.

In a survey study performed comparing alcohol or drug use by pharmacy and nursing students and with pharmacists and nurses, predictors of lifetime illicit drug use by pharmacists and nurses included having a family history of drug problems, greater amount of past-month alcohol use, lack of religious affiliation and notably greater access to drugs [60]. Predictors for use of an illicit drug (any Schedule I or unprescribed drug use) by pharmacy and nursing students included a family history of drug problems, less drug access and cigarette use in the past year. Interestingly enough, lower drug access was a significant predictor for lifetime illicit substance use by pharmacy and nursing students, suggesting that when substances were unavailable in the workplace, students were more likely to obtain them elsewhere. Despite a reassurance of anonymity, students may also have been reluctant to admit to such behavior due to the fear of being discovered. In support of this notion, none of the students in the study reported diverting any medications from where they work, yet a greater number of pharmacy and nursing students in the same sample reported use of prescription medications than among the general population [60]. We know that various sources for drug use include the home [108] and friends [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"], but we also know that sources include the workplace as well [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"].

Where pharmacy students worked did not appear to be related to disproportionate drug use; however, a greater number of retail pharmacists reported illicit drug use than pharmacists in other pharmacy practice areas [60]. When parsing out comparisons of individual drugs, except for marijuana, consistent with the Hughes et al. [48] data, a higher proportion of the general population reported use of street drugs such as cocaine, hallucinogens and inhalants. A greater number of health care professionals and students, however reported use of drugs to which they typically had access such as opioids and anxiolytics [60]. In sum, quantitative and qualitative studies have all demonstrated that increased drug access in an unrestrictive environment provides an important substrate permissive of drug use by health care professionals. The available studies are consistent for studies of nurses [118], pharmacists [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] [72], certain types of physicians [114] and health care professionals in general [23, 83] that report drug access to be a key element leading to drug misuse and abuse in health care professionals. Efforts to restrict

drug access in every setting, as well as increased vigilance to monitor drug procurement and drug disposition by clinicians who dispense from their offices should be considered a priority.

Family History of Alcohol and Drug Use

Without a doubt, the greatest concern for health care professionals, as it is for the public, are alcohol use disorders [87]. Lifetime prevalence of alcohol abuse in the United States is 17.8% and alcohol dependence is 12.5%. Past 12-month prevalence of alcohol abuse is 4.7%, while alcohol dependence over the same period is 3.8% [44]. Alcohol dependence is significantly more prevalent among men, whites and younger unmarried adults, and lifetime alcohol abuse is highest among middle-aged Americans [44].

Twin studies of alcoholics have highlighted the possibility of genetic components of alcoholism [94] while other researchers [105] have also sought genetic markers for individuals with a positive family history for alcoholism. Studies have demonstrated that first degree relatives (parent, sibling or offspring) are more likely to use alcohol, become alcohol dependent and are at substantially higher risk to develop problems with alcohol sometime during their lives [88]. Family history of alcoholism has been estimated to be approximately 38% in the United States [43].

A retrospective review of substance use and addiction in medical students, residents and physicians [33], suggested that the most predictive factor for alcoholism in physicians was a positive family history for alcoholism. Kenna and Wood [62] reported that significant bivariate correlations between positive family history and pattern of alcohol use ($r = 0.31$), as well as positive family history for drug problems and current drug use ($r = 0.55$), existed for physicians alone. There is the possibility that there were genuine relationships between those physicians reporting a positive family history for alcoholism and their alcohol use and between a positive family history for drug problems and drug use. Physicians are trained diagnosticians and can putatively accurately assess the presence or lack of alcohol and drug use problems by family members. These diagnoses may have led to a more accurate assessment of family members, thereby reducing measurement error in this particular group.

Numerous studies also demonstrate that first degree relatives are at substantially higher risk to develop problems with alcohol sometime during their lives [88]. Coombs [23] proposed that the health care professions attract "people vulnerable to drug abuse because of emotional impairment due to alcoholic and emotionally abusive parents" ([23], p. 192). Several studies of dental students [12, 100–102] previously speculated that many dentists perhaps come from dysfunctional families or families with a history of alcoholism or chemical dependency. Sammon et al. [100], for example, reported that 35–39% of students at two dental schools had an alcoholic parent or grandparent, and Sandoval et al. [101] reported that 15% of all dental students at the University of Texas had a family history of alcoholism and 17% of illicit drug use. In a more recent study, however, dentists reported the fewest family members with alcohol problems of any health care professional group [62], suggesting there is little evidence that dentists are at greater risk than other health care professionals to report a family history of alcohol problems.

Several other studies have also reported high rates of positive family history for alcoholism for health care students and health care professionals as well. For example, in a comparison of chemically dependent and nondependent nurses, Sullivan [110] reported that 62% of chemically dependent nurses reported an alcoholic family member compared with 28% for non-chemically dependent nurses. Additionally, in a sample of recovering pharmacists, Bissell et al. [10] reported a positive family history for alcoholism rate of 55–58% in recovering pharmacists, slightly higher than the 47.4% prevalence estimate reported by Kenna and Wood [59] in a survey. What of course must be considered between the two rates are the differences

between the two study populations: one clinical [10] and the other population based. In college students, Tucker et al. [120] reported a positive family history for alcoholism in 28.1% in a sample of pharmacy students, and Kriegler et al. [66] established that a positive family history for alcoholism was reported by 38.3% of nursing student respondents. In a measure including eight close relatives (other studies typically included parents, grandparents and siblings), Kenna and Wood [58] reported a positive family history for alcoholism in 46% of pharmacy students and 74.5% of nursing students surveyed.

In a follow-up study of 479 licensed health care professionals (68.7% response), researchers sought to ascertain whether positive family history for alcoholism and positive family history for drug problems were more prevalent among nurses than among dentists, pharmacists and physicians and if an association between positive family history for alcoholism or positive family history for drug problems and current alcohol or drug use, respectively, existed [62]. Nurses reported a significantly higher prevalence of positive family history for alcoholism than other groups of health care professionals, ($P<0.001$) (see Fig. 1), and nurses also reported significantly higher prevalence of positive family history for drug problems than dentists and physicians ($P<0.01$), but not pharmacists (see Fig. 2). The study also demonstrated that positive family history for alcoholism in nursing was not associated with either amount of current alcohol use or abstinence. On the other hand, as previously noted, among physicians alone, relationships between alcohol use and positive family history for alcoholism as well as between drug use and positive family history for drug problems were significant. The results of this study support the notion that positive family history for alcoholism and positive family history for drug problems differ across groups of health care professionals.

While speculated, no one truly understands why a significant number of people with a positive family history for alcoholism appear to select nursing as a profession. Some have suggested that the desire to go into nursing emanates from the family of origin [66] and that nurses assume parental roles taken on in childhood [82]. For example, in a study of the characteristics of chemically dependent nurses [110], 48% indicated that while growing up, they had

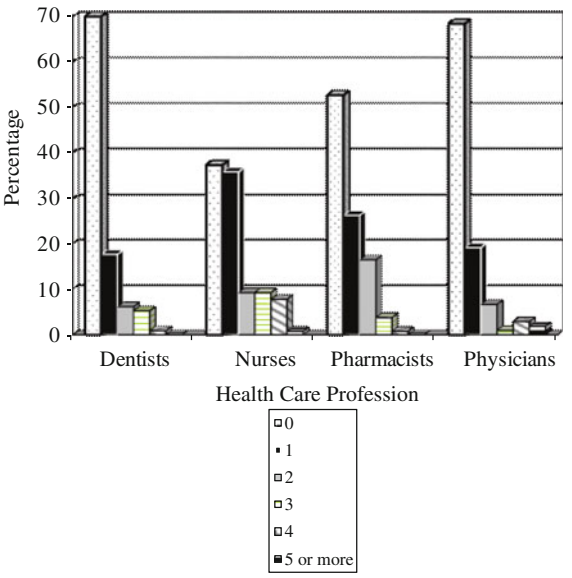

Fig. 1 Family history of alcoholism among health care professionals ($n = 479$)

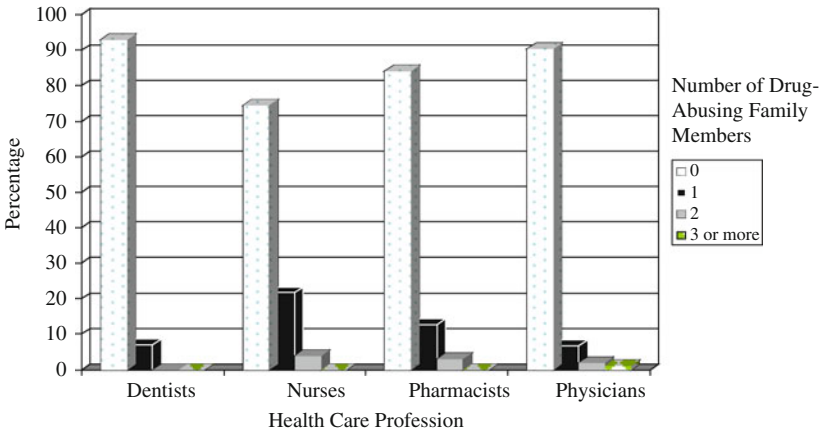

Fig. 2 Family history of drug abuse among health care professionals ($n = 479$)

acted in some type of parental role compared with only 22% of nondependent nurses. In order to delineate the association between nursing and family history of alcoholism, more research into the familial dynamics or individual differences of nurses and nursing students needs to be performed.

Professional Invincibility

Many health care professionals assume that their education, intelligence and knowledge of pharmacology will provide immunity from substance related impairment [23]. This self-deception of "professional invincibility" are attitudes of denial of impairment. More importantly, intervention is difficult in health care professionals as denial to the existence of a substance related problem contributes to continued substance use, abuse and dependence [106, 113]. Hankes and Bissell [42] referred to this air of invincibility in physicians as "MDeity" (p. 890). The attitude that health care professionals are selectively immune to the pharmacological actions of addictive medications—based primarily on their knowledge of drug action—has been the subject of retrospective accounts given by many health care professionals [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] [23]. The health care professionals may believe that their education particularly with respect to drug titration, makes them impervious to physical or psychological dependence, or the unconsidered equivalent, drug addict. Health care professionals are good at hiding their addiction by walking a "pharmacological tightrope" [23]; they tend to take greater amounts and a wider variety of drugs, making them more difficult to treat [115]. Perhaps, then, it is this attitude of pharmacologic invincibility that becomes the fundamental problem with substance use experimentation and addiction in health care professionals, particularly those who choose to treat themselves or who continue treatment beyond the period of illness or at dosages escalating beyond those required to circumvent tolerance.

Pharmacological Optimism

"Pharmacological optimism," or the anticipated benefits of medication use, has also been suggested to be a contributing factor in the development of chemical impairment by health care professionals. In 2000, pharmaceutical companies spent 15.7 billion dollars on drug promotion

that grew to almost 30 billion dollars by 2005 [29], with most of the expenditure aimed toward health care professionals [37]. Although pharmaceutical companies relentlessly directly target consumers, the impact does not compare to the decades-long indoctrination that health care professionals have received. Moreover, in view of a health care professional's training and education, familiarity with drugs is an important aspect of professional competency. Development of beliefs about the anticipated outcomes using drugs can be assumed to be a logical extension of knowledge of a drug's effect.

The literature has been inconsistent in defining "pharmacological optimism". For example, one researcher defined pharmacological optimism as "a generalized positive belief about the efficacy of drugs for managing symptoms as measured by an individual's willingness to use psychoactive drugs under varying circumstances" ([36], p. 48). Though reported to be based on alcohol expectancy literature [14], the measure developed did not assess specific beliefs about the effects of psychoactive drugs but misoperationalized the concept as a general willingness to use psychoactive drugs [34].

A qualitative study of health care professionals suggested that pharmacological optimism was synonymous with the concept of "better living through chemistry" ([23], p. 187), which suggests that all ills can be cured with a medication. While pharmacological optimism was one of several key factors considered to contribute to substance use and abuse by health care professionals, the author did not further define or quantitatively assess the construct [23]. Trinkoff and colleagues [119] suggested that pharmacological optimism may occur as a result of highly specialized knowledge about drugs. For example, self administration practices by health care professionals may occur as a result of the development of attitudes and or beliefs that drugs may be the quickest route to change one's feelings and mood. Trinkoff et al. measured pharmacological optimism with the combination of access to drugs and knowledge of drugs, reporting pharmacological optimism to be significantly associated with past-year substance use, but only when access was not included in the analysis [119].

Other researchers suggest that pharmacological optimism is more specifically based on beliefs of a drug's anticipated effect and conceptually similar to alcohol and other drug expectancies [64]. Alcohol [14, 96], marijuana and cocaine [50, 103] expectancies are beliefs about the effects of these specific drugs that develop prior to and as a result of their use and show significant variability across levels of use.

To test this theory related to prescription medications, Kenna and Wood [64] developed scales to measure pharmacological optimism and one's willingness to use drugs of abuse [34]. The authors administered a self-report cross-sectional survey to upperclassmen and graduate pharmacy and nursing students as well as comparable non-health care students ($n = 401$). The results demonstrated that while pharmacological optimism predicted unique variance in drug use over a person's willingness to use a drug, no differences were demonstrated between health care and non-health care students on pharmacological optimism, nor was pharmacological optimism associated with greater drug use by health care students. In sum, while the results support the existence of pharmacological optimism, these beliefs ultimately did not appear to facilitate drug use by health care students over and above experiential or occupational circumstances such as workplace access to substances.

Negative Proscriptions

Winick [122] proposed a theory that the incidence of substance abuse is highest in those groups in which easy drug access, role strain and disengagement from negative proscriptions exist. Disengagement from negative proscriptions regarding substance use may be an important correlate to one's level of association with conventional institutions and subsequent risk for substance use. While difficult to measure directly, both religiosity (internal factors) and social networks (external factors) have been

hypothesized to be important conjoined factors to measure negative proscriptions. Religiosity has been hypothesized to be an internal factor that may mitigate substance use [99]. One's social network has been found to be an important external factor, linked to one's reference group, norms and peer group choices that may promote drug use [51]. Trinkoff et al. [119] tested the utility of this theory in 3,600 nurses and reported that nurses were more likely to use drugs when drug access increased, social networks contained drug users and religiosity decreased. These data also suggest that weak attachments to negative proscriptions (low religiosity and social networks that promote drug use) and high drug access are influences related to one's drug use.

Social and Professional Influences

Social influences have been hypothesized to play a central role in models of substance initiation [39] and are considered among the strongest correlates of alcohol use and misuse [45]. Within the social influence framework, two types of social influences ("active" and "passive") are proposed [39]. "Active" social influences consist of explicit offers to use drugs or alcohol that require an immediate response from the individual offered the substance and are seen as important sources for substance use initiation. "Passive" social influences include both social modeling and perceived peer norms. Social modeling involves observing drug or alcohol use by one's family or friends. Perceived norms are beliefs surrounding what referents consider or perceive as normal drinking or drug use that may affect both behavior and attitudes about alcohol or drug consumption. In short, these social influences are the means by which a person may gain information simply by observing another's behavior or developing a sense or misperception of what level of substance use is ongoing and acceptable by peers. It is thought that this information may influence future behaviors. For example, social modeling by family members has been hypothesized to be a risk factor in nurses [110]. Significant differences were found when comparing drinking behaviors in the families of chemically dependent and non-chemically dependent nurses; 32% of the chemically dependent nurses reported heavy drinking at home during childhood as compared with only 10% of the non-chemically dependent nurses [110]. Moreover, Dabney [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] reported from the qualitative arm of his study of 50 recovering pharmacists that 30% of these health care professionals were encouraged by peers and supervisors that it was acceptable to use drugs to be able to function and perform at work. Kenna and Wood [59] demonstrated that social influences, primarily active offers of drugs and to a lesser degree social modeling of drug use, were strong predictors of current drug use in college students. These analyses suggest that peer groups and social networks play an important role in the use of drugs in this population.

As an occupational hazard, health care professionals frequently receive offers to attend dinners at which alcohol is served without cost. These dinners are intended to inform health care professionals about specific treatment protocols or new drugs that have recently become available. For example, Kenna and Wood [61] reported that physicians received significantly more offers to drink alcohol than other health care professionals offered alcohol by pharmaceutical companies ($P<0.001$). In the same study it was also found that dentists received significantly more offers to drink alcohol in social situations than other health care professionals ($P<0.01$). As for prescription medications, Clark and colleagues [20] reported that physicians wrote more prescriptions for family, friends and colleagues immediately upon receiving prescriptive authority. While not statistically significant, there results however do suggest that physicians, dentists and potentially other health care professionals are asked to provide prescriptions or medications to friends, family and other colleagues.

Age and Substance Use

The data from studies consistently demonstrate that older health care professionals drink significantly more alcohol than younger health care professionals, a finding that is supported by both quantitative and qualitative data in health care professionals. For example, McAuliffe et al. [71] first reported that among physicians, heavy alcohol use (five or more drinks at one time on five or more days during the past 30 days) increased with age. Moreover, heavy alcohol use by pharmacists declined only slightly after peaking at ages 31–40 years. Notably, each professional group in the McAuliffe et al. study had their own distinctive trend of heavy alcohol use across age. Drinking habits among doctors were not associated with medical specialty or type of practice, but were positively related to gender (men greater than women) and to age (older were more apt to qualify as heavy drinkers than younger doctors). Hughes et al. [48] reported that physicians were more likely to report past-year alcohol use than age and gender matched cohorts to the general population. On the contrary, after peaking at ages 21–25 years, past-year alcohol use, binge and heavy alcohol use, all decrease with age among United States adults [86].

Qualitative studies also report that older substance impaired health care professionals have a tendency to be more alcohol involved than younger ones. Retrospective studies with health care professionals [111, 114] suggest that younger health care professionals tend to use a greater variety of drugs in addition to alcohol than older health care professionals. For example, Talbott et al. [114] examined the substance abuse patterns and specialties in 1,000 substance impaired physicians referred for treatment in Georgia and reported that younger physicians tended to be more polydrug involved than older physicians, who tended to use alcohol alone. General population data would suggest that combined alcohol and illicit substance use peaks in the range of 18 to 25 years of age [86]. Similarly, in a study of nurses, Sullivan et al. [111] reported that alcohol was the most common drug of dependency and that women and older registered nurses tended to use alcohol alone while younger registered nurses tended to report narcotic dependency more frequently. In a study of recovering pharmacists, Bissell et al. [10] found that by the age of 49 years, the majority of pharmacists in their study abused alcohol alone.

Alcohol, Tobacco, and Other Drug Use in the Health Care Professions

Dentists

While there is no overwhelming evidence that dentists are at a higher risk to develop alcohol dependence than the general population, alcohol use and misuse appears to be the most notable substance use problem facing dentistry. As previously noted, dentists engage in other social interactions that promote their alcohol use [61]. Nearly every major alcohol use standard assessed indicated that dentists were significantly more likely than other health care professionals surveyed to self-report use and misuse of alcohol [62]. Compared with other health care professionals, dentists reported a higher lifetime prevalence of alcohol use, significantly greater past 30 day quantity and frequency of alcohol use, greater past-year and past-month binge drinking (5 or more drinks for men or 4 or more drinks for women at one time) as well as greater daily use. When compared with United States general population data for individuals 35 years of age and older at the time [85], dentists reported a greater prevalence of lifetime alcohol use and past-year binge drinking [62]. These data are consistent with retrospective treatment records of 2,015 health care professionals in Georgia's substance abuse treatment program in which dentists, in addition to physicians, were more likely to be exclusively alcohol dependent [35].

Information is limited as to why alcohol use, misuse and problems appear to be higher among dentists compared with other health care professionals. Hankes and Bissell [42] pointed out that good data regarding substance use for dentists were extremely limited; this has not changed. Putatively, causes could be linked to several risk factors previously noted in the general population such as gender, family history, income and social factors [44].

Certainly, one could assume that alcohol use differences may be related to the gender imbalance of more men in the dental profession, and men report more alcohol use than women [65]. More so than in any other health care professional group surveyed [62], more dentists were men (85%), which was consistent with American Dental Association [1] data reporting that almost 83% of dentists were men. However, it is important to note that 74% of the physicians in the Kenna and Wood [62] study were men, and physicians reported the least amount of alcohol use of any of the professions. Additionally, while there were no differences between men and women regarding regular alcohol use, analyses demonstrated there to be no gender difference on weekly quantity and frequency of alcohol use in health care professionals in general.

One potential explanation for the increased alcohol use by dentists may be related to higher income. In other words, the use of alcohol may increase with increased incomes [38]. Previously, Hughes et al. [48] noted that the prevalence of alcohol use was greater among physicians than in the general population by virtue of their socioeconomic class and not related to the profession of medicine. Consistent with Hughes et al. [48], lifetime prevalence and past-year binge drinking reported by physicians, was higher than reported for the general population [61, 85]. While dentists did report the highest mean income of all health care professional groups, they also reported income only slightly greater than physicians, who reported the least amount of alcohol use of all health care professional groups. In short, dentists drank significantly more alcohol than physicians, yet dentists and physicians reported essentially the same income. Furthermore, nurses and pharmacists reported a substantially lower income than dentists and physicians and still reported greater lifetime prevalence of alcohol use and past-year binge drinking than the general United States population and physicians. The results reported by Kenna and Wood [61] support the notion that alcohol use may, indeed, vary by virtue of health care profession and independent of socioeconomic status.

As noted, social factors might significantly impact alcohol use by dentists. An underlying social structure defines and shapes a relationship between alcohol use, alcohol involvement and group membership. One must consider that dentistry is also a business, and networking through memberships in various organizations is an important part of building a successful dental practice [68]. Kenna and Wood [61] reported that, during the past year, dentists were offered alcohol by friends and colleagues significantly more often than any of the other health care professional groups ($P<0.01$). In addition, while nurses knew significantly more heavy drinkers or alcoholics than pharmacists and physicians in their "social networks," there was no significant difference between dentists and nurses, perhaps suggesting that a strong social interaction component, more than any other risk factor, may contribute to alcohol use and misuse by dentists.

Nurses

In 1991, Nancy Valentine's study of Massachusetts nurses led her to conclude that alcohol use by her sample was low compared with use by the physicians, pharmacists and students in the McAuliffe et al. [72] study. More recently, however, alcohol use by nurses overall was surprisingly high given the overwhelming proportion of women compared with the other health care professional groups [61]. Nurses used less (mean use) alcohol than only dentists surveyed, but not significantly less. While nurses reported fewer mean drinks per day than dentists, they also reported more mean monthly

alcohol use than pharmacists and physicians. Moreover, while nurses reported less past-year "binge" drinking than the other three health care professional groups, they reported more past-year binge drinking than the general population aged 35 and over, despite the fact that they are largely female. Results from the Kenna and Wood [61] study report higher lifetime (67%) and past-year (22%) binge rates compared with rates reported by Trinkoff and Storr [117] in a comparably sized study (54.4 and 19.3%, respectively). In a larger study performed by Trinkoff and colleagues [118], 17% of nurses reported binge drinking during the past year (n=3,919). In the Kenna and Wood study [61], 55% of nurses reported they used alcohol on at least four days or more a month during the past year, and only 20.2% of nurses reported they were non-drinkers.

Surprisingly, one of the primary substance use concerns for nurses compared with other health care professionals continues to be cigarette use. Padula [93] previously suggested that the level of smoking in the nursing profession was unacceptably high, higher than other health care professionals, and should be cause for concern within the profession. Consistent with Padula's findings, more recent research reported that past-month cigarette use by nurses was significantly greater than any other health care professional group [59], though the past-month rate was less than half the rate reported by similarly aged peers in the general population [85].

A significant number of nurses also report use of illicit drugs. For example, Trinkoff and Storr [117] reported significant rates for lifetime (41%) and past-year (3%) marijuana use by nurses in their study. Lifetime marijuana use self-reported by nurses in the Kenna and Wood [57] study was 57.4%, and past-year use by 4.7%, which was less than the 61% lifetime use reported by experimenters in the Sullivan et al. [111] study of nurses, but consistent with the 37.3% lifetime use reported by nurses surveyed in New York [22] and by 37% of nurses surveyed in Massachusetts [Valentine N (1991) Stress, alcohol and psychoactive drug use among nurses in Massachusetts. Brandeis University, Boston, MA, "An Unpublished Dissertation"].

Nurses also report extensive non-prescribed prescription medication use. For example, 14% of the nurses in the Kenna and Wood [57] study reported ≥61 non-prescribed medication taking episodes, which was more than any of the other professions surveyed. Lifetime non-prescribed opioid use reported by nurses ranges from 52% [Valentine N (1991) Stress, alcohol and psychoactive drug use among nurses in Massachusetts. Brandeis University, Boston, MA, "An Unpublished Dissertation"] to 45.7 % [117] to 21% [57]. In addition, when combining one or more episodes of lifetime drug or medication use, 63.6% of nurses reported use of one or more drugs [57], which is less than rates reported by 68.6% of nurses surveyed by Trinkoff and Storr [117] and 73.7% surveyed by Valentine [Valentine N (1991) Stress, alcohol and psychoactive drug use among nurses in Massachusetts. Brandeis University, Boston, MA, "An Unpublished Dissertation"]. However, when compared with the general population, with a few exceptions (e.g., cigarettes consistently, minor differences with cocaine and hallucinogens), lifetime, past-year and past-month substance use rates were higher among nurses [57].

Though still high compared with the general population, one possibility for the reduced drug use among nurses over the last 20 years may be twofold. First, the mechanism for access to prescription medications in many facilities has changed a great deal. The link between access and drug use has been noted by many researchers [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] [23, 114, 117, 118]. In order to meet Joint Commission [53] requirements to maintain strict controls over medications to promote patient safety, most hospitals use automated machines that control and dispense medications to nurses for patients. One of the major advantages of these dispensing units is to maintain accurate counts of controlled drugs that must be verified at each shift change. Potential unauthorized access can be more readily detected. Though speculative, the automation of dispensing has probably reduced the access-prescription

medication use link for many nurses. Second, the steady decline of drug use in society in general [86] is also likely an important factor in this observation.

A number of nurses in the Kenna and Wood [57] study reported iatrogenic drug exposure as they had been prescribed medications such as minor (e.g., C-III–C-IV) and major (C-II) opioids by practitioners. This finding was consistent with Valentine's [Valentine N (1991) Stress, alcohol and psychoactive drug use among nurses in Massachusetts. Brandeis University, Boston, MA, "An Unpublished Dissertation"] study that reported prescribed drug use was much higher in nurses than other health care groups used for comparison, which led Valentine to conclude that "the path to dependence for nurses is use of drugs as a consequence of treatment under another provider's direction" [Valentine N (1991) Stress, alcohol and psychoactive drug use among nurses in Massachusetts. Brandeis University, Boston, MA, "An Unpublished Dissertation"; p. 651]. While the issue regarding gender has generally not been considered, data suggest there is an increased likelihood that more women than men will visit a physician and receive a prescription. In a report on the ambulatory care of patients in the United States [15], women were 33% more likely than men to visit a doctor, even after accounting for pregnancy associated visits. Moreover, the rate of physician's office visits for such reasons as annual exams and preventive services was 100% higher for women than men. Furthermore, prescriptive habits differed as well. Women were more likely to receive medications such as non-narcotic analgesics and antidepressants than men. The likelihood that a group such as nurses that is predominately female would report more iatrogenic contact with various addictive substances is consistent with this notion.

Pharmacists

The data suggest that pharmacists are not inclined to drink more alcohol than other groups of health care professionals. The mean drinks per month reported by pharmacists surveyed by Kenna and Wood [61] was 18.4 drinks, which was comparable to the rate of 21.2 drinks per month reported by McAuliffe et al. in 1991 for pharmacists [71]. One possible reason accounting for the slight difference might be attributed to the dominance of men (84%) in the McAuliffe et al. study compared with only 59% of men in the Kenna and Wood study. Twelve percent of pharmacists also reported past-month use of five or more drinks or "binge drinking" [61] which was comparable to 9.3% of physicians reporting binge drinking by Hughes et al. [48].

Based on qualitative studies [10, 23], alcohol remains one of the salient drugs of choice for substance impaired pharmacists, though it is important to note that alcohol was rarely the sole drug of choice. Bissell et al. [10] reported that only 21% of the pharmacists in their study were "addicted" to alcohol alone while 77% were addicted to a combination of alcohol and other drugs, most always prescription medications.

As noted by Bissell et al. [10], the combination of alcohol and prescription drugs presents a more formidable threat to pharmacists, and that the pathway to addiction for most pharmacists who may become impaired is probably through polydrug use [10]. That is, alcohol in combination with medications, most notably minor opioids and anxiolytics, comprise the bulk of current substance use by pharmacists. Seldom are pharmacists addicted to just a prescription medication [10].

Studies using varying designs suggest that pharmacists do use drugs and suffer the consequences of their use [8]. These include quantitative [74, 92] qualitative [10, 70], retrospective [35] and combination designs [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"]. There is currently no evidence that total lifetime or past-year drug use by pharmacists significantly exceeds that of other major groups of health care professionals or the general population [57]. Yet, pharmacists by virtue of their ease of access may be at greater risk to use prescription

medications than the general population. It appears that the greatest threat to pharmacists is non-medical opioid, stimulant and anti-anxiety drug use due to easy availability. McAuliffe [70] initially reported what he called "non-therapeutic" opioid use by health care professionals. The health care professionals interviewed described their progression of opioid use that led to becoming addicted. A high rate of self treatment with tranquilizers was also noted in the McAuliffe et al. [74] study that included pharmacists. Most non-prescribed opioid and anti-anxiety drug use seems to be for self-diagnosed ailments and most stimulant use is reported to be for facilitating performance, such as staying awake, performing better and studying [72].

As reported, lifetime stimulant use by pharmacists was 15.8% [57], and was greater than twice the general population rate. Access to drugs by pharmacists would most likely explain the differences in prescription medication use between the general population and pharmacists. Consistent with studies of resident physicians who gain access to prescriptive privileges at that stage of their medical career [20, 49], opioid and benzodiazepine self-treatment represented the bulk of prescription medication use by resident physicians. The majority of pharmacists who report the unauthorized use of prescription medications, not surprisingly, initially did so after leaving college [24]. Dabney reported that 40% of pharmacists surveyed had used prescription medications without a physician's authorization, and 20% reported they had done so five or more times in their lifetime. It was proposed that diversion was the primary source for obtaining these medications [8], and that access to medications is therefore a prerequisite to use for many pharmacists. However, as noted by Trinkoff and Storr [117], perhaps access alone is necessary but may not be sufficient to foster the conditions that promote drug use in health care professionals. Access in a permissive environment, coupled with drug use knowledge, the lack of education of the developmental dynamics of addiction [69] and peer, academic or occupational influences that don't dissuade substance use, appear to be the primary factors contributing to illicit prescription medication use [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] [23, 114, 117, 119]. Among other legal and ethical concerns for such behavior is the concern with pharmacists self-diagnosing their condition. A common theme with pharmacists who were interviewed for the Bissell et al. [10] study was that while pharmacists sought help, they often misdiagnosed their substance use problem and sought ineffectual or misplaced support and did not see, or were unable to correctly diagnose, their own addiction.

Physicians

With the exception of anxiolytics, physicians appear to be less likely to use alcohol, tobacco or other drugs than other health care professionals or the general population [57]. For example, McAuliffe et al. [71] reported that physicians drank 20.3 drinks per month in their study and concluded that there was no reason to suspect that alcohol use by physicians differed from other professionals. More recently [61], physicians reported consuming an average of only 17.9 drinks per month, which was also the lowest monthly mean total of any health care professional group. Not only was alcohol use lower than in other health care professional groups surveyed, alcohol use was lower compared with previous data reported by Hughes et al. [48] and McAuliffe et al. [71]. Physicians' lifetime prevalence (92.3%) was similar to the general population (85.8%) as was past-year binge drinking (22.1% vs. 18.6%, respectively), though past-month binge drinking was much lower (7.7% vs. 16.2%, respectively) [61].

As noted earlier, an important social-professional contributor to alcohol use includes alcohol served by pharmaceutical companies at education seminars. A Kaiser Family Foundation [3] study of physicians found that of 2,608 physicians polled, 61% received free meals, drinks, travel and tickets from pharmaceutical companies. Pharmaceutical companies

are providing alcohol at continuing education seminars as a part of a marketing approach targeting practitioners [97]. Some estimate that 12% of a pharmaceutical company's marketing budget (12.5–15 billion dollars a year) is targeted at physicians [4]. While the use of alcohol by physicians does not appear to be a problem, alcohol continues to be served by pharmaceutical companies to provide sales representatives the opportunity to engage health care professionals and facilitate conversations regarding the use of their particular medication. Kenna and Wood [61] reported that physicians were offered alcohol by pharmaceutical companies, significantly more often than all other health care professionals.

As for other drug use, Kenna and Wood [57] reported that the prevalence of lifetime street drug use among physicians exceeded rates reported by the general population, some other health care professional groups in the study, and rates reported previously by Hughes et al. [48]. For example, lifetime prevalence of marijuana use by physicians (51.9%) exceeded rates reported by the general population (31.6%), by physicians in the Hughes et al. study (35.6%), as well as rates reported by pharmacists (44.4%) and dentists (48.7%) in the Kenna and Wood [57] study. Furthermore, Kenna and Wood [57] reported that the lifetime prevalences of cocaine (17.3%) and hallucinogen (11.5%) use by physicians were the highest among health care professional groups used for comparison and higher than both the general population (11.8 and 10.1%, respectively) and the physicians surveyed (10.3 and 7.8%) by Hughes et al. [48]. Results regarding past-year use of street drugs by physicians from the Kenna and Wood [57] study, however, were consistent with data previously reported by McAuliffe et al. [72] and Hughes et al. [48], and self-prescribed minor opioid use among physicians was far lower in the Kenna and Wood study. In addition, past-year minor opioid use (1%) was only one-eighth the rate reported by pharmacists (8.3%). On the other hand, prevalences of anxiolytic use by physicians were the highest among health care professional groups and were much higher than rates reported for the general population [85]. Despite this, reported rates have been dropping. For example, past-year use by physicians was 4.8%, a rate higher than reported by pharmacists (4.5%), nurses (3.1%), dentists (2.7%) and the general population [57], whereas past-year use of benzodiazepines (anxiolytics) was 11.4% as reported by Hughes et al. and 9% in the McAuliffe et al. study.

In terms of onset of use, initiation of street drugs often begins in college, high school or earlier; only opioid and anxiolytic use began during residency [18, 49]. Hughes et al. [48] suggested that unsupervised opioid and anxiolytic use could contribute to substance abuse or dependence in physicians, particularly in light of the results in their study that found that physicians were more likely than age and gender peers to have used alcohol, minor opioids and anxiolytics.

Identifying Drug Problems in Health Care Professionals

Job performance issues such as excessive absenteeism, errors, frequently changing jobs, calling in sick or offering to work overtime, frequent wasting medication, sleeping on duty and always giving maximum doses of medications are a few of the important behavioral signs useful to identify substance abuse problems in health care professionals [95]. Additionally, there are several symptoms of alcohol or drug abuse that co-workers may experience such as memory blackouts, emotional lability, withdrawal from family or co-workers, depression, insomnia, slurred speech, disappearing frequently or the odor of mouthwash or mints on their breath (Table 1). In fact, some of these markers may hold the key to the type of impairment. For example, unexplained work absenteeism may indicate an alcohol abuse or dependence problem since, in addition to hangover, home is the more convenient place to store and access this drug of choice. By contrast, consistently volunteering to work overtime, or arriving at work when not scheduled, provides an impaired co-worker

Table 1 Signs and symptoms of potential chemical impairment in a co-worker

- The odor of alcohol on the breath or strong odor of mouthwash or mints to mask the alcohol.
- Hand tremor that occurs when in alcohol withdrawal (such as in the morning)
- Excessive perspiration
- Absence from work without notice, frequent absenteeism or late for work
- Unexplained disappearance during work for long periods of time
- Sleeping or dozing off while on duty or complaints of difficulty sleeping
- Frequent bathroom breaks
- Volunteering for overtime or being at work when not scheduled to be there.
- Deterioration in personal appearance
- Reports of illness, minor accidents and emergencies
- Confusion, memory loss and difficulty concentrating
- Heavy drug waste and or drug shortages
- Inappropriate prescriptions for large narcotic doses
- Increase in medication order entry errors or sloppy recordkeeping.
- Work performance that alternates between periods of high and low productivity.
- Unreliability in keeping appointments and meeting deadlines
- Personality changes and mood swings

the opportunity to access controlled substances not available at home. Unfortunately, such symptoms are more easily identified with hindsight than before a co-worker is identified with an alcohol or drug use disorder.

Governmental, state, local, corporate and hospital employers use statistical analysis to monitor worker access to specific drugs performed on a periodic basis. Subsequently, at the person level, if a particular health care professional appears to consistently access controlled drugs at higher rates than peers, a more formal investigation is begun, perhaps instituting use of investigators, covertly employing video cameras or auditing the site.

The Intervention of Health Care Professionals

Data suggests that denial is often greatest for those health care professionals who are the most addicted [42]. Health care professionals often use a greater amount of drugs for longer periods of time, for they can go undetected by their ability to use various drugs to cover drug side effects [23]. Often the only time health care professionals are caught is through a drug audit by supervisors or internal security measures.

Probably one of the most difficult professional decisions a health care professional can make is to intervene on behalf of a co-worker who has an alcohol or drug problem. Given the seriousness of dependence disease and its treatment, intervention can present problems at many levels for both individuals. Despite these difficulties, it is important to recognize that health care professionals with alcohol or drug problems in retrospect feel that an intervention probably saved their lives [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"]. Also, while at the time of their discovery these individuals were devastated, the reality is that after receiving treatment the majority do successfully return to work [80].

Interventions are different for health care professionals than are other interventions for others. The intervention is professionally based and focused on practice. The intervention team must recognize that the professional's identity is fused with the role they perform, and the intervention must focus on objective data from their investigation. There are potentially significant financial implications if the professional is unable to practice, so leverage during the intervention is focused on ability to practice and maintaining employment [112].

There are three major reasons why early intervention and treatment for health care professionals is desirable: (1) it should lower the risk of patient care errors due to substance impairment;

(2) it helps the health care professionals prevent overdose that could result in their own death, suicide or other problems from adverse drug reactions and (3) the health care professionals may have an easier experience with drug withdrawal and less resistance to treatment. There are also advantages for health care professionals who come in for treatment on their own as they are protected by confidentiality laws which protect their identity. In these cases, neither the employer nor the state are notified of treatment. This can protect the health care professionals from loss of privileges or licensure, vs. if their addiction were to become known to the Drug Enforcement Administration or state licensure boards, and is a powerful incentive to engage in the recovery process. Additionally, the health care professionals may be able to stay at work and not suffer economic hardships that accompany forced loss of licensure due to discovery. This is not necessarily the best treatment strategy, as treatment may require work modification to restrict access to substances. Finally, if treatment is successful, the health care professionals won't be subjected to stigma associated with loss of licensure.

Once an individual's alcohol or drug problem surfaces, treatment decisions are generally tailored to his or her needs. Although a thorough discussion of the diverse treatment options are better covered elsewhere in this book, certain basic goals of treatment include matching the patient to the correct level of care, such as deciding whether someone is better suited to inpatient versus outpatient treatment [83] are also relevant for health care professionals. Beyond placement, fundamental components of treatment include individual and group therapy, pharmacotherapy when appropriate, urine drug monitoring and 12-step facilitation. Twelve-step programs include Alcoholics Anonymous, Narcotics Anonymous as well as programs targeted toward health care professionals such as Caduceus, International Pharmacists Anonymous (a psychosocial support group specifically for pharmacists), International Doctors in Alcoholics Anonymous and many others.

There is relatively little research assessing risk factors for relapse or treatment success of recovering health care professionals. In a retrospective cohort study of 292 health care professionals enrolled in the state of Washington's Physicians Health Program, only about 25% of the study population had one or more relapses [28]. The risk of relapse was significantly increased in health care professionals who had used a major opioid, had a coexisting psychiatric illness or reported a family history of an alcohol or drug disorder. Co-existing risk factors and previous relapse significantly increased the likelihood of relapse.

For health care professionals formally referred to treatment programs, one of the keys to re-entry is signing a contract that delineates what is expected by the treatment agency or wellness program. These programs are responsible for overseeing treatment plans, urine drug monitoring and advocating for health care professionals with licensing boards. Generally, treatment is successful whether initiated by the health care professional or others. In 1988, for example, a survey examined pharmacist assistance programs in all 50 states and the District of Columbia [80]. While the survey reported that only 20% of impaired pharmacists in these treatment programs voluntarily disclosed their chemical use problem, just over 88% successfully completed treatment and returned to practice. More recently, McLellan et al. [79] reported on urine drug monitoring during a 5-year follow-up study of 802 physicians in 16 state Physician Health Programs. At the conclusion of the study, 81% were licensed and working. In sum, these studies suggest that the goal of returning a recovering health care professional to practice with the proper aftercare and monitoring program is realistic with a good chance of success.

Prevention and Education

What seems clear from the data presented is the need to highlight: (1) an appropriate respect for

alcohol use and, in particular, misuse; (2) the dangers of self-treatment, especially with any controlled prescription medications and (3) recognizing risk factors such as family history of alcohol or drug use that may predispose individual health care professionals to subsequent substance abuse under the right conditions as with other non-health care professionals.

That substance use rates reported by most of the studies referred to in this chapter would not be categorized as psychoactive substance abuse or dependence using criteria from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision [27], should not imply that health care professionals are safe from addiction. Health care professionals work in stressful positions and people outside of each profession have little connection with the specific responsibilities and demands of each. In addition, health care professionals work with medications that are efficacious when used properly but when abused may facilitate a quick progression to dependence under the proper circumstances. Self-treatment removes the opportunity for oversight of a provider for appropriateness of use. Furthermore, as qualitative and review studies have determined [23, 24, 32, 70], substance related impairment often includes diverted medications. Non-prescribed substance use, no matter how infrequent and how little, is just as illegal for health care professionals [7] as it is for the general population.

Wright [123] admonished the medical profession for attempting to simply provide more substance abuse education for physicians and students, arguing that it was the type of education that was being presented that was questionable. Therefore, the quality of education with regard to medication use, be it alcohol or otherwise, cannot be stressed enough. Understanding the "disease model" is critical to the professional development of clinicians but doesn't provide the sort of preventative information necessary to sensitize one to substance use or abuse either in patients or in themselves. Education in the context of requiring health care students to attend Alcoholics Anonymous, Narcotics Anonymous, or Caduceus groups and sitting in on group counseling sessions or attending talks by health care professionals who have been alcohol and other drug dependent as they detail their story of addiction may provide the pathways that connect theory with practice. The data would suggest that the triggers and risk factors are different for each health care profession, but the interventions and successful treatments that promote abstinence, with minor variations, are similar.

While some suggest that stress alone does not cause addiction [10], the added factor of medication availability may enhance risk [23, 83, 117, 119], as availability has been found to be a significant risk factor for many health care professional groups [Dabney D (1997) A sociological examination of illicit prescription drug use among pharmacists. University of Florida, "An Unpublished Dissertation"] [72, 117]. The data suggest the majority of the initiation of minor opioid and anxiolytic use by health care professionals occurred after college when access increased in the workplace though obtaining prescriptive authority. In a similar manner, prescription medication initiation today by adolescents is primarily from available unused medications left and forgotten in the home medicine cabinet [109].

Universities and colleges routinely encounter the consequences of unhealthy alcohol or drug use by health care professionals but do not systematically present medical education designed to prevent these behavioral misadventures. The importance and quality of education with regard to alcohol or drug use, be it prescription medications or otherwise, cannot be stressed enough. While there has been some progress in curriculum and faculty development in many health care professional schools, much more needs to be accomplished for substance abuse education generally and the vulnerability of health care professionals specifically. It appears that medical education about substance use disorders generally is scanty at best. For example, when the physician Leadership on National Drug Policy conducted a survey of over 1,500 medical students at a random sample of 15 schools, 56% responded that they had received little education

about drug and alcohol abuse, and 20% said they received none [47].

A recent successful national training project for interdisciplinary faculty development across several traditional health professions as well as allied professionals and dentistry issued a strategic plan to improve health care professional education and reviews progress in several health disciplines [40]. That strategic plan made recommendations to strengthen substance abuse medical education: "because of health professional's vulnerability to impairment, information about the causes, risk factors, symptoms, and treatment options for substance abuse needs to be developed further and taught to all health professionals," ([41], p. 158). The plan further acknowledges that "Chemically dependent professionals unfortunately do not readily recognize their own impairments. . ..Guilt and shame over past behaviors prevent health professionals from admitting their problems, seeing the difficulties that addiction has caused in their lives, and voluntarily seeking help" ([41], p. 158).

As for the curriculum, understanding the "disease model" is critical to the professional development of clinicians but doesn't provide the sort of preventative information necessary to sensitize one to substance use or abuse either in patients or in themselves. Recommendations suggest that education in the context of requiring health care students to attend Alcoholics Anonymous, Narcotics Anonymous or Caduceus groups or sitting in on group counseling sessions give them a direct sense of the power of addictive disease and the strength needed to attain and maintain recovery.

Introduction

Substance abuse and dependence are considered significant problems in society warranting identification and treatment. However, substance misuse, abuse, and dependence in older adults are complex issues that are often not recognized and, if recognized at all, under-treated. Substance misuse/abuse, in particular, among elders is an increasing problem. Older adults with these problems are a special and vulnerable population that can benefit from elder-specific strategies focused on their unique issues associated with alcohol and medication/drug misuse/abuse in later life. There are concerns in the field that the standard diagnostic criteria for abuse/dependence are difficult to apply to older adults, leading to under-identification and treatment. This chapter will cover four major areas that can benefit both research and clinical professionals working with older adults: (1) prevalence, impact, and correlates of the substance abuse in this population; (2) screening and identification; (3) use of brief interventions to either encourage behavior change or facilitate treatment entry, if needed, and (4) treatment research and related issues.

Prevalence and Impact of Substance Use Among Older Adults

Community surveys have estimated the prevalence of problem drinking among older adults to

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_70,

range from 1 to 16% [2, 34, 53, 58, 59]. These rates vary widely depending on the definitions of older adults, at-risk and problem drinking, alcohol abuse/dependence, and the methodology used in obtaining samples. The National Survey on Drug Use and Health (2002–2003) found that, for individuals aged 50+, 12.2% were heavy drinkers, 3.2% were binge drinkers, and 1.8% used illicit drugs [59]. Estimates of alcohol problems are much higher among health care-seeking populations, because problem drinkers are more likely to seek medical care [64]. Early studies in primary care settings found that 10–15% of older patients met the criteria for at-risk or problem drinking [12, 27]. Two studies in nursing homes reported that 29–49% of residents had a lifetime diagnosis of alcohol abuse or dependence, with 10–18% reported active dependence symptoms in the past year [47, 62]. In 2002, over 616,000 adults aged 55 and older reported alcohol dependence in the past year (*Diagnostic and Statistical Manual of Mental Disorders*, 4th edition definition): 1.8% of those aged 55–59, 1.5% of those aged 60–64, and 0.5% of those aged 65 or older [57]. Although alcohol and drug/medication dependence are less common in older adults when compared to younger adults, the mental and physical health consequences are serious [45]. A new study using the 2005–2006 National Survey on Drug Use and Health [17] showed a significant level of binge drinking among those aged 50 to 64. The authors also found that 19% of the men and 13% of the women had two or more drinks a day, considered heavy or "at-risk" drinking. The survey also found binge drinking in those over 65, with 14% of men and 3% of women engaging in binge drinking.

Medication Misuse

Misuse of medications by older adults is perhaps a more challenging issue to identify. Older adults are at higher risk for inappropriate use of medications than younger groups. Older adults use more prescriptions and over-the-counter medications than other age groups, and studies show that about a quarter of older adults use psychotherapeutic medications, with 27% of all tranquilizer prescriptions and 38% of sedative hypnotics written for older adults. There over 2 million serious adverse drug reactions yearly, with 100,000 deaths per year. Adverse drug reactions are especially prominent among nursing home patients with 350,000 events each year [42, 50]. Older persons regularly use on average between two and six prescription medications and between one and three over-the-counter medications [49]. A survey of social services agencies indicated that medication misuse affects 18–41% of the older clients served, depending on the agency [73, 76].

Combined alcohol and medication misuse has been estimated to affect up to 19% of older Americans [55]. Substance abuse problems among elderly individuals often occur from misuse of over-the-counter and prescription medications. Drug misuse can result from the overuse, underuse or irregular uses of either prescription or over-the-counter medications. Misuse can relatively easily become abuse [66, 76]. Additionally, co-factors such as alcohol, and/or mental health problems, older age, and being female also increase vulnerability for misusing prescribed medications [36, 37].

Vulnerabilities for Substance Use Problems

Older adults have specific vulnerabilities for substance abuse problems due to the physical and psychological changes that accompany aging. These may include loneliness, diminished mobility, impaired sensory capabilities, chronic pain, poor physical health, and poor economic and social supports [26, 74]. Older adults also have an increased sensitivity to alcohol, over-the-counter medications, and prescription medications. The age-related decrease in lean body mass compared to total volume of fat, and the decrease in total body volume increase the total distribution of alcohol and other mood-altering chemicals in the body which increases vulnerability. Additionally, central nervous system

sensitivity increases with age. Liver enzymes that metabolize alcohol and certain other drugs are less efficient with aging.

A major concern in working with older adults is the interactions between alcohol and medications, particularly psychoactive medications, such as benzodiazepines, barbiturates, and antidepressants. Alcohol use can interfere with the metabolism of many medications and is a leading risk factor for the development of adverse drug reactions [15, 38, 46, 60]. There are individuals for whom *any* alcohol use, coupled with the use of specific over-the-counter/prescription medications, can be problematic. Further, co-occurring psychiatric conditions including comorbid depression, anxiety disorders, and cognitive impairment can be a complication of alcohol and medication abuse in older adults [16, 65].

The medical and emotional consequences of heavy or excessive alcohol consumption have been well documented. However, there is now more evidence of the medical risks of moderate alcohol use for some older adults. Moderate alcohol consumption has been demonstrated to increase the risk of strokes caused by bleeding, although it decreases the risk of strokes caused by blocked blood vessels [43]. Moderate alcohol use has also been demonstrated to impair driving-related skills even at low levels of consumption and it may lead to other injuries such as falls [64]. Of particular importance to the elderly is the potential interaction between alcohol and both prescribed and over-the-counter medications, especially psychoactive medications such as benzodiazepines, barbiturates and antidepressants, as discussed above. Alcohol is also known to interfere with the metabolism of medications such as digoxin and warfarin [1, 38, 46].

Comorbidities

There are a number of physical and mental health comorbidities associated with alcohol/medication/illicit drug misuse/abuse. In working with older adults, the most difficult-to-identify symptoms are often mental health-related. Epidemiologic studies have demonstrated that alcohol use in the presence of psychiatric symptoms is a common problem with wide reaching consequences in younger age groups. There is less research on the comorbidity of alcohol and psychiatric conditions in later life. Among 216 elderly presenting for alcohol treatment, Finlayson and associates found 25% had an organic brain syndrome (dementia, delirium, amnestic syndrome), 12% had an affective disorder, and 3% had a personality disorder [37]. In a similar study, Blow and colleagues reviewed the diagnosis of 3,986 Veterans Administration patients (aged 60–69) presenting for alcohol treatment [17]. The most common comorbid psychiatric disorder was an affective disorder found in 21% of the patients. Findings from the Liverpool Longitudinal Study found a five-fold increase in psychiatric illness among elderly men who had a lifetime history of five or more years of heavy drinking [70].

Comorbid depressive symptoms are not only common in late life but are also an important factor in the course and prognosis of psychiatric disorders. Depressed alcoholics have been shown to have a more complicated clinical course of depression with an increased risk of suicide and more social dysfunction than non-depressed alcoholics [24]. Moreover, they were shown to seek treatment more often. Relapse rates for those who were alcohol dependent, however, did not appear to be influenced by the presence of depression. Alcohol use prior to late life has also been shown to influence treatment of late-life depression.

Sleep disorders and sleep disturbances represent another group of comorbid disorders associated with excessive alcohol use. Alcohol causes well-established changes in sleep patterns such as decreased sleep latency, decreased stage IV sleep, and precipitation or aggravation of sleep apnea [79]. There are also age-associated changes in sleep patterns including increased rapid eye movement episodes, a decrease in rapid eye movement length, a decrease in stages III and IV sleep, and increased awakenings. The age-associated changes in sleep can all be

worsened by alcohol use and depression. Moeller and colleagues demonstrated in younger subjects that alcohol and depression had additive effects upon sleep disturbances when occurring together [52]. Furthermore, sleep disturbances (especially insomnia) have been implicated as a potential etiologic factor in the development of late-life alcohol problems or in precipitating a relapse [61]. Sleep disturbance is relatively common in older adulthood. Separating out the role of alcohol or drugs and psychiatric symptomatology with the overlay of sleep issues requires time and non-judgmental questioning to elicit the nature of the problems and to work toward positive outcomes.

Identifying Alcohol and Drug Use Problems in Older Adults

Many older individuals have unique drinking patterns and alcohol-related consequences, social issues, and treatment needs, compared to their younger counterparts [3, 8, 35]. Because of this, assessment, intervention, and relapse prevention planning for alcohol problems in late life are likely to require elder-specific approaches. The majority of older adults who are experiencing problems related to their drinking do not meet *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision [5] criteria for alcohol abuse or dependence [15, 21, 63]. Alcohol problems are typically thought to occur in persons who consume larger quantities and drink frequently. For some older individuals, any alcohol use can present problems, particularly when coupled with some psychoactive medications. *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision criteria are widely used and distinguish between abuse and dependence. However, these criteria may not be appropriate for many older adults with substance use problems because people in this age group do not often experience the legal, social, or psychological consequences specified in the criteria. In addition, a lack of tolerance to alcohol may not be as appropriate an indicator of alcohol-related problems in older ages. Most *Diagnostic and Statistical Manual of Mental Disorders* criteria for tolerance are based on increased consumption over time. This does not take into account physiologic changes of aging that can lead to physiologic tolerance at lower levels of alcohol consumption. Finally, the physical and emotional consequences of alcohol use may not be as relevant identifying alcohol problems in older adults.

Table 1 shows some of the signs of potential problems related to alcohol use or alcohol/medication misuse in older adults. Although some of these symptoms can be applied to other conditions in older individuals, they are important markers that provide the opportunity for professionals to ask more questions and determine differential diagnoses. Given the high rate of utilization of medical services by older adults, physicians and other health care professionals can be the key to identifying those in need of brief interventions and/or treatments and providing appropriate care based clinical need.

Table 1 Signs of potential problems related to alcohol and medication/drugs in older adults (need for differential diagnosis)

Anxiety	Increased tolerance to alcohol
Depressed feelings	Unusual response to medications
Disorientation	New difficulties in decision-making
Excessive mood swings	Poor hygiene
Falls, bruises, burns	Poor nutrition
Family problems	Idiopathic seizures
Financial problems	Sleep problems
Headaches	Social isolation
Incontinence	

Classification of Alcohol Use Patterns and Problems in Older Adults

There are two main methods that have been used over many years to understand alcohol problems in older adults: (1) the medical diagnostic approach, and (2) the spectrum-of-use approach. Both approaches use criteria that may not always

apply to older adults and can lead to under-identification of alcohol use problems in this population. These were originally described in 1990 by Atkinson [6] and have been applied in the literature since then.

The Medical Diagnostic Approach involves applying criteria for alcohol abuse/dependence to the older adult population as they are applied to younger adults. Clinicians often rely on the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision [5], a widely used set of criteria that distinguish between abuse and dependence. These criteria may not apply to older adults with substance use problems because they do not often experience the legal, social, or psychological consequences specified in the criteria. For example, "a failure to fulfill major role obligations at work, home, or school" may be less applicable to retired persons with fewer familial and work obligations [21]. A lack of tolerance to alcohol may not indicate that an older adult does not have problems related to alcohol use. Moreover, *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision criteria for tolerance are mostly based upon increased consumption over time which ignores the physiologic changes of aging that would account for physiologic tolerance in the setting of decreased alcohol consumption.

The spectrum-of-use approach uses definitions of abstinence, low-risk use, at-risk use, problem use, and alcohol/drug dependence to determine problems related to use. The spectrum-of-use categories are derived from both the clinical and research expertise of professionals in the field. Definitions for older adults regarding abstinence, low-risk, at-risk, and problem use, and abuse/dependence focus primarily, but not exclusively, on alcohol [11, 13].

Abstinence refers to drinking no alcohol in the previous year. Approximately 60–70% of older adults are abstinent. If an older individual is abstinent, it is useful to ascertain why alcohol is not used. Some individuals are abstinent because of a previous problem with alcohol. Some are abstinent because of recent illness, while others have life-long patterns of low-risk use or abstinence. Those who have a history of alcohol problems may require preventive monitoring to determine whether any new stressors could exacerbate an old pattern.

Low-risk use is alcohol use that does not lead to problems. Older adults in this category drink within recommended drinking guidelines (no more than 1 drink/day or 7 drinks/week, never more than 2 drinks on any one drinking day), are able to employ reasonable limits on alcohol consumption, and do not drink when driving a motor vehicle or boat, or when using contraindicated medications. Low-risk use of medications/drugs would generally include using medications following the physician's prescription. However, a careful check of the number and types of medications, and whether or not the patient is taking psychoactive medications, is important because medication interactions/reactions are not uncommon in older adults and the mix of medications and alcohol can be problematic. These individuals can benefit from preventive messages but may not need interventions.

Use that increases the chances that an individual will develop problems and complications is at-risk use. Persons over 65 who drink >7 drinks/week—one per day—are in the at-risk use category. Although they may not *currently* have a health, social, or emotional problem caused by alcohol, they may experience family and social problems, and, if this drinking pattern continues over time, health problems could be exacerbated. Brief interventions have been shown to be useful for older adults in this group as a prevention measure.

Older adults engaging in problem use are drinking at a level that has already resulted in adverse medical, psychological, or social consequences. Potential consequences can include injuries, medication interaction problems, and family problems, among others. It is important to reiterate that some older adults who drink even small amounts of alcohol can experience alcohol-related problems. Although quantity and frequency of alcohol use are important indicators of potential problems, they may not be the only marker for the need to intervene. The presence

of consequences, even if alcohol use is low, can be a key leading to the need for brief advice or brief treatments.

Alcohol or drug dependence refers to a medical disorder characterized by loss of control, preoccupation with alcohol or drugs, continued use despite adverse consequences, and physiological symptoms such as tolerance and withdrawal. Formal specialized treatment is generally used with persons who meet the criteria for alcohol abuse or dependence and who cannot discontinue drinking with a brief intervention protocol. Nonetheless, pre-treatment strategies are also appropriate for individuals with the highest problem severity. Brief interventions were recommended by the Center for Substance Abuse Treatment's Treatment Improvement Protocol on brief interventions and brief therapies for substance abuse, for use either as a pre-treatment strategy to assist individuals on waiting lists for formalized treatment programs—in the case of those who meet abuse or dependence criteria with no physical dependence or withdrawal—or as an adjunct to specialized treatment to assist with specific issues (e.g., completing homework for treatment groups, attendance at work, adherence to the treatment plan) [12].

Drinking Guidelines for Screening

The National Institute on Alcohol Abuse and Alcoholism and the Center for Substance Abuse Treatment's Treatment Improvement Protocol on older adults [21] recommended that persons aged 65 and older consume no more than 1 standard drink/day or 7 standard drinks/week [31, 54]. In addition, older adults should consume no more than 2 standard drinks on any drinking day.

The drinking limit recommendations for older adults are consistent with data regarding the relationship between consumption and alcohol-related problems in this age group [29, 30]. Recommendations are also consistent with the evidence on the beneficial health effects of drinking [30, 48, 67]. These are simply guidelines. There are individuals for whom abstinence is the best course due to medications used and physical and mental health disorders. Those decisions need to be made on a case-by-case basis.

Screening for Alcohol/Medication Problems in Older Adults

To practice prevention and early intervention with older adults, clinicians need to screen for alcohol use (frequency and quantity), drinking consequences, and alcohol/medication interaction problems. Screening can be done as part of routine mental and physical health care and updated annually, before the older adult begins taking any new medications, or in response to problems that may be alcohol- or medication-related. Clinicians can obtain more accurate histories by: asking questions about the recent past; embedding the alcohol use questions in the context of other health behaviors (i.e., exercise, weight, smoking, alcohol use), and paying attention to non-verbal cues that suggest the client is minimizing use (i.e., blushing, turning away, fidgeting, looking at the floor, change in breathing pattern). The "brown bag approach"—where the clinician asks the client to bring all of his/her medications, over-the-counter preparations, and herbs in a brown paper bag to the next clinical visit—is often recommended to determine medication use. This provides an opportunity for the provider to determine what the individual is taking and what, if any, interaction effect these medications, herbs, etc., may have with each other and with alcohol.

Screening questions can be asked by verbal interview, by paper-and-pencil questionnaire or by computerized questionnaire. All three methods have equivalent reliability and validity [10, 40]. Any positive responses can lead to further questions about consequences. To successfully incorporate alcohol (and other drug) screening into clinical practice with older adults, it should be simple and consistent with other screening procedures already in place [13].

Before asking any screening questions, the following conditions are needed: (1) the

interviewer needs to be empathetic and nonthreatening; (2) the purpose of the questions should be clearly related to health status; (3) the client should be alcohol free at the time of the screening; (4) the information must be confidential, and (5) the questions need to be easy to understand. In some settings (such as waiting rooms), screening instruments are given as self-report questionnaires with instructions for patients to discuss the meaning of the results with their health care providers.

The following interview guidelines can be used. For patients requiring emergency treatment or for those who are temporarily impaired, it is best to wait until their condition has stabilized and they have become accustomed to the health setting where the interview will take place. Signs of alcohol or drug intoxication should be noted. Individuals who have alcohol on their breath or appear intoxicated give unreliable responses, so consideration should be given to conducting the interview at a later time. If this is not possible, findings and conditions of the interview should be noted in the medical record. If the alcohol questions are embedded in a longer health interview, a transitional statement is needed to move into the alcohol-related questions. The best way to introduce alcohol questions is to give the client a general idea of the content of the questions, their purpose, and the need for accurate answers [14]. This statement should be followed by a description of the types of alcoholic beverages typically consumed. If necessary, clinicians may include a description of beverages that may not be considered alcoholic (e.g., cider, low alcohol beer). Determinations of consumption are based on "standard drinks". A standard drink is a 12-ounce bottle of beer, a 4-ounce glass of wine, or 1½ ounces (a shot) of liquor (e.g., vodka, gin, whiskey).

Screening for alcohol use and alcohol-related problems does not always follow a standardized format. Additionally, not all standardized instruments exhibit good reliability and validity when used with older adults. There are a few screening instruments that have been used effectively with older adults. In addition to quantity/frequency questions to ascertain use, the Michigan Alcoholism Screening Test-Geriatric Version, the Short Michigan Alcoholism Screening Test-Geriatric Version, and the Alcohol Use Disorders Identification Test are often used with older adults. Of these, the Michigan Alcoholism Screening Test-Geriatric Version and the Short Michigan Alcoholism Screening Test-Geriatric Version were developed specifically for older adults. The Alcohol Use Disorders Identification Test, developed by the World Health Organization, has been tested in a number of countries with various populations.

The Michigan Alcoholism Screening Test-Geriatric Version was developed at the University of Michigan [18] as an elderly alcoholism screening instrument for use in a variety of settings. The Michigan Alcoholism Screening Test-Geriatric Version was the first major elder-specific alcoholism screening measure to be developed with items unique to older problem drinkers. It is a 24-item scale with a sensitivity of 94.9%, specificity of 77.8%, positive predictive value of 89.4%, and negative predictive value of 88.6%. The Short Michigan Alcoholism Screening Test-Geriatric Version is a 10-item validated form [19].

The Alcohol Use Disorders Identification Test is well-validated in adults under 65 in primary care settings [9, 33, 71] and had initial validation in a study of older adults [19]. The Alcohol Use Disorders Identification Test is a 10-item scale with alcohol-related information for the *previous year only*. The questionnaire is often used as a screener. The recommended cut-off score for the Alcohol Use Disorders Identification Test has been 8, but Blow and colleagues [20] found a Cronbach's alpha reliability of 0.95, sensitivity of 0.83 and a specificity of 0.91 in a sample of older adults with a cut-off score of 7.

Broad-Based Assessment of Substance Use Problems

Clinicians can follow-up the brief questions about consumption and consequences such as

those in the Michigan Alcoholism Screening Test-Geriatric Version and the Alcohol Use Disorders Identification Test with more in-depth follow-up questions, where appropriate. In addition, information obtained in the "brown bag approach" regarding medication use will assist in making any diagnoses and brief intervention or treatment plans.

The use of validated substance abuse assessment instruments will provide a structured approach to the assessment process as well as a checklist of items that should be evaluated with each older adult receiving a substance abuse assessment. Specialized assessments are generally conducted by substance abuse treatment program personnel or trained mental and physical health care providers [51].

Despite problems with criteria used to assess older adults for substance use disorders, two structured assessment instruments are recommended [21], the Structured Clinical Interview for the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition, Revised [77] and the Diagnostic Interview Schedule. The Structured Clinical Interview for the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition, Revised is a multi-module assessment that covers disorders of: substance use, psychosis, mood, anxiety, somatoform, eating, adjustment, and personality. It takes a trained clinician approximately 30 minutes to administer the 35 questions, which probe for alcohol abuse or dependence. The Diagnostic Interview Schedule was originally developed by Robins and colleagues [69] with *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition criteria and has been updated as *Diagnostic and Statistical Manual of Mental Disorders* criteria have evolved. The Diagnostic Interview Schedule is a highly structured interview that does not require clinical judgment and can be used by non-clinicians. The Diagnostic Interview Schedule assesses both current and past symptoms and is available in a computerized version. It has been translated into a number of languages including Spanish and Chinese.

Use of Brief Alcohol Interventions with Older Adults with Substance Dependence

Low intensity, brief interventions are cost-effective and practical techniques that were used as an initial approach to at-risk and problem drinkers in primary care settings and well validated through many studies in primary care [80] and emergency medicine settings [44]. In general, the results of brief intervention studies support the recommendations of the Center for Substance Abuse Treatment expert committee report [12] and the National Institute on Alcohol Abuse and Alcoholism [56] that early identification/screening and brief interventions are effective, should be a matter of routine practice in primary and other health care settings to detect patients with hazardous or harmful patterns of alcohol use. Early identification and secondary prevention of alcohol problems directed in straightforward, non-technical terms at an audience likely to be motivated to change could have broad positive public health implications. It appears that brief interventions with one or a few sessions have the potential of reaching the largest number and broadest spectrum of individuals from diverse settings.

There had been much less attention given to the use of brief interventions with older adults. The spectrum of alcohol interventions for older adults ranges from prevention/education for persons who are abstinent or low-risk drinkers, to minimal advice or brief structured interventions for at-risk or problem drinkers, and formalized alcoholism treatment for drinkers who meet the criteria for abuse and/or dependence. Formalized treatment is generally used with persons who meet the criteria for alcohol abuse or dependence and cannot discontinue drinking with a brief intervention protocol. Nonetheless, pre-treatment brief intervention strategies can be appropriate for this population. Brief alcohol interventions have been shown to be effective with older adults who are at-risk and problem drinkers [22, 34] and were recommended

by the Center for Substance Abuse Treatment Improvement Protocol on brief interventions and brief treatments for substance abuse. There are two main goals of brief interventions: (1) to motivate the individual to cut down or stop using, *or* (2) to motivate the individual who has more serious substance use problems to seek brief or more formalized treatment.

By following the categorization of patterns of use (see above)—at-risk use, problem use, abuse/dependence—clinicians are given flexible guidelines to work with older adults across the spectrum of problems related to alcohol and medications/drugs. Brief interventions can offer a step toward assisting this vulnerable group of older adults to make changes in their alcohol/medication/drug use that can have positive health benefits.

Detoxification and Withdrawal

Alcohol withdrawal symptoms commonly occur in individuals who stop drinking or markedly cut down their drinking after regular heavy use. Alcohol withdrawal can range from mild and almost unnoticeable symptoms to severe and life-threatening ones. The classical set of symptoms associated with alcohol withdrawal includes autonomic hyperactivity (increased pulse rate, increased blood pressure, and increased temperature), restlessness, disturbed sleep, anxiety, nausea, and tremor. More severe withdrawal can be manifested by auditory, visual, or tactile hallucinations, delirium, seizures, and coma. Other substances of abuse such as benzodiazepines, opioids and cocaine have distinct withdrawal symptoms that are also potentially life threatening. Elderly individuals have been shown to have a longer duration of withdrawal symptoms, and withdrawal has the potential for complicating other medical and psychiatric illnesses. There is no evidence, however, to suggest that older individuals are more prone to alcohol withdrawal or need longer treatment for withdrawal symptoms [25, 64]. Because of the potential for life-threatening complications, clinicians caring for older clients who may be abusing substances need a fundamental understanding of withdrawal symptoms and the potential complications as well as when to refer clients to treatment.

Formal Substance Abuse Treatment Outcomes for Older Adults

There has been very little research on the treatment outcomes and the unique needs of older adults in formal substance abuse treatment settings. Because traditional residential alcoholism treatment programs provide services to very few older individuals, sample sizes for treatment outcome studies have often been inadequate. The development of elder-specific alcoholism treatment programs in recent years may facilitate studies of this special population's needs.

Although alcoholism is a significant and growing health problem in the United States [4], there have been few systematic studies of formal alcoholism treatment outcome for older adults [8]. The study of treatment outcomes for older adults who meet the criteria for alcohol abuse/dependence has become a critical issue because of their unique needs for targeted treatment intervention. Because traditional residential alcoholism treatment programs generally provide services to few older adults, sample size issues have been a barrier to studying treatment outcomes for elderly alcoholics in most settings. The development of elder-specific alcoholism treatment programs in recent years has provided sufficiently large numbers of older alcoholics to facilitate studies of this special population [8]. A remaining limitation with this population is the lack of longitudinal studies of treatment outcomes. Previous research on elderly alcoholism treatment can be divided into two broad categories: treatment compliance studies and prospective studies of treatment outcomes.

Few older adults ever enter formal treatment for substance abuse. The Drug and Alcohol Services Information System report noted that

66,500 adults ages 55+ were admitted to treatment during 2002 [58], meaning that 0.1% of the over 62 million individuals in that age group in the United States receive substance abuse treatment. It is relatively rare that screening of older adults is conducted in primary care, emergency care, social service, and aging services settings, making the low rates of treatment unsurprising.

New Models for Screening and Treatment

The Substance Abuse and Mental Health Services Administration's Center for Substance Abuse Treatment published the Treatment Improvement Protocol #26 titled "Substance Abuse among Older Adults" [21]. It provided recommendations from the expert panel on innovative models for screening, brief intervention, and brief treatment approaches appropriate for the older population.

Several states followed the guidelines and recommendations and implemented screening and brief intervention services where older adults can be found (at home, senior centers). Brief interventions involve offering 1–5 "one on one" sessions. Brief interventions for older adults with alcohol problems or risk of such problems have been implemented in a number of settings including primary care [15]. Others have implemented more formal, elder-specific treatment using "brief therapy" or brief treatment employing relapse-prevention models, cognitive-behavioral treatment, and self-management skills [28]. This methodology has been implemented in day treatment or outpatient settings [32, 72, 75, 76].

Studies of Treatment Compliance in Older Adults

Treatment outcomes research on older adults with substance use disorders has focused primarily on compliance with treatment program requirements, with an emphasis on the individuals' fulfillment of prescribed treatment activities and goals, including whether or not those in recovery returned to drinking [8, 21]. The few studies that have addressed these issues in the aging population have shown that age-specific programming improved treatment completion compared with mixed-age treatment [7, 21, 64, 68].

There have been major limitations in the treatment compliance literature on older adults and few prospective studies conducted. Data issues have including a lack of drinking outcome data, failure to report on treatment dropouts, and variations in definitions of treatment completion. In addition, there have been few prospective treatment outcome studies including sufficiently large numbers of older subjects who meet the criteria for alcohol dependence have been conducted to address the methodological limitations of prior work.

Limitations of Treatment Outcome Research

Although it is important to examine factors related to completion of treatment to have a better understanding of client characteristics for those who complete treatment, the lack of information on treatment dropouts or on short- or long-term treatment outcomes, the paucity of females in these studies, the widely varying age cutoffs for inclusion in studies, and the use of "abstinence only" as the outcome, it may be more useful in future studies to measure more clearly non-abstinent drinking outcomes along dimensions such as whether drinkers ever drink to the point of intoxication, binge drinking episodes, consequences over time, physical and mental health status changes, and psychological distress changes over time. Finally, testing elder-specific treatment with mixed-age treatments will help to shape the field in the future as greater percentages of adults reach older ages.

Future Trends: Impact of the "Baby Boom" Cohort

The use of illicit drugs is currently relatively rare in this in older adults. However, research suggests that the number of illicit drug users in older adulthood is likely to increase due to the aging of the "baby boom" generation.

Older adults' higher risk for alcohol and medication, coupled with the rapid growth in this population, highlights the need for targeted intervention, treatment, and relapse prevention strategies. Demographic projections indicate that the aging of the "baby boom" generation will increase the proportion of persons over age 65 from 13% currently, to 20% by the year 2030 [78]. The extent of alcohol and medication misuse is likely to increase significantly as the "baby boom" cohort ages, due to both the growth in the older population as well as cohort-associated lifestyle differences [23]. The projected increase in the number of older adults with substance abuse problems is associated with a 50% increase in the number of older adults and a 70% increase in the rate of treatment needed among older adults [39].

Recent studies of consumption patterns suggest that the baby boom generation, as it continues to age, could maintain a higher level of alcohol consumption than in previous older adult cohorts [23]. Rates of heavy alcohol use have been shown to be higher among baby boomers than in earlier cohorts [46]. In addition, drug use is heightened in the baby boomer cohort [39, 66]. The increasing rate of problem substance use in this population may be attributed to an increase in problems related to the use of illicit drugs or non-medical use of prescription medications [23, 39, 41]. Further, these projections may be underestimates, as criteria used to define problem substance use may not be most appropriate for older populations. Increased substance abuse, coupled with the projected increase in the older adult population, will place increasing pressure on the treatment programs and health care resources [76].

Older adults are a diverse population with substance use patterns that differ across individuals and groups and cover the spectrum of use patterns include abstinence, low-risk use, at-risk use, problem use, and abuse/dependence. Developing brief, cost-effective methods to work with older adults who are experiencing problems related to their use of alcohol, medications, and illicit drugs is becoming a more crucial issue in this era of changing demographic and substance use patterns. It will be the challenge for current and future clinicians, trainers, and researchers to develop methods to ensure more positive outcomes for vulnerable older citizens.

Introduction

Several drugs and chemicals are known to be teratogenic to the human embryo when administered throughout pregnancy, especially during the period of organogenesis. The evidence for their teratogenicity has been shown by human epidemiologic and clinical studies as well as in studies carried out in animals such as rats, mice, rabbits, and primates. The most important disadvantage of the animal models used is the interspecies differences in toxicity and teratogenicity. These teratogenic insults occurring during embryonic life may be present immediately after birth, at infancy, or even later in life, especially if the damage involves the central nervous system [82]. Moreover, many of the insults to the central nervous system occur in the second and third trimesters of pregnancy, when most other organs have already passed the stage of active organogenesis. Briefly, the main stages of the human central nervous system development are the formation of the neural folds, their closure to form the neural tube that closes completely towards the end of the fourth week post-fertilization, and the formation of the main brain vesicles during weeks 5 and 6, with the medulla, pons, and midbrain undergoing much of their active development during that time. However, the cortical

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_71,

plate starts to develop mainly during weeks 8–9 post-fertilization, and the cerebellar cortex develops even later, mainly during the second and third trimesters of pregnancy. The cerebral cortex continues to develop actively throughout gestation and even in the early postnatal life, mainly by forming the different cortical layers, neuronal growth and sprouting, synapse formation, and myelinization. It is, therefore, expected that psychotropic agents such as ethanol, opioids, cannabis, and cocaine, as well as different psychotropic drugs, may affect the development of the central nervous system almost throughout the entire pregnancy [96, 81, 82]. Hence, such late effect will not necessarily be manifested by morphological changes in the central nervous system but rather by more subtle changes in intellectual capacity, learning ability, attention span, and behavior.

In this chapter, we will discuss only the possible effects of ethanol, opiates, cannabis, and cocaine use during pregnancy on the human embryo and fetus. We will survey studies concerning substance-abusing women either throughout pregnancy or following sporadic use. We also will discuss some animal studies, especially those related to mechanism of action. Unlike other drugs that impact the central nervous system or other organs, all drugs of abuse may affect both the mother and embryo, inducing mainly, but not exclusively, behavioral problems and intellectual deficits.

Effects of Maternal Alcohol (Ethanol) Consumption During Pregnancy

History of Alcohol Effects in Pregnancy

The history of maternal alcoholism and development of the offspring goes back to the Bible and to early Greek mythology. Samuel the prophet forbids Samson's mother from drinking wine during her pregnancy because she is going to give birth to an exceptional child blessed by God with special power, and the bridal couple, in Carthage, was forbidden to drink wine on the wedding night to prevent the birth of a defective child. In 1834, a report to the House of Commons (by a select committee investigating drunkenness) indicated that some of the alcoholic mothers gave birth to infants with "a starved, shrivelled and imperfect look". Later, in 1900, the earliest suspicion of the teratogenic effects of alcohol came from Sullivan, who reported an increase in the rate of abortions and stillbirths as well as increased frequency of epilepsy among live-born infants of chronic alcohol-abusing women [54]. The teratogenic effects of ethanol on human fetuses were first reported by Lemoine et al. in 1968. He described a common pattern of birth defects in 127 children born to alcoholic mothers in France that included growth deficiency, psychomotor retardation, low IQ, and atypical electroencephalogram [65]. Alcohol was used at the time to prevent premature labor, and its use was so widespread that if any causal correlation existed between prenatal alcohol use and birth defects, it should have been recognized and reported long before 1973. The adverse/harmful effects of alcohol use during pregnancy have been suggested for decades, and despite the numerous case reports, the implication of alcohol as a teratogen was greeted with skepticism by the medical community. Furthermore, it was rather difficult to document or diagnose formally the constellation of problems observed in these children, until guidelines for fetal alcohol syndrome were established [92].

Effects on the Developing Embryo and Fetus

Fetal Alcohol Syndrome and Alcohol Effects

Basically there seem to be 3 categories of prenatal exposure to ethanol related to the amount of alcohol ingested: exposure to heavy drinking (over 100 g of ethanol/day), which may cause

fetal alcohol syndrome, exposure to moderate drinking (between 50 and 100 g of ethanol/day), which may result in "alcohol effects" (the differences between these categories are not sharp), and binge drinking-occasions with intakes of 4–5 drinks of ethanol (altogether more than 100 g of ethanol/drink) [61, 73]. Most investigators are in agreement that binge drinking also may cause damage to the developing fetal brain [61, 83]. The amount of alcohol ingested, the length of the period of alcohol use, and the developmental stage of the embryo and fetus at exposure mediate the effects of ethanol intake on the developing fetus. It is important to note that a meta-analysis of reports on the incidence of fetal malformations in moderately alcohol-abusing women during pregnancy did not show an increase in congenital defects [86]. Alcohol drinking, even in moderate amounts, also is associated with an increased risk of spontaneous abortions, especially in the first trimester of pregnancy, and with infertility in males and females [61].

It has been demonstrated by many investigators that high alcohol consumption during pregnancy may seriously affect the embryo. The severity of the malformations ranges from fetal alcohol syndrome, which is evident in 4–6% of infants of heavy-drinking mothers, to minor effects, such as low birth weight, intrauterine growth retardation, a slight reduction in IQ of the infants, and an increased rate of congenital anomalies [54, 55, 65, 83, 92].

Alcohol consumption during pregnancy was associated with a variety of abnormalities in the newborn. However, the most common, serious, and specific syndrome of combined defects-fetal alcohol syndrome-has been described only for regular/daily alcohol users [2, 54, 65, 92]. Recognition of the syndrome was made by Drs. David Smith and Kenneth Jones in 1973 based on the evaluation of eight children born to mothers who were defined as chronic alcoholics [56]. The principal features of fetal alcohol syndrome were determined as prenatal and postnatal growth deficiency, short stature, developmental delay, microcephaly, fine-motor dysfunction, and facial dysmorphism manifested by short palpebral fissures, long smooth philtrum, thin vermilion border of upper lip, and maxillary hypoplasia. In addition, there may be cleft palate, joint anomalies, altered palmar creases, and cardiac anomalies [54]. The above-described facial dysmorphism tends to improve with the advancement in age of the affected individuals.

Anomalies of Other Organs

Alcohol is known to affect not only the central nervous system but also organs that are developmentally related to central nervous system derivatives, including those developmentally dependent on neural crest cells like the craniofacial complex and the heart.

Oro-Facial Clefts

A number of reports addressed potential correlation between alcohol consumption and oral clefts. However, effect estimates were often unstable due to numbers of the cases studied. In a case control surveillance study, Meyer et al. [75] collected 5,956 live-born infants with cleft palate, cleft lip, or both. Based on the maternal report of alcohol use during the first 4 months of pregnancy, the authors failed to link low levels of alcohol use and oral clefts. Even the highest level of alcohol consumption (three or more drinks per week, three or more drinks per drinking day, and maximum daily consumption of five or more drinks) did not result in a higher number of infants born with a cleft than did the use of less than one drink per week or less than one drink per drinking day. In addition, folic-acid-supplemented multivitamins used by some of the women did not modify the association between oral clefts and ethanol consumption [75]. Contradictory results were reported by Romitti et al. [95] based on the data from the National Birth Defects Prevention Study. The authors found a weak correlation between average periconceptional alcohol consumption and all orofacial clefts (combined and

isolated clefts). A moderate link was identified for multiple clefts and for Pierre-Robin syndrome. Estimates for this latter phenotype, however, were based on small numbers, reflecting the study criteria to exclude cases of known etiology. An increased risk of orofacial clefts was observed among infants born to binge-drinking (five or more drinks per occasion) mothers exposed in the first trimester of pregnancy. Maternal binge drinking may be particularly harmful since it results in a greater peak of blood ethanol concentration and, therefore, a prolonged alcohol exposure [24].

Cardiac Anomalies

There is sparse literature dealing with the effects of alcohol abuse in pregnancy on cardiac anomalies. It is accepted that about one-third of children with alcohol embryopathy will also have congenital cardiac problems. Krasemann and Klingebiel [64] retrospectively reviewed electrocardiographic and echocardiographic data of all patients with clinical signs of alcoholic embryopathy between the years 1976 and 2003. Electrocardiographic and echocardiographic measurements often showed slightly altered values in individuals with alcoholic embryopathy, resulting in the conclusion that alcohol abuse during pregnancy as a primary toxin can lead to minor cardiac abnormalities, even without structural congenital cardiac defects [64].

Reduced Fetal Growth

Intrauterine growth restriction is a well-known feature of alcohol embryopathy. There is a growing mass of literature suggesting the evidence of postnatal long-term height and weight deficits among children born to ethanol-using women. Further, Covington et al. [21] found a moderating effect of maternal age on children's weight at age 7, as children born to women over 30 years of age at the time of birth had significantly lower weight compared with those born to younger women [21].

Behavioral and Developmental Changes

Alcohol is considered one of the risk factors for attention deficit hyperactivity disorder, independently of prenatal nicotine exposure or other familial risk factors. One study showing a positive correlation between alcohol and attention deficit hyperactivity disorder included 26 prenatally alcohol-exposed children. Of the 24 children followed up, 10 were diagnosed with attention deficit hyperactivity disorder, 2 with Asperger syndrome, and 1 with mild mental retardation. The severity of the disorder correlated in a linear pattern with the amount of alcohol used by the mother during pregnancy. This effect was reversible, since discontinuation of alcohol consumption by the 12th week resulted in normally developed children. Moreover, consumption of less than one alcoholic drink per day in the last 3 months of pregnancy, despite heavier drinking earlier, did not result in attention deficit hyperactivity disorder, learning disabilities, or cognitive impairment at the age of 14 years [77].

It has been difficult to define and characterize developmental risks associated with binge drinking or moderate drinking in pregnancy [41], and some studies failed to demonstrate an association between alcohol exposure and sustained attention performance in school-aged children [10].

Alcohol in pregnancy may affect intellectual ability, which, together with attention span and behavior, is considered a higher function of the cerebral cortex. Studies in 7-year-old schoolchildren following prenatal exposure to moderate amounts of alcohol show a decrement of 7 points in IQ [108].

In addition, alcohol may affect the cerebellum. In the human cerebellum, Purkinje cell migration is completed and dendritic outgrowth begins around gestational week 26, extending to the third trimester of pregnancy. Consequently, a period of enhanced vulnerability of Purkinje

cells to binge alcohol exposure in humans would be predicted near the end of the second trimester and may extend over the first half of the third trimester [42]. Cerebellar developmental disorders and disproportionate reduction in the anterior cerebellar vermis have been identified by magnetic resonance imaging in children who were exposed prenatally to alcohol during each trimester of pregnancy [89]. Decreased cerebellar growth and decreased cranial-to-body growth in fetuses of alcohol-abusing mothers were also observed on fetal ultrasound performed in the 18th week of gestation [46]. If the mothers stopped drinking at the beginning of pregnancy, cerebellar growth was normal.

Mechanism of Alcohol Teratogenicity

Different mechanisms have been offered to explain the teratogenic effects of alcohol on the developing embryo. They stem from results of different experimental studies and include the following: (1) increased oxidative stress, (2) disturbed glucose, protein, lipid, and DNA metabolism, and (3) impaired neurogenesis and increased cellular apoptosis, especially of neural crest cells [16, 48, 59, 83].

Oxidative Stress

One process implicated is an alteration in the reduction-oxidation reaction status in the central nervous system. This hypothesis was supported by studies demonstrating that ethanol mediated changes in the production and/or activity of endogenous antioxidants in various organs, including the cerebellum and placenta [48, 59, 83].

Oxidative stress has been increasingly recognized as one of the mechanisms underlying ethanol toxicity. Ethanol can induce oxidative stress directly by formation of free radicals, which react with different cellular compounds, or indirectly by reducing intracellular antioxidant capacity, such as decreased glutathione peroxidase levels. The levels of oxidative stress markers were studied in placental villous tissue following 2 h of ethanol perfusion [59]. The results demonstrated a significant increase in oxidative stress, primarily involving the nitric oxide pathway in the trophoblast and DNA damage in the villous stromal cells. Alcohol-induced oxidative stress was also found to increase lipid peroxidation and damage protein and DNA.

Disturbed Prostaglandin Synthesis

Alcohol is known to affect prostaglandins, hence influencing fetal development and parturition. When mice were treated with aspirin (a prostaglandin synthesis inhibitor) prior to alcohol exposure, aspirin pretreatment reduced by 50% the alcohol-induced malformations in comparison with mice treated with aspirin after alcohol exposure [90].

Effects on Neurons

Several studies in rats and mice have shown that in utero exposure to alcohol caused structural defects in the hippocampus, cerebellum, and neural crest cells, with increased cell death [16, 48, 91].

In light of those different mechanisms of action, it is reasonable to presume that alcohol-induced teratogenicity is probably the result of injuries caused by several mechanisms [18].

Prevention and Treatment

Prevention

Since the diagnosis of fetal alcohol syndrome in young children is often difficult, the first challenge is identification and follow-up of children at risk. The second challenge is to prevent this disorder by preventing alcohol drinking. Unfortunately, there are only a few reports demonstrating success in reducing drinking of alcohol in pregnancy, and these reports even

declined from 1995 to 1999. The rate of binge drinking apparently remained stable, and chronic heavy drinking remained unchanged, suggesting that the education programs were not effective. Preventing alcohol abuse must, therefore, start with educational programs in schools and later during academic studies. Prevention programs need to be addressed primarily toward high-risk individuals and groups [53].

Treatment During Pregnancy

Assuming that oxidative stress is one of the major routes of ethanol-induced damage, it is reasonable to supplement with antioxidants in an effort to attenuate this damage. Antioxidants, such as vitamin C, vitamin E, folic acid, beta-carotene, and flavonoids can be supplemented by food, therefore reversing other nutritional deficits common among this population [18]. However, to our knowledge, only a few, if any, such programs exist.

Lactation

As alcohol is transferred to human milk, reaching levels similar to those in maternal serum, women drinking high amounts of alcohol should refrain from nursing their infants. Moreover, nursing infants suckle lower amounts of alcohol-containing milk. If nursing mothers drink only small-to-moderate amounts of alcohol, they should wait 2–3 h before nursing their infants [99].

Prevention and Treatment of Alcohol-Exposed Pregnant Animals

Alcohol-exposed C57BL/6 J mice were injected twice with 2.9 g/kg, 4 h apart, of EUK-134 (a potent synthetic superoxide dismutase plus catalase mimetic) on their 9th day of pregnancy. EUK-134 supplementation induced a notable reduction in cell death of the apical ectodermal ridge of the newly forming limb buds in ethanol-exposed embryos and reduced the forelimb malformations by about half (67.3–35.9%) [17].

Further support for the efficiency of antioxidants in attenuating the teratogenic effects of alcohol consumption throughout pregnancy comes from Wentzel et al. [116], who studied the effects of 5% vitamin E added to food on the outcome of ethanol-exposed rat pregnancies, showing a reduced rate of malformed or dead fetuses, but no change in the alcohol-induced reduction of body weight.

Animal Models for Alcohol-Induced Embryopathy

The growth spurt of the human brain is mainly during the third trimester of pregnancy, continuing into postnatal life. In rats, the brain growth spurt takes place entirely in the postnatal period. Therefore, rats must be exposed to alcohol during the equivalent periods of the brain development in humans, which is only in the early postnatal life [72]. The reduced Purkinje cell number demonstrated by Goodlett et al. [42] supports the contention that a significant amount of pathological loss of post-mitotic Purkinje cells occurs, yet it is dependent on the time of alcohol exposure. Hamre and West [45] found in newborn rats that postnatal days 4–6 were the most sensitive period for cerebellar Purkinje and granule cell loss following binge alcohol exposure [45].

Alcohol exposure of pregnant rats, equivalent to all three trimesters of human pregnancy, was shown to reduce cerebellar Purkinje cell numbers compared with the group that was exposed only in the third or first and second trimesters equivalent. In contrast, exposure to alcohol in the third trimester equivalent yielded a decrement in the olfactory bulb mitral cell numbers as compared with other timing groups (first or second trimesters) [45, 72].

Similar results were demonstrated by Ramadoss et al. [89] utilizing an ovine model to determine the critical period of vulnerability of fetal Purkinje cells following prenatal alcohol abuse, mimicking a human binge pattern during

the first and third trimesters of pregnancy. In these animals, unlike the rat model, the entire brain development occurs in utero. They found that the fetal cerebellar Purkinje cells are sensitive to alcohol throughout gestation [89]. The short- and long-term effects of ethanol were studied by Dembele et al. [23] in 7-day-old and 3-month-old rats following alcohol exposure. They found that prenatal ethanol exposure led to hypothalamic oxidative stress persisting into adult life and being significantly higher among the group of older rats, implying long-term damage of ethanol consumption during pregnancy [23].

In a meta-analysis of 22 studies using different strains of rats and one study on mice, Chotro et al. [19] found in 18/22 studies that prenatal exposure to ethanol increased ethanol intake among the offspring. The four remaining studies failed to show any effect whatsoever, a result interpreted and explained as the age of testing, 120 days and over [19]. Simpson et al. [103] have shown that alcohol exposure in rats decreased fetal body weight and bone length and delayed skeletal ossification. These effects persisted postnatally, leading to growth plate abnormalities and decreased skeletal maturity scores at 2–4 weeks of age. Fetal alcohol syndrome-like craniofacial malformations were demonstrated by Rogers et al. [94] following treatment of pregnant C57 BL/6 J mice with methanol on GD-7 during gastrulation. These malformations included anophtalmia, microphtalmia, holoprosencephaly (in varying degrees), and ear and jaw malformations [94]. The involvement of ethanol in cardiac anomalies was also studied in rats. Alcohol administration during pregnancy reduced cardiac mass and depressed function, evidently, due to microstructural changes of the myocytes, even when affected animals reached adulthood [64].

Conclusions

Maternal alcohol ingestion in pregnancy may have deleterious effects on the central nervous system and other organs of the developing embryo and fetus, depending on the dose and duration and on the developmental stage of the embryo at exposure. These embryotoxic effects of alcohol were observed in many animal species. It is, therefore, important to reduce alcohol drinking during pregnancy to a minimum. However, as of today, it is still difficult to define the minimal dose that will affect the developing embryo and the exact dose-response relationship.

Heroin-Dependent Mothers in Pregnancy

Pregnant mothers who are heroin dependent often belong to one of the following three categories: (1) women treated with opiates (i.e., methadone and in recent years also buprenorphine or naltrexone) and who carefully follow the treatment regimen, (2) women treated with opiates but who on occasion also use heroin or other “street drugs”, and (3) women addicted to heroin or other opiates and who hence use heroin, depending on availability. These women also have periods without drugs, a fact that may result in withdrawal symptoms in the mother and the fetus. In many cases, these mothers also use other psychotropic drugs such as benzodiazepines, phenothiazines, or barbiturates. Rarely, they may also use cocaine. Many of these women also smoke cigarettes and/or ingest different amounts of ethanol (alcohol). Moreover, they often do not seek medical care and suffer from medical neglect even during pregnancy. The addicted mothers are at increased risk for various acute and chronic serious infections, such as hepatitis B, hepatitis C, and HIV [82].

Relation Between Substance Abuse and Attention Deficit Hyperactivity Disorder

Several studies have found an association between attention deficit hyperactivity disorder and substance abuse. The prevalence of substance abuse is, therefore, much higher among

persons with attention deficit hyperactivity disorder, which was found to be common among opioid (heroin) abusers [117]. It is more difficult to treat opioid-dependent individuals with attention deficit hyperactivity disorder than it is to treat those without it [117]. Moreover, stimulant treatment of adolescents with attention deficit hyperactivity disorder can effectively reduce the rate of substance abuse [62, 117]. In addition, there seem to be specific differences between drug abusers with and without attention deficit hyperactivity disorder. Drug abusers with attention deficit hyperactivity disorder report an earlier start to use the substances; their substance abuse is more severe, and they may also need treatment for their attention deficit hyperactivity disorder to achieve abstinence. Similar types of genetic polymorphism to genes related to dopamine metabolism have been found among individuals with attention deficit hyperactivity disorder and those who are heroin dependent. For example, several investigators have shown in heroin-dependent individuals, or those with other substance abuse, a polymorphism to the catechol-O-methyl transferase gene, to the dopamine D4 receptor, or to the mu-opioid receptor gene [63, 102]. Similar gene polymorphism was also observed in individuals with attention deficit hyperactivity disorder.

Effects of Heroin and Opiates on the Fetus and Newborn

Although several reports of children with congenital anomalies born to heroin-dependent mothers have been published, there is no consistent pattern of anomalies and heroin is not considered to be a teratogenic agent and, in contrast to cocaine, is not considered to cause intrauterine fetal bleeding or abruptio placentae [27, 69, 70, 93, 107, 109, 112]. However, heroin (and opiate) use during pregnancy is associated with increased prematurity, low birth weight, small head circumference, and increased neonatal and perinatal mortality. Withdrawal symptoms may also develop in 40–80% of the newborns; a high incidence of sudden infant death syndrome during the first year of life was also described, although this is subject to some debate [57]. The use of methadone during pregnancy seems to be much safer for the developing embryo and fetus, with relatively few side effects, but withdrawal symptoms are frequent in the offspring of methadone-treated mothers to the same extent as with heroin.

Effects on Postnatal Development

Developmental delay, as well as behavioral and emotional problems, was often encountered in children born to drug-dependent mothers using heroin or methadone during pregnancy [27, 69, 70, 93, 107, 109, 112]. Some investigators have demonstrated an improvement of the developmental scores in these children with the advancement of age, but others have not. A high proportion of children suffered from inattention, hyperactivity, aggressiveness (attention deficit hyperactivity disorder), and lack of social inhibition [15, 28, 78–81, 100].

The environment in which a child is raised seems to be one of the most important factors that determine his or her developmental outcome. In children born small for their gestational age, the parental socioeconomic status influences the development, especially during the early years of life, with children in families from lower socioeconomic status failing to show developmental recovery. In fact, the relative impact of the clinical and biological factors of these children seems to be overshadowed by the "family" factors [114]. A similar phenomenon was repeatedly described in very low-birth-weight infants, where the major factors affecting cognitive development of the children were the home environment and their neurological status [12].

Studies describing the development of children born to heroin-dependent mothers often suffer from the fact that there may be many confounding factors influencing the results. They are often influenced by the fact that they suffer from

significant neglect. The outcome, therefore, is the result of interaction between in utero exposure to heroin and the postnatal environment. Hence, it is important, in evaluating the outcome of these children, to compare them with relevant controls [78–81].

We had the opportunity to study the developmental outcome of children born to heroin-dependent mothers who were either raised at home or sent for adoption (or foster homes) immediately after birth or at a very young age [78–81]. Since there is evidence of a correlation between socioeconomic status and cognitive functioning of children, and most adoptions are into middle or high socioeconomic status environments, adoption should have a positive effect on cognitive functioning [12, 13, 97]. Indeed, most adopted children score in the normal range on assessment of emotional development. This enabled us to "isolate" the prenatal effects of heroin on neurobehavioral development from the postnatal possible impact of environmental deprivation, which is so common in families of drug addicts.

Comparison groups were composed of children born to heroin-dependent fathers, children with severe environmental deprivation born to non-addicted parents of low socioeconomic status, and a group of normal, age-matched children. About 400 children from 6 months to 12 years of age were studied [78–81].

A lower birth weight and a shorter gestation were recorded in the children born to heroin-dependent mothers and, to a lesser degree, in the children born to heroin-dependent fathers when compared with the other groups. The head circumference and height at examination were lower in the children born to heroin-dependent mothers raised at home in comparison with controls. There was no difference in the weight at examination among the different groups of children.

Intellectual Developmental Outcome

We have found that preschool-aged children born to heroin-dependent fathers, thereby not being exposed in utero to heroin, function as poorly as children born to heroin-dependent mothers. However, paternal drug use in itself did not have a more deleterious effect on school-aged children than parental low socioeconomic status, and children born to non-addicted parents who suffered from environmental deprivation performed even less well than those born to heroin-dependent fathers or to mothers with non-addicted fathers. Finally, when preschool-aged children born to heroin-dependent mothers were adopted at a young age and hence raised in a "good" environment, their intellectual function was similar to that of control children. These results show that in utero exposure to heroin per se does not affect the cognitive ability of preschool-aged children, and most harm to those children is caused by their "poor postnatal environment" because the mother is heroin addict. However, there was a high rate of children with behavioral problems among those born to heroin-dependent mothers raised at home [79].

We then studied similar groups of children aged 6–12 years who attended regular school [80, 81]. At that age, the children born to heroin-dependent mothers had a very high rate (54%) of inattention and hyperactivity (attention deficit hyperactivity disorder). The rate of attention deficit hyperactivity disorder was reduced to 24% in the heroin-exposed adopted children while 24% of those born to drug-dependent fathers (and not exposed to heroin) had attention deficit hyperactivity disorder. It is important to add that 21% of the children with environmental deprivation had attention deficit hyperactivity disorder, while none of the control children had it, as evidenced from the abbreviated Conner's Questionnaire. We also studied their arithmetic and reading abilities and found that it was poor in the children born to heroin-dependent fathers, in those born to heroin-dependent mothers when raised at home, and in the children with environmental deprivation. However, the adopted children at that age had slightly lower cognitive abilities compared with controls, though the difference was not statistically significant. Their arithmetic and reading abilities were also lower.

As it is possible that the high incidence of inattention, hyperactivity, and behavioral disorders found among the children in our study is related to a high incidence of attention deficit hyperactivity disorder among their parents, who were, therefore, prone to substance abuse more than the general population, we used the Wender-Utah questionnaires to assess for maternal attention deficit hyperactivity disorder. We indeed found a very high rate of attention deficit hyperactivity disorder among drug-dependent mothers. However, there was no correlation with the rate of attention deficit hyperactivity disorder among their children, implying that in utero heroin exposure is responsible, at least partially, for the high rate of attention deficit hyperactivity disorder among the heroin-exposed children, whether raised at home or adopted. This is probably attributed to both genetic and environmental factors. This is in line with other studies showing a high rate of attention deficit hyperactivity disorder among the offspring of heroin-dependent parents [62, 117].

We also studied the development of these groups of children at 12–17 years of age. The findings were similar to those observed in children at school age, with a high rate of attention deficit hyperactivity disorder and learning and behavioral problems in the heroin-exposed children. Moreover, adolescents born to heroin-dependent mothers raised at home performed less well than adolescents with environmental deprivation, implying that heroin might have affected some of the higher cortical functions that are related to learning abilities and attention span. In that context, we should mention that other investigators [98, 106] have found that exposure to multiple risk factors is associated with poor developmental outcomes. Therefore, in utero heroin exposure and postnatal poor environment may have a multiple and long-lasting deleterious effect.

Our results, showing the benefit of a good postnatal environment on the intellectual and behavioral outcome of children born to heroin-dependent mothers, emphasize the importance of social and educational services for improving the outcome of children of drug-dependent parents, as well as of children from low socioeconomic status families.

Since in many cases where the mother is drug dependent it is expected that the father will be addicted as well, it is important to mention that children born to drug-dependent fathers were also shown to be at risk for developmental problems. Sowder and Burt [106] found that children born to heroin-dependent fathers were at high risk for early school behavioral and learning problems. Similarly, children born to drug-free parents of a similar underprivileged environment and low socioeconomic status were also at risk for early school problems, but to a lesser extent. These results are similar to our findings in school-aged children. Herjanic et al. [50] found slow mental development in 44% of children born to heroin-dependent fathers. By age 12, conduct disorders and behavioral problems were common among these children. Behavioral problems, attention deficit disorder, and attention deficit hyperactivity disorder were also described in the offspring of cocaine-using mothers [117]. Thus, whenever both parents are addicted, their children seem to be at higher risk than when only the mother is addicted.

Treatment of the Pregnant Mother

The most common approach for treating opiate addicts, whenever weaning is unsuccessful, is methadone treatment [14, 30]. Since it is not accepted to wean pregnant women from heroin, methadone is the preferred treatment in pregnancy. The daily doses vary and range from 10–20 mg up to 100 mg or even more, according to the individual needs. Pregnancy outcome in women who are on strict methadone treatment throughout the entire pregnancy and attend antenatal care seems to be good, with very little long-term effects on the infants except neonatal abstinence symptoms that are common and necessitate transfer to neonatal special care units [14, 81]. However, there seems to be no correlation between the presence of withdrawal

symptoms and developmental outcome even in children born to heroin-dependent mothers [79].

In the last few years, there have been two additional successful approaches to treatment, using either buprenorphine or naltrexone (an opiate antagonist) in low, intermediate, or high doses. In some cases, buprenorphine was administered through slow-release implanted devices [52]. Both of these methods are quite successful in maintaining normal pregnancy outcomes, but they do not seem to be superior to methadone in terms of maternal retention of treatment [74]. However, it is possible that these new modes of therapy are superior to the traditional methadone treatment for the fetus, as prematurity, fetal weight at birth, and other pregnancy complications were lower than with methadone maintenance, and not different from the control population [22].

Lactation

As heroin and other opiates are transferred to human milk, reaching relatively high levels, women using heroin or other opiates, including methadone, might be advised to refrain from nursing their infants, depending on the dose [99]. This is because of the depressive effects of large amounts of opiates on the central nervous system, including the possibility of causing respiratory depression in the suckling infants.

Animal Models for Heroin- and Opiate-Induced Fetal Damage

There are not too many studies on the effects of heroin on pregnancy in animals. This stems from the fact that in the absence of structural anomalies following exposure to heroin and opiates in experimental animals, it is difficult to use animal models that mimic the behavioral changes observed in men [53]. However, several studies were carried out on pregnant mice and rats, demonstrating functional and pathological changes in various parts of the brain in the offspring [47, 51, 57, 105]. Such studies have used in pregnant rats osmotic mini-pumps with opiates or opiate antagonists-buprenorphine, naloxone, and methadone-demonstrating changes in mu-opioid receptor G protein in the offspring, with male offspring showing more sensitivity than females [51]. Slotkin et al. [105] found in mice that administration of heroin during pregnancy causes changes in the hippocampal cholinergic neurons of the offspring, as it induced a deficit in muscarinic cholinergic receptor-induced translocation of protein kinase C gamma. These authors also demonstrated changes in adenylyl cyclase, the latter changes also occurring in the cerebellum where there are only few cholinergic neurons. Changes in signaling proteins distal to neurotransmitter receptors were proposed by the authors as a general mechanism related to several neuroteratogens [105]. Whether these changes are relevant to the human situation is currently unknown.

Of special interest is the fact that grafting of neural progenitor cells into the hippocampus of these mice offspring at adulthood reversed the behavioral deficits observed in non-treated, heroin-exposed mice [58].

Conclusions

Heroin exposure in utero seems to have little effect on the intellectual ability of young children if they are raised in a supportive environment. However, it induces a high rate of attention deficit hyperactivity disorder, which seems to be attributed to the direct effect of heroin on the fetal brain as well as to genetic and environmental factors. We should, therefore, try to improve the home environment of the children born to heroin-dependent mothers and thus minimize the damaging effects of maternal drug addiction. These results emphasize the importance of availability of social and educational services to improve the outcome of children of drug-dependent parents as well as of children from low socioeconomic status families.

Mothers Using Cannabis (Marijuana, Hashish) During Pregnancy

Cannabis

The cannabis plant has been cultivated for centuries and its leaves used as a source of recreational drugs. The dried leaves and flowering parts of the cannabis plant are known in different parts of the world by a variety of names, including Indian hemp and marijuana. The extract of the plant is termed hashish. Although many active compounds with various effects are found in the cannabis plants, the primary active agent is delta-9-tetrahydrocannabinol. This agent has been used recently for increasing appetite and controlling nausea. The main recreational use of cannabis is by smoking [33–38, 47]. The use of cannabis in pregnancy is quite common; in meconium analyses from about 1,000 newborns in Barcelona, Spain, traces of cannabis were found in 5.3% of the newborns. By this method it is possible to detect cannabis use only starting from the second trimester of pregnancy; hence, the true percentage of use is apparently even higher [71].

Delta-9-tetrahydrocannabinol is known to cross the placenta and may, therefore, affect the developing fetus [11]. Women who smoked various numbers of marijuana cigarettes during pregnancy may have impaired fetal growth and hence lower-than-normal birth weight with differences from controls of about 100 g. A continuous use of marijuana during pregnancy is also associated with lower gestational age at birth of about one week. Both phenomena seem to be dose related. There seems to be no increase in the rate of major congenital anomalies associated with the smoking of even large numbers of marijuana cigarettes. As most women who smoke marijuana also smoke cigarettes, it is important to control in such studies for cigarette smoking. Indeed, a meta-analysis of reports available through 1996 did not find a significant association between maternal cannabis use and birth weight when the possible effects of cigarette smoking were controlled [25]. There is no effect of marijuana use during pregnancy on subsequent childhood growth or pubertal development [37, 38].

Marijuana smoking is known to increase the content of carbon monoxide in the blood much more than regular cigarette smoking [99]. Hence, one of the suggested mechanisms for the possible negative effect of marijuana on fetal growth focuses on the relatively large increases in carboxyhemoglobin generated by smoking marijuana [118]. This effect reduces the oxygen-carrying capacity of the maternal blood, impairs the release of oxygen from hemoglobin in the tissues, and indirectly impairs fetal oxygenation. Placental blood flow also may be reduced by the increase in maternal heart rate and blood pressure that may accompany marijuana smoking. Delta-9-tetrahydrocannabinol may also, after its trans-placental passage, decrease fetal heart rate.

In several case control studies, marijuana smoking was associated with an increased rate of gastroschisis and ventricular septal defect but not with neural tube defects [110]. There is no pattern of anomalies associated with cannabis use. We should remember that women using cannabis also often use alcohol and smoke cigarettes.

Neonatal Effects

Increased tremulousness, altered visual response to light stimulus, withdrawal-like crying, and alteration in neonatal sleep pattern have been reported in newborn infants of marijuana-smoking mothers [20]. As with other signs of abstinence following maternal use of psychotropic agents, these findings usually diminish within several weeks.

Postnatal Developmental Effects

The studies on long-term developmental follow-up of children born to mothers using cannabis during pregnancy are mostly negative, with no long-term effects of marijuana on intellectual

abilities. In a series of studies performed by Fried et al., prenatally marijuana-exposed children were followed up until school age [34–37]. The children antenatally exposed to marijuana had, up to 4 years of age, a slight delay on cognitive testing due to some impairment in brain executive functions, especially verbal and memory abilities. It is interesting to note that similar findings were reported by these authors following cigarette smoking in pregnancy but not after exposure to low amounts of alcohol [35]. While these children were re-examined at 60 and 72 months of age, the language delay of the prenatally marijuana-exposed children disappeared, while in the children prenatally exposed to cigarette smoke it did not [36].

Lactation

Delta-9-tetrahydrocannabinol and its metabolites are concentrated in breast milk and absorbed by the nursing baby [85]. Although specific adverse effects have not been identified, one author recommends that breastfeeding be discontinued if marijuana is being used by the mother [18, 99]. The American Academy of Pediatrics lists marijuana among drugs of abuse that should not be ingested by nursing mothers.

Animal Studies

Several animal studies have shown teratogenic effects of marijuana, producing limb, digit, and neural tube closure defects in rats, while others were negative [40]. Pregnant hamsters injected with marijuana extract or resin had an increased incidence of malformed offspring, and high doses of a marijuana extract induced neural tube closure defects and phocomelia in rabbits [39].

Animal studies with delta-9-tetrahydrocannabinol itself have produced similar conflicting results. No teratogenic effects were noted in several studies in rats, hamsters, or chimpanzees [43].

Mothers Using Cocaine in Pregnancy

Historical Background

Cocaine is an alkaloid extracted from the leaves of the plant Erythroxylan coca. It was first isolated by Friedrich Gaedcke, a German chemist, in 1855 and has a long history of medical and recreational use. Cocaine causes transient euphoria through the well-documented biochemical stimulation of the dopaminergic system, apparently by inhibiting the dopamine transporters; however, the mechanism of the lasting and inheritable effects of cocaine is known only partially [3, 87].

For thousands of years, coca has been used in South America for special medical purposes and as a general stimulant, and remains one of the commonly used medicines in different areas of Peru and Bolivia. Cocaine was the first effective local anesthetic, and when its danger became obvious and substitutes were available, especially in the 1930s, its medical use declined [44]. The use of coca in pre-Hispanic America is confirmed by archeological and artistic sources (sculptures, ceramics, fabrics, and pictures). Diffusion of these pieces of evidence, historical and geographical, seems to point to the fact that coca was a strong, central element in the union of the different cultures of the continent [29].

The Aymara Indians of the Andes Mountains were the first to consume coca, which was reserved in the beginning to the priests and princes in religious ceremonies, extending later to the common people. Coca and cocaine were used once more in the nineteenth century. In 1870, Angelo Mariani brought to the market a kind of wine based on coca extract, with a great success. A competitive drink was produced by Pemberton in the USA, named “Vin Francais Cola”.

Cocaine was used medically for the treatment of asthma and hay fever, was officially agreed upon by the famous scientific societies in America, and was finally abandoned [1].

In 1559, the Italian neurologist Mantegazza was the first to try out the remedy on himself, advocating the use of coca as an internal medicine. In psychiatry, cocaine was used in patients with melancholia, exhaustion (physical and psychic), cachexia, and later as a substitution therapy for morphine addicts. Cocaine was first used in 1884 as a local anesthetic agent, first in eye surgery and later applied in dentistry and minor surgery. Among other indications, cocaine was aimed to treat asthma, pregnancy vomiting, and cramping pains [111]. Nowadays, cocaine is mainly used for recreational purposes. However, chronic users may develop addiction, dependency, and tolerance to cocaine.

Effects of Cocaine on the Embryo and Fetus

Cocaine is a small molecule, largely un-ionized at physiological pH; therefore, it readily crosses the placental barrier, and, because of a lower pH in the fetal blood, it flows readily from the maternal into the fetal blood. Due to low levels of esterases in the fetus, it is only slowly metabolized. By causing vasoconstriction, cocaine can induce fetal brain ischemia. As described in several studies, cocaine abuse during pregnancy was able to induce premature birth, lower birth weight, more respiratory distress, bowel and cerebral infarctions, reduced head circumference, and increased risk of seizures [60].

From the mid 1980s into the early 1990s, numerous reports raised concerns referring to the possible teratogenic effects of cocaine abuse in pregnancy on the embryo and fetus. Most observations included congenital anomalies, especially of the central nervous system, limbs, urogenital and gastrointestinal systems, growth retardation, microcephaly, central nervous system infarction, seizures, cortical atrophy and cysts, intraventricular hemorrhage, and sudden infant death.

More recent studies, however, did not find any clear association between prenatal cocaine exposure and an increased rate of major congenital anomalies. Behnke et al. [7] studied the rate of major anomalies in 272 offspring of 154 mothers using cocaine or crack during pregnancy in comparison with 154 control infants and found no difference between the groups in the rate of congenital anomalies. However, they found decreased birth weight, birth length, and head circumference among the cocaine-exposed infants and an increased rate of prematurity. Similarly, Bauer et al. [5] investigated the association between prenatal exposure to cocaine and the medical condition of the newborn infants. The observations demonstrated a decrease in birth weight (536 g), body length (2.6 cm), and head circumference (1.5 cm) among cocaine-exposed newborns, who were also born about 1.2 weeks earlier. Although relatively frequent among the exposed children, the central and autonomic nervous system symptoms attributed to cocaine effects were usually transient. These authors, too, did not find an increased rate of congenital malformations among the cocaine-exposed infants [5]. Thus, if an increase in major anomalies exists, it is small and without any specific pattern of anomalies. There may be, however, an increase in prenatal cerebral hemorrhages and infarctions as well as placental injuries.

Developmental Outcome

To assess the impact of cocaine exposure of the fetus on neonatal auditory information processing ability, Potter et al. [88] used habituation and recovery of the head-turning toward an auditory stimulus (across the 3 phases of the procedure). Their results exhibited a response pattern that is consistent with a slower speed of auditory information processing, implying that cocaine is a neuroteratogenic agent during the newborn period. Similarly, in a prospective longitudinal study of 154 mothers using cocaine during pregnancy, Eyler et al. [26] observed in their neonates, while using blinded developmental examinations, fewer alert periods and less

alert responsiveness, implying a reduced state of regulation, especially when cocaine was used in the third trimester of pregnancy.

However, studies on the later postnatal cognitive development of children prenatally exposed to cocaine report on contradictory results, and the majority of studies did not find a deleterious effect of cocaine alone on the intellectual abilities of the children. Assessing the possibility of an independent link between the levels of prenatal cocaine exposure and developmental test scores (after controlling for the confounding variables alcohol, cigarettes, and marijuana), Frank et al. [31] failed to find any significant interaction between prenatal exposure to cocaine or cigarettes on the Bayley Scales of Infant Development. In a later study, when analyzing cocaine exposure in pregnancy and IQ scores, they failed to find a distinct negative effect of cocaine on global or specific cognitive competence in preschool-aged children [32].

Singer et al. [104] studied the cognitive abilities at 4 years of age of 190 children prenatally exposed to cocaine in comparison with 186 non-exposed children who demonstrated environmental deprivation. There was no difference between the groups, and both had lower-than-average full-scale IQ scores. However, differences between the groups were found in several subscales of the Wechsler Preschool and Primary Scale of Intelligence-Revised (the psychometric test used by the investigators). These were in visual spatial skills, general knowledge, and arithmetic skills, where the cocaine-exposed children performed less well in comparison with the non-exposed. The results of this study, which were very similar to our findings in prenatally heroin-exposed children [79, 80], clearly demonstrate the importance of the environment for early cognitive development.

One important additional negative effect of cocaine exposure was implied by Noland et al. [76], showing in school-aged children a higher rate of commission errors on the Continuous Performance Task and suggesting that cocaine-exposed children had difficulty maintaining a good attention span. These results, again, are similar to those observed by us in children prenatally exposed to heroin [80].

Effects of Gender

Beeghly et al. [6] found that in utero cocaine-exposed girls scored lower on language-related tasks than boys at 6 years but not 9 years of age. Bendersky et al. [8] found that in utero cocaine-exposed 5-year-old girls were less likely to engage in aggressive behavior than similarly exposed boys. The results suggest that gender may be a risk factor among children who have been prenatally exposed to cocaine for some cognitive developmental processes and a protective factor for problematic social behavior.

Mechanisms of Action

Despite two decades of research, the mechanism underlying the cocaine-induced brain damage is still under debate [49]. Speculation on the mechanism of action of cocaine runs basically in two directions: cocaine-induced transient hypertension and vasoconstriction that damages the placenta, inducing placental infarctions with partial or complete abruption [9, 113], or increased oxidative stress [83, 119]. Since the first mechanism is now under debate, we will expand mainly on the second mechanism.

The mechanism of increased oxidative stress induced by cocaine was apparently first proposed by Zimmerman et al. [119]. However, in their study, the addition of antioxidants to the cocaine-treated mice did not prevent the occurrence of neural tube defects, possibly casting some doubt on this proposed mechanism.

Other more recent studies, however, suggest that oxidative stress is an important mechanism of cocaine teratogenesis. The offspring of cocaine-injected, pregnant rats showed low levels of nitric oxide in the brain on the first two postnatal days; these returned to normal on the fourth day. Thiobarbituric acid-reactive species

content in the hippocampus of cocaine-injected rats was, however, increased during days 1–4, showing an oxidative stress-related increase in lipid peroxidation. Prenatal cocaine-injected rats demonstrated, at day 25, significant learning impairment in the water-maze test as compared with non-treated rats, and had increased thiobarbituric acid-reactive species in their brain. This demonstrates that learning in the treated rats causes higher oxidative stress in the brain, possibly related to their impaired learning ability [4]. It can, therefore, be summarized that oxidative stress is playing an important and significant role in cocaine-induced disruption of the central nervous system.

To understand further whether cocaine-induced oxidative stress also causes apoptosis, Poon et al. [87] monitored the oxidative stress and apoptotic effects in human neuronal progenitor cells (Clonexpress) exposed to cocaine during culture. The results showed a significant increase in oxidative stress at 48 h, followed by cell death at 72 h. Thus, whenever the antioxidant capacity is compromised (e.g., in fetuses or in old age), the cocaine-induced damage may be higher.

Lipton et al. [67, 68] investigated whether cocaine-induced constriction of the umbilical/placental vessels that induce significant changes in uterine and placental blood flow also causes oxidative stress. They found that following a single prenatal injection of cocaine in pregnant rats, there was a reduction in the levels of reduced glutathione and of reduced alpha-tocopherol in the fetal brains. In addition, there was an elevation of the oxidized form of alpha-tocopherol. As to oxidized glutathione, a rise was found in the fetuses at the ovarian extreme, where the greatest degree of vasoconstriction was demonstrated, and a decrease in the fetuses at the cervical extreme, where cocaine-induced vasoconstriction is the least. The authors speculate that cocaine-induced vasoconstriction causes increased oxidative stress, thus tying both mechanisms of action. They also show the important role of oxidative stress in the teratogenic mechanism [68].

Prevention and Treatment

Home Intervention Programs for Children Prenatally Exposed to Cocaine

Regardless of drug exposure, children living in poverty are at risk of cognitive delays. Children from low-income families exhibit intellectual declines as toddlers and preschoolers. Indeed, home intervention programs or adoption at a young age yielded higher cognitive scores among drug-exposed infants [79, 80]. Schuler et al. [101] studied the effect of home intervention programs on the infants' developmental outcome among a group of inner-city residents with low socio-economic status. They found that home intervention led to higher scores on the Bayley Scales of Infant Development, mainly of the Mental Developmental Index. These developmental scores, however, declined during the first postnatal 18 months [101].

To determine the relation between prenatal cocaine exposure and children's standardized cognitive tests at age 4, Frank et al. [32] assessed 91 children, using the Wechsler Preschool and Primary Scale of Intelligence-Revised or the Wechsler Intelligence Scale for Children, 3rd ed. Unlike other widespread assumptions relating to the disabling effects of prenatal cocaine exposure on the cognitive abilities of preschool children, Frank et al. strengthened other studies' results, claiming that exposure during pregnancy does not negatively affect the global or specific cognitive functions [32]. They also suggested that children known as being prenatally exposed to cocaine benefit from the early intervention and preschool program.

Intervention Programs for the Mothers

Intervention for cocaine-using mothers during pregnancy should use programs similar to those used in non-pregnant women. The dropout rate from such programs was significantly lower than in non-pregnant women, implying-as was also

found for the treatment of pregnant women dependent on other drugs-that pregnancy may be a good time for prevention of further use of substances that may cause addiction [115].

Lactation

As cocaine and metabolites are transferred to human milk, reaching relatively high levels, women using cocaine should be advised to refrain from nursing their infants, depending on the dose. However, if there is only occasional use, then refraining from breastfeeding for about 24 h following intake is sufficient [99].

Studies in Animals

One of cocaine's important actions is to block the reuptake of dopamine, serotonin, and norepinephrine. In a rat model prenatally exposed to cocaine, Keller and Keller [60] examined the extracellular fluid levels of dopamine, serotonin, and metabolites and found changes in their levels compared with controls, together with long-term behavioral abnormalities. These changes subsided with the advancing age of the rats, similar to the behavioral changes that are observed in the offspring of cocaine-using mothers.

Investigating in utero cocaine-exposed rhesus monkey offspring, Paul et al. [84] found that two-thirds of controls and only a quarter of exposed subjects demonstrated clear evidence of reversal learning (i.e., the ability to adapt to the new environmental contingencies in a seemingly simple way). Zimmerman et al. [119] demonstrated that in mice, cocaine caused vasodilation in the fetal vasculature and an increased rate of neural tube defects, hypoplastic prosencephalon, and microcephaly. The administration of the antioxidants 2-oxothiazolidine-4-carboxylate and a-phenyl-N-t-butyl significantly reduced cocaine-induced vasodilation; however, it did not prevent neural tube defects [119]. Cocaine's vasoconstrictive property on the uterine and placental vasculature is enabled by its potential to increase catecholamine levels (especially norepinephrine) via inhibition of its reuptake. However, He and Lidow [49] found that the cocaine-induced vasoconstriction of the utero-umbilical and fetal brain vessels in the rhesus monkey does not seem to be the main cause of the cerebral damage, and that cocaine damages the fetal brain by a different mechanism. They examined the possible correlation between high levels of the cocaine metabolite benzoylecgonine, a potent vasoconstrictor, and cocaine-induced abnormal brain lamination and found that benzoylecgonine did not induce any brain damage while cocaine did.

Lipton et al. [68] found that cocaine can differentially reduce dopamine and glial-derived neurotrophic factor levels depending upon the fetus' location in the uterus. The extent of dopamine depletion was in correlation with the extent of cocaine-induced restriction of uterine blood flow, as indicated by additional studies [68].

A survey of studies in non-human primates indicates that prenatal cocaine exposure interferes with structural and biochemical development of the brain, consequently resulting in postnatal and adulthood behavioral deficits. Differences in the outcome between various models of prenatal cocaine exposure are likely to reflect the route, dose, gestational period, and daily pattern of cocaine use. This fact is most relevant to studies in human populations with cocaine abuse [66].

Introduction

Forensic psychiatry is the branch of psychiatry that addresses the intersection of psychiatry and the law. In the practice of medicine, psychiatry, and a variety of other clinical professions, legal or forensic issues are commonly encountered. Confidentiality, for instance, is a key legal and ethical concern in general medical and psychiatric practice but is subject to special treatment in certain addiction treatment settings, which may result in the federal confidentiality statute coming into play. It is important in the clinical practice of addiction medicine and psychiatry to be aware than this statute supersedes state confidentiality laws, broadly defines the confidential doctor/agency–patient/client relationship, and outlines sanctions for violating the statute, which could include loss of federal funding or special tax status for the agency in question. This chapter will address the range of forensic issues that are relevant for practicing physicians, psychiatrists, and addiction specialists and may be of interest to a wide variety of health professionals and scientists. Working in forensic environments is, essentially, practicing forensic medicine. For instance, in the above example, managing the special confidentiality requirements for certain patients or clients suffering from addictive illness requires forensic expertise and knowledge of the federal confidentiality statute and its implications. Further, physicians frequently venture into the forensic realm when they are asked to give opinions about disability, whether a patient can give informed

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_72,

consent for treatment, or whether an intoxicated individual could form the specific intent to commit a crime. Assessing fitness for duty in a physician with alcoholism or comorbid addiction and mood disorder and addressing the relevant regulatory (licensing board) issues, opining about the meaning of a positive drug screen in a medical review officer role, and treating addiction in correctional settings are other examples of the enormous scope of forensic situations in psychiatric and other medical practice. Needless to say, working with attorneys in many contexts and testifying in a court of law are forensic activities commonly encountered in medicine.

Because forensic issues flow from the law, not medicine, many doctors are uncomfortable with the concepts and demands of working at the clinical/forensic intersection. Physicians frequently see forensic issues as intrusive in their work rather than protective of their patients, and many do their best to avoid the courtroom. The authors encourage the reader to cultivate interest in the dynamic body of statutes, courts, and cases that constitute the law; familiarity will breed comfort. From the opposite vantage point, while the law has long addressed problems of mental illness, especially the law regarding criminal responsibility, it has been slow to recognize addictive illness, which until relatively recently was seen as moral weakness or depravity. At least some of this problem has to do with the voluntary element in drug use [8]. Courts and lawmakers are obviously not immune to biased societal attitudes toward those who suffer from addictive disease; nor are they educated about the nature of such illness.

In this chapter, we have chosen to organize the material according to the forensic context, including civil, criminal, and regulatory environments, and to first review some of the essential differences between the style of thinking and nature of practice in forensic contexts compared with the usual clinical thinking in medical practice. The authors also have chosen to include new and emerging areas of forensic interest, in part to underscore the dynamic nature of this field.

The Forensic Evaluation Process

There are two essential differences in performing any evaluation in a forensic context when compared with performing a clinical examination, be it determining whether someone is disabled, competent to make a will, or criminally responsible. Because the findings and opinions in forensic evaluations are meant to be communicated to another party, confidentiality is limited, though obtaining a release of information for that party is often advisable, depending on the context. Also, the purpose of the examination is to evaluate and reach conclusions regarding the referral questions, not to provide medical care to the examinee. It is not a doctor–patient relationship in the usual sense. Because an examinee often expects both help and at least a measure of confidentiality, both of these differences should be communicated to the examinee at the outset. Even after such advisement, examinees often lapse into looking upon the physician as a helper, so the physician should be alert to signs of this and be prepared to remind the examinee about the context. It is equally important for examiners to be watchful for signs that they want to help the examinee. Examiners also should carefully consider their feelings about and reactions to the examinee, which if left unattended could interfere with being neutral and objective. If the examiner develops doubts as to whether the examinee is competent to understand or agree to the conditions of examination, the report should reflect how this was assessed and the conclusions reached.

There are other technical differences between forensic evaluations and clinical evaluations. Because of the need to answer specific and complex questions, forensic evaluations often take more time than clinical evaluations and may require several interviews. Consider an examination in which a psychiatrist is asked to opine whether, due to hallucinogen intoxication, a criminal defendant was able to form the specific intent to commit a capital crime. Reviewing all relevant documents such as police investigative records and medical records will be an

essential task. Incomplete review of documents will undermine the authority of a forensic evaluation. Collateral information is frequently necessary, often from several sources. In assessing whether or not a physician is alcohol dependent, speaking to his or her spouse, employer, and office and hospital staff will be helpful. Forensic reports should be quite detailed, specifically addressing the referral questions in the context of a complete report, including all the data from the examination. This requires that the referral questions be accurately understood by the examiner. This in turn necessitates spending as much time as necessary communicating with the referring party—a court, lawyer, regulatory board, or employer—and making sure that all relevant documents are in the examiner's possession.

Medical and Legal Terminology and Reports of Evaluation

Encountering words that sound like clinical terms but are in fact legal terms is a common situation in forensic work. Other words may be "terms of art" within the legal system and cannot be defined. The forensic examiner must learn about and consider the legal framework. For instance, in Colorado, the Medical Practices Act, the law that regulates medical practice, lists "habitual intemperance" as unprofessional behavior for a physician [41]. "Habitual intemperance", a 19th-century expression used in many laws created in that era, is not in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision [3]. Is it the equivalent of substance dependence? Does it include substance abuse? The forensic examiner cannot actually answer these questions without a legal definition. Asking for such a definition from the lawyers involved in the case is always a good step; the evaluator would be told, in this case, that it is a "term of art". The examining physician may be unable to say whether their clinical diagnosis meets the standard for this term. The answer may be left to a fact finder, which in the legal system is a judge or jury. The term "disability" appears in the same Colorado statute referenced above. The state may act against a license on the basis that the physician has a "disability". Again, this term is legal rather than medical in its meaning, referring to a condition that would meet the statutory requirement for unprofessional conduct. Now the examiner has the complex task of sorting out whether habitual intemperance is a disability, whether a *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision—defined substance use disorder is a disability, and the relationship between clinical disability and disability under the statute.

In writing reports, physicians should discuss the relationship of a diagnosis or other clinical term to the legal terms used under that statute, regulation, bylaw, or definition in question. For instance, in the above example, if a substance-related disorder is found, the report should review how the diagnosis was reached, sort out the relationship of the clinical and legal terms, and acknowledge any outside sources of information used to understand the legal terms, in the process of answering the referral questions.

Working with Attorneys; Testimony

Due to space limitations, the authors give only a brief introduction to these topics. The reader is referred to forensic psychiatry texts or other works for this information [63, 68]. In these areas, the need for neutrality and objectivity, necessary in all forensic work, is paramount. The "hired gun", a medical evaluator who will testify favorably for any side, regardless of the facts, is anathema to the medical profession. The American Academy of Psychiatry and the Law has published ethics guidelines [1]; these should be reviewed carefully by physicians anticipating these activities. Remaining neutral may be harder than one imagines because of doctors' natural wish to be helpful to whoever is asking for their opinion. One must keep in mind that it is actually helpful for an attorney to hear an opinion unfavorable about his or her client

or case. In court, even the appearance of advocacy or subjectivity is deadly to the credibility of the medical expert witness. Ultimately, credibility is the only currency of the medical expert. A corollary of this principle is that the attorney representing the opposing side in an adversarial proceeding has a duty to attack the credibility as well as the opinions of the medical expert. While it is not easy to remain neutral and objective in the face of such attack, it is easier if one conceptualizes it as part of the job.

Psychiatrists and other physicians, as opposed to forensic psychiatrists, may testify only occasionally, so that lessons learned once may be forgotten before the next occasion arises. The authors recommend that physicians consult their forensic colleagues, forensic texts, and the attorneys involved in the case for help in orienting or re-orienting themselves to the demands of testimony, be it in court or in deposition.

Compulsion and Responsibility

In all of the legal environments discussed below, the psychiatrist may be asked to discuss the voluntary element involved in all substance use and what it means and implies about the character, reliability, credibility, and responsibility of the addicted individual. Kalivas and Volkow have written that understanding addiction must involve understanding why addicted persons continue to be vulnerable to relapse even after extended abstinence and understanding their difficulty in curbing drug-seeking behavior even in the face of serious adverse consequences [32]. The authors will not review here the recent advances in understanding of the neurobiology of addiction, as this subject is covered elsewhere in this book. Generally, as Kalivas and Volkow have argued, the brain circuitry involved in motivation is reorganized by repeated use of addictive compounds such that addicted individuals find that drugs of abuse become more salient than "natural" reinforcers such as food and sex. Thus, loss of pleasure from natural rewards accompanies loss control over the drug and drug seeking, and evolves from the high of initial drug use and the later blurring of recreational and addictive patterns of use. Kalivas and Volkow concluded, "Addiction can be viewed as a pathology in how importance is attached to stimuli that predict drug availability and how the brain regulates (chooses) behavioral output in response to those stimuli. Thus, end-state addiction is characterized by the excessive motivational importance of drug seeking." Hyman [30] proposed that addiction involves "pathological usurpation" or hijacking of the neurobiological substrates for learning and memory, which under ordinary conditions shape essential survival behaviors that arise in response to natural rewards and their cues. It is clear that addictive illness involves and produces a profound alteration in the nature of choice and decision-making about drug seeking, drug using, and the consequences of addictive drug use.

Bonnie [8] discussed issues concerning an addict's choice about using drugs. He rightly pointed out that one can resist a compulsion and that having a hard choice and having no choice are profoundly different conditions. While the "voluntariness" of drug-seeking behavior may be altered by addiction due to the neurobiologic vulnerabilities of addicts, drug use is not involuntary. Limited volition and lack of volition are fundamentally different. Bonnie explored issues of the addict's responsibility for becoming addicted, for behaviors caused by addiction, and for sustaining sobriety after diagnosis and treatment. In his analysis, staying sober is the clearest responsibility. Whether or not his view of responsibility for relapse comports with the science of how the brain is enduringly altered by addictive experience, the fact that the realistic threat of adverse consequences of relapse improves relapse rates underscores pragmatically the concept of responsible choice.

The addiction psychiatrist who is interested in the legal framework for considering these issues should be familiar with landmark judicial decisions in landmark cases. The United States Supreme Court has ruled in three such cases. *Robinson v. California* [62] held that it was unconstitutional to convict a person for being an

addict because to do so would be to punish him for having a disease, in violation of the Eighth Amendment, which prohibits cruel and unusual punishment. But what about behavior caused by or related to addictive illness? Is that punishable? In *Powell v. Texas* [59], the high court ruled that an extension or broad reading of *Robinson* would not hold. Powell was convicted of public drunkenness, and argued that this was a symptom of a disease, alcoholism, and that he was powerless to control it. The Court ruled that Powell could not be found criminally responsible for being an alcoholic but could be found responsible for being drunk in public. The majority of the justices decided that although Powell was an alcoholic, he did not experience an "irresistible compulsion" that he was "utterly unable to control". Bonnie wrote that the justices in *Powell* were cautious about accepting that conditions that impair volition (such as kleptomania and pyromania) could excuse criminal conduct, and were reluctant to constitutionalize addiction as a justification for such behavior; to do so would "unsettle the law of criminal responsibility". Ironically, this case represented Powell's 100th conviction for public drunkenness. (Criminal responsibility is discussed further, below.)

Montana v. Egelhoff [49] is a more recent landmark case. Egelhoff was convicted of murder even though he argued that his blood alcohol level of 0.36% rendered him incapable of the mental state required for conviction of the crime. The Montana criminal code excluded consideration of voluntary intoxication in determining the mental state of a defendant. The Montana Supreme court overturned the trial court, arguing that "all relevant evidence" should be considered when evaluating whether Egelhoff acted "knowingly and purposefully", the mental state required for conviction. The United States Supreme Court upheld the ruling of the lower court, not the Montana Supreme Court. Though four-fifths of the states permitted the use of information about intoxication in addressing whether a defendant had the mental capacity to form the specific intent to commit a given crime, the Court noted that under well-established common law, voluntary intoxication did not excuse committing a crime. The Court held that general acceptance of taking intoxication into consideration when determining mental state did not make such consideration fundamental. (See below for a discussion of diminished capacity.)

In the future, the neurobiology of choice, volition, and motivation will be better worked out, which will lead to even more spirited discussion of these matters in the courts and in forensic psychiatry. It is wise for all the physicians involved in addiction medicine to keep up with these developments. It will be a challenge to weigh and understand the significance of the effects of illness on behavior and responsibility for that behavior.

Civil Matters

Involuntary Commitment

State and federal laws govern involuntary commitment of a psychiatric patient and/or addicted individual, though there is considerable variation from state to state. Grounds for civil commitment are usually that the individual suffers from a mental disease that is causing dangerousness to self or others or grave disability. Because substance use disorders are mental illnesses according to the psychiatric nomenclature, they qualify as a "mental disease" that causes dangerousness or grave disability. However, there is state-to-state variability in this, as well as variable interpretation of the involuntary commitment statute in a given state over time. Further, some states have separate involuntary commitment laws specific to alcohol and/or drug problems. Those states also may require that an individual committed under such a statute be treated in a facility approved and designated by the responsible state agency. Such a facility need not be a psychiatric hospital. When addictive illness is comorbid with another psychiatric disorder that is also a cause of the dangerousness or disability, civil commitment to a psychiatric facility is appropriate. It is essential for psychiatrists and

other physicians to familiarize themselves with the range of statutory obligations and conditions for civil commitment in the jurisdiction in which they practice, including the regulations and case law in situations in which addictive disorder is the mental disease. In states with such laws, familiarity with specific commitment statutes for alcohol or drugs (and in some states it is only one or the other) is similarly necessary.

Civil Competencies

There are many areas in which a psychiatrist may be asked to evaluate whether someone is competent. These include competence to sign in to a hospital voluntarily, to consent to other surgical procedures, to sign a contract, and to make a will, among others. Addictive disorders can impair these competencies. Impairment is characteristically caused by problems with cognition or judgment related to intoxication, withdrawal, persistent cognitive problems caused by substance use, or the combined impairment of these functions linked to the addiction and a co-occurring psychiatric illness. In determining competence, one must know the criteria for competence for the particular act in question. It is wise to ask the attorney or court requesting the evaluation to provide the examining psychiatrist with a copy of the statute or case that defines the competence. If the examiner finds that the examinee is not competent, the report should be accompanied by an explanation of how the substance-related illness was diagnosed, how specific symptoms resulted in the compromise of competence, and which criteria for competence are compromised by those symptoms.

Disability

Eligibility for disability benefits and eligibility for protections under disability laws are the two areas to be covered in this section. The reader should note that "disability" is another word with a meaning that differs across contexts, in this case even across forensic contexts.

If an individual is covered by private disability insurance, the meaning of "disability" is defined by the policy. The evaluating physician should review that definition and be clear about the criteria before rendering an opinion [44]. Criteria can include being unable to perform all duties of the job or able to perform only one or more duties. The policy may cover disability for a specific job, say, transplant surgeon, or although the examinee is a transplant surgeon the policy may only cover the more general job of physician. In the latter circumstance, even if the physician could no longer work as a transplant surgeon as a result of addictive illness, the examiner could find the doctor "disabled" under the policy only if the doctor could no longer work in any field of medicine as a physician. In some policies, the coverage is job specific for a period of time, then general. Some disability carriers do not ask the evaluating physician to render an opinion about disability (a legal adjudication regarding whether they have met policy criteria for being found disabled) but rather ask for an opinion about impairment (a medical conclusion about loss of function) [44]. If rendering an opinion that an examinee who is suffering from a substance-related disorder (or additional other mental disorder) is impaired, the evaluator should describe how the diagnosis was reached, note the symptoms present, and illustrate how the symptoms cause loss of specific functions. If rendering an opinion about disability, one must add an account of the job duties affected by this impairment and address the policy criteria for disability. In looking at these questions, a physician could consider whether the claimant is disabled by active addiction, the need to obtain treatment, the need to pursue recovery activities so extensive as to preclude work, the need to recuperate and convalesce, or the need to handle a specific stressor [16]. Disability companies may be reluctant to consider the risk for relapse as relevant to disability and prefer to address only here-and-now impairments and restrictions related to active disease or treatment. If the examiner believes that relapse is a major clinical

risk and danger, it is vital to explain this in detail. For instance, one study of resident anesthesiologists addicted to the parenteral use of fentanyl found that when, after treatment, they returned to the operating room, death was a first symptom of relapse in an extraordinarily high number of cases [42] (though subsequent studies cast doubt on this finding [17, 55, 70]). It has thus been argued that this specific pattern of addiction renders an anesthesiologist permanently disabled from operating room practice. The authors note that many disability companies stress that losing one's license to practice one's profession, even if due to illness, does not necessarily imply that the professional is disabled.

Because both other psychiatric disorders and medical disorders often complicate addictive illness, the presence of such illness should be noted in disability-related examinations. How each disorder affects the other (for an excellent discussion of this, see Weiss [80]) and the ways in which functional impairment and limitations are produced (or not) are essential aspects of such a discussion.

Social Security provides disability benefits through Social Security Disability Insurance and Supplemental Security Income. The criteria for a finding of disability are specified in the Social Security regulations but will not be reviewed in this chapter (see [44]) because substance-related disorders alone do not qualify someone for compensation in this system. The Contract with America Advancement Act of 1996 abolished substance use disorders as a cause of disabling impairment. If an individual suffers from other psychiatric or medical disorders and also from addictive disease, he or she may qualify, but only if he or she would continue to be disabled upon stopping the use of substances [44]. In the same way, in the absence of another psychiatric or medical condition, an individual is not eligible for disability benefits under the Veterans Administration by virtue of suffering from an addictive disorder alone [6]. The reason for this exclusion relates to a United States Supreme Court ruling concerning a Veterans Administration case in which the alcoholic drinking was determined to be willful misconduct, and willful misconduct disqualifies someone for such benefits under Veterans Administration regulations [74].

Protections from workplace discrimination for disabled persons are offered by the Americans with Disabilities Act of 1990 [4]. The statute defines a covered disability as one that substantially limits one or more major life activities as a result of illness. The Americans with Disabilities Act protections require an employer to offer reasonable accommodation to a qualified (disabled) individual in performing his or her basic job functions unless such accommodation would impose undue hardship on the employer [24]. Those suffering from addictive disorders may be covered under the Americans with Disabilities Act, but only in a limited and specific manner. The Americans with Disabilities Act differentiates alcohol and illegal drugs, and protects those addicted to them differently [81]. Those with alcohol dependence are protected under the Americans with Disabilities Act, but in order for those addicted to illegal drugs to be protected they must be in or have completed treatment for addiction and must not be currently using such drugs. The Americans with Disabilities Act only protects those addicted to legal but controlled substances if they are under the care of a licensed health care professional. An addict's posing a danger to the safety of others (or possibly oneself) is not covered under the Americans with Disabilities Act. Courts have issued contradictory opinions as to whether the employee is protected in cases when performance problems or workplace misconduct is clearly causally related to the addictive disorder. Performance problems caused by using alcohol away from work may not be protected [6]. Recent case law has limited the Americans with Disabilities Act protections afforded to those with substance use disorders [81].

Professional Liability

Issues in the prescribing of addictive compounds to a variety of patients and in the management

of addicted individuals can give rise to malpractice claims and litigation. The most common allegations in such litigation include that prescribing addictive medication led to the death or suicide of a patient or to the patient developing an addictive illness, or that failure to assess and diagnose addictive illness led to inappropriate prescribing or inappropriate monitoring of addictive medications. Most of these claims involve the prescribing of opioids or benzodiazepines. Less commonly, such suits allege failure to recognize alcohol dependence or to consider the risks of cross-addiction. Cross-addiction is sometimes narrowly conceptualized as a person addicted to one drug becoming addicted to another substance. However, a more common cross-addiction problem is relapsing on one's drug of choice because of exposure to another drug of abuse. Litigation also arises out of the alleged failure to obtain informed consent concerning the addictive characteristics of medications prescribed for a variety of conditions and the ensuing risk of developing addictive illness [6].

Suicide is the most frequent precipitant for malpractice claims against psychiatrists and is not an uncommon source of claims for other medical practitioners who treat addictions and other mental disorders. Those who suffer from addictive illness, alone or with co-occurring other psychiatric conditions, are at significantly increased risk for suicide. Obviously, attempted suicide also is commonly associated with substance intoxication. Substance-related disorders and depression commonly co-occur either because addiction causes depression, depression heightens the risk for addiction, or they exist independently and affect each other. Since addiction also impacts the social and occupational arenas, morbidity and losses further enhance suicide risk. Clearly, managing suicide risk is an integral part of the job for anyone treating substance-related disorders.

Strategies for managing chronic non-malignant pain in a person suffering from an opioid or other addictive disorder remain controversial, as is the related question of the frequency with which pain patients develop addictive illness when treated with opioids [12]. All pain patients should be assessed for substance-related disorders and for risk factors for developing such disorders. Assessing the patient, discussing risks with the patient, and documenting one's reasoning about the risks and benefits of the prescribed treatment are all central to the management of liability risk in these cases.

The forensic assessment of alleged medical negligence requires being familiar with the standard of care concerning the medical practice at issue. Given that malpractice cases involving the management and treatment of addiction may also include questions on a wide range of subjects, such as the treatment of a co-occurring psychiatric illness, the appropriateness of prescribing and following the use of addictive substances, or the meaning of toxicology or autopsy findings in a person with an addictive disorder, it is necessary for the medical expert to know the relevant standards of care, including the presence of controversies and other unsettled areas of clinical protocol. It is vital for medical experts to be clear to referring parties as to the areas and limits of their expertise.

Confidentiality

The federal confidentiality statute (42 CFR, Part 2) was intended to guarantee that an individual who voluntarily seeks treatment for addictive illness is not subject to a penalty that someone who does not seek treatment for the same condition would not suffer—that penalty being loss of confidentiality concerning the addictive condition [22]. While this law specifically addresses alcohol or drug treatment programs or those who receive federal funds or federal exemptions (such as federal tax-exempt status), it is prudent to consider that it applies to all treatment and evaluation settings. The law greatly restricts communication about such a client or patient without a signed, written release of information. A few examples of communication permitted by the

statute include when there is a need to: address a life- or health-threatening medical emergency, report a crime committed in the program setting or in which treatment personnel are victims, report child abuse, or respond to a court order (among other conditions). Note that a subpoena is not a court order and is not an exception to the statute. The authors recommend consulting with an attorney knowledgeable about 42 CFR, Part 2, if treatment records are subpoenaed; responding to a subpoena without contesting it has been the source of successful litigation alleging violation of confidentiality. Under the statute, patients may rescind their release of information at any time, except when their treatment is a condition of parole or probation. The law presents many complexities that require interpretation in the context of each treatment situation. When does a person acquire the status of "patient" for whose protection the law provides? At the point of referral, the first phone call, or the first visit? This is only one of the myriad questions that may arise, given the breadth and complexity of the law. The structure of each program, agency, or other practice environment may be sufficiently unique that legal consultation is necessary to understand the implications of this statute. Other issues may arise because of conflict between the federal statute and various state laws. Generally, federal law trumps state law in confidentiality unless state law is more restrictive. Sorting out a program's or physician's risks and responsibilities requires careful thought and often legal input. For a more extensive discussion of 42 CFR, see [9].

Another law that protects the privacy of patient information is the Health Insurance Portability and Accountability Act of 1996, promulgated by the United States Department of Health and Human Services. This law applies to a variety of health care providers, including addiction treatment programs, if they electronically transmit individually identifiable patient information. However, because the confidentiality requirements are stricter in 42 CFR, Part 2, the authors will not address the Health Insurance Portability and Accountability Act in this chapter.

Duty to Protect or Warn

A physician's or psychiatrist's duty to warn or protect a specific person whose safety has been threatened by a patient may be in conflict with other legal and ethical requirements of medical practice, such as protecting the confidentiality of the threatening patient. That the patient suffers from an addiction neither alters the essence of this duty nor makes the conflict easier to resolve. This duty originated with *Tarasoff*, a California Supreme Court decision [73]. While this ruling has evolved in California, it is the basis of similar laws or case law in most states. The duty to warn is usually met by notifying the threatened person or the police of the patient's threat to harm; the duty to protect also may be met by involuntary commitment of the patient. Because law and case law vary so considerably between states, physicians and program personnel should be knowledgeable about the duty as it applies in the jurisdictions in which they practice. A major difference in the manner in which warnings should be given when the threatening patient is in addiction treatment, versus other psychiatric or medical treatment, is that under 42 CFR, Part 2, the notification to the threatened person or to law enforcement should not reveal that the patient is suffering from a substance-related disorder.

Child Custody

Child custody proceedings are at best adversarial and at worst a vitriolic environment. Even when divorce is first raised, in the hope to gain leverage or advantage, one parent may threaten the other that his or her real or alleged substance abuse will damage rights to child custody. It is not unusual for these questions to be raised in the custody proceedings, and addiction experts are frequently retained to evaluate such cases. In practice, courts vary considerably in how much weight they give to a mere history of an addiction in a parent. Many courts have ruled that a

parent who has obtained appropriate help for his or her addiction and/or can demonstrate recovery or abstinence is not disadvantaged. On the other hand, the court will want to know the evaluator's opinion as to whether or not the parent suffers from such a condition, his or her degree of insight, whether he or she has had appropriate treatment, the outcome of treatment, the prognosis, etc. The evaluator also should address the impact of the substance-related disorder on—and its interaction with—other medical and psychiatric illness. The court may ask for the evaluator's treatment recommendations. The evaluator also should be prepared to discuss the question of whether a child has been harmed or neglected by an addicted parent and the likelihood of this occurring in the future. The standard used by the courts in these proceedings is the parent's ability to attend to the best interests and safety of the child or children [33].

Criminal Matters

Competence to Stand Trial

Competence to stand trial in a criminal matter is related to the current mental state of the individual charged with a crime, not to his or her state of mind at the time of the crime's commission. Neither intoxication from a substance of abuse nor withdrawal from such a drug is likely to impair such competence because these conditions would have resolved long before the pre-trial process. Nevertheless, accused persons have been known to come to their competence evaluation severely intoxicated in hopes of being found incompetent. Some examples of substance-related conditions that can impact competence include enduring toxic states, such as an amphetamine- or hallucinogen-induced psychotic disorder, which may last for weeks, other persistent conditions, which may last months or longer, and brain injury caused by drug use.

Dusky v. United States [19] is the landmark United States Supreme Court case that defines incompetence to proceed in a criminal matter. It is utilized in all states with minor variations. *Dusky* states, "The test must be whether he [the defendant] has sufficient present ability to consult with his attorney with a reasonable degree of rational understanding and a rational as well as a factual understanding of the proceedings against him." The competence evaluator must examine carefully the current mental condition of the examinee, asking very specific questions about his or her comprehension of the legal process and assessing the ability to work rationally with the attorney in his or her defense. To determine a defendant's knowledge of the legal process, forensic examiners frequently ask defendants to recite and discuss the charges against them and the job of the various players in the courtroom. In determining their ability to cooperate with their attorney, it is useful to ask how they decide what is pertinent to discuss with their attorney and how they manage their relationship with their attorney when there is divergence about the best way to defend the case. It is also key to determine how accurately the defendant understands the possible outcomes of various legal strategies in the case. In all cases where the examiner finds incompetence, the written report and subsequent testimony should note the diagnosis and symptoms and describe the manner by which the symptoms interfere with competence criteria in *Dusky*. The examiner also should recommend any treatment that might restore competence and the likelihood of restoration. Because—as noted above—substance-related disorders only lead to incompetence proceeding under narrow conditions, it is especially important to explain how and why the condition continues to affect the accused, which will require knowledge of the toxicity of the drug responsible for the disorder and/or the nature of the brain injury associated with the use of that substance.

Sanity and Diminished Capacity

The question of sanity in a criminal case has to do with the state of mind of the defendant at the time of commission of the criminal act, not with his or her mental state at the time of

trial. The insanity defense has its roots in the common law of England, which recognized that under specific circumstances a mentally ill person should not be held responsible for a criminal act. In the majority of states (38) in the United States, the definition of insanity applies to defendants who, as a result of mental disease or defect, are unable to know or understand the nature and quality of their criminal act or are incapable of distinguishing right from wrong in relation to that act. This test is referred to as the M'Naghten standard, named after the defendant in an 1843 case in England [48]. M'Naghten is a cognitive standard, referring to what a defendant fails to know and understand. Several states use both the cognitive test and a volitional test. The volitional arm is often modeled after the standard published by the American Law Institute [2]. This volitional test considers that defendants can avoid criminal responsibility if they were, as a result of mental disease or defect, unable to conform their behavior to the requirements of the law. In most cases and jurisdictions, substance use of any kind, even when the defendant suffers from a substance use disorder, is not an allowable defense under an insanity plea in a criminal case. Most courts have found that voluntary ingestion of a substance of abuse does not excuse criminal behavior. That drugs of abuse and addictive illness can impair volition, however, may be relevant in states with a volitional arm in the law that governs the insanity defense. Clearly, it is imperative that forensic examiners know the laws in the state or states in which they practice so that they know exactly the applicable definition(s) of insanity, including the conditions that are excluded as arguments. When in doubt, the examiner should request that the referring court or attorney give him or her a copy of the relevant laws and cases.

A few specific clinical situations involving substance use may be relevant to sanity even under a strict cognitive test, such as involuntary intoxication, in which the defendant was poisoned or tricked into using a drug that resulted in criminal behavior. Another example is when a criminal act was committed during a withdrawal delirium. In a few states, a persistent drug-induced psychosis may be an admissible factor in an insanity defense. *People v. Kelly* [58] is a California case in which Kelly attempted to kill her mother after recent exposure to mescaline and a long history of hallucinogen use. She believed that her mother was "with the devils". She had a previous history of persistent psychotic states related to drug use and remained psychotic for several months after she attempted to kill her mother. The court ruled: "We hold that such a temporary psychosis which was not limited merely to periods of intoxication. . .and which rendered defendant insane under the M'Naghten test constitutes a settled insanity that is a complete defense to the offense here charged." In other states, in lower courts, cases similar to *Kelly* have not been opened to the insanity defense. *Kelly* also referred to "settled psychosis" and brain damage; brain damage due to addiction under certain circumstances may be used in an insanity defense [33]. *Kelly* also termed Kelly's mental condition as one of "pathological intoxication", further confusing an already puzzling concept [56]. "Pathological" or "idiosyncratic" intoxication is a state in which an individual undergoes a strange and previously unfamiliar reaction to drug exposure. There are a few jurisdictions in which the occurrence of pathological intoxication has qualified a criminal defendant to use the insanity defense.

Diminished capacity is another important legal concept in the domain of criminal responsibility; it is a partial defense, and, as in *Egelhoff* (see Section "Compulsion and Responsibility"), voluntary ingestion of a substance of abuse may be considered relevant. This defense only applies in cases in which a conviction requires proving that the defendant had the specific intent to commit the crime, meaning that the defendant had to deliberate or harbor the thought of the specific crime. Specific-intent crimes include first- and second-degree murder, as opposed to most felonies, which require proving only general intent for conviction. If upon examination a forensic evaluator finds, and the fact finder—the judge or jury—agrees, that due to ingestion of a drug of abuse a defendant could not form the

specific intent to commit second-degree murder, then the accused can only be found guilty of the lesser charge of manslaughter. Like the insanity defense and most other matters considered in this chapter, the diminished capacity (or "diminished responsibility") defense varies between jurisdictions. In fact, California has abolished the diminished capacity defense and replaced it with the concept of diminished actuality [61, 79]. Under this structure, the issue thus becomes whether a defendant actually formed specific intent, not whether he or she had the capacity to do so. A psychiatrist or other forensic evaluator cannot opine on the question of what actually happened; this is a question that can only be addressed by the finder of fact. The evaluator may still testify about the state of mind of the accused and the effects of drug use on his or her mental state. This may provide some information for the fact finder about specific intent. Knowing current state law is again necessary for psychiatrists and other forensic evaluators involved in evaluating someone in which such a defense is being considered.

In alcoholic blackouts, there is anterograde amnesia for some or all events that transpired during a drinking experience. In typical cases, the individuals are described by others as behaving purposefully, but they cannot recall their actions. Controversy about whether blackouts should be considered under the concept of diminished capacity rests on the issue of whether or not the individual experiencing the blackout is capable of forming criminal intent. The blackout syndrome certainly occurs, and memory loss is an essential feature, but whether or not behavior performed during a blackout is intentional is not clear [26, 43].

Imperfect self-defense is another construct in which substance use may be relevant in a criminal defense. The essential element is that the defendant believes, incorrectly, that he or she was in danger and the criminal act was thus believed to be in self-defense to prevent bodily harm or injury. Consider a person who kills another because of such a belief—a paranoid delusion caused by chronic stimulant dependence. If persuaded that this were the case, a court might find such a defendant guilty of manslaughter rather than murder.

Sentencing

The sentencing phase of a criminal trial is another arena in which a court may hear expert testimony about substance use and addiction, though it is hard to predict whether this testimony will be seen as aggravating or mitigating. Consider a vehicular homicide case in which at sentencing the addiction expert presents information about the defendant's severe sedative dependence and how sincere and successful the accused has been in subsequent recovery since the homicide. The defense may call the expert in hopes that the jury will think about a lesser sentence but find the jury members irate that the defendant did not responsibly seek treatment before anyone was killed, and thus be inclined toward a harsher sentence. Similarly, in death penalty cases, it may be difficult to predict whether testimony about drug or alcohol use or addiction will be viewed as aggravating or mitigating by a judge or jury. The ability of the expert witness to communicate effectively is of paramount importance in this phase of a criminal trial.

Pregnancy, Harm to the Fetus, and Child Abuse

In alarming developments, pregnant women have been successfully prosecuted for harming their fetuses by abusing drugs. Many states have seen such cases, but the first two, both in South Carolina, are instructive. In *Regina McKnight* v. State of South Carolina [39], McKnight's stillborn child's blood contained cocaine metabolites. She was charged with homicide by child abuse and sentenced to a 20-year jail term. In *Cornelia Whitner* v. State of South Carolina [83, 84], Whitner's child was taken from her care after testing positive for cocaine metabolites. Whitner was prosecuted under South Carolina's child neglect statute for having exposed her fetus

and subsequent child to cocaine. She was sentenced to a jail term of 8 years. The Supreme Court of South Carolina upheld these decisions upon appeal. The United States Supreme Court denied *certiori*—that is, declined to review either case on further appeal. This was despite numerous national professional organizations, such as the American Academy of Addiction Psychiatry and the American Psychiatric Association, having filed amicus briefs on behalf of *McKnight*.

In *Whitner*, the potential harm to the fetus was considered to be information that she should have considered to be ". . .well documented and in the realm of public knowledge. . . ." Thus, the court considered Whitner "on notice that her conduct in utilizing cocaine during pregnancy constituted child endangerment", as if knowledge could be expected to serve as the antidote to addictive drug use. The Court in *McKnight* reasoned similarly, finding that she had the requisite criminal intent to kill her child (defined as "the person causes the death of a child under the age of eleven while committing child abuse or neglect, and the death occurs under circumstances manifesting an extreme indifference. . .to human life" [66]). The successful prosecution of these cases followed from the interpretation that the South Carolina child abuse and neglect statutes applied to the unborn. McKnight pointed to sections of those statutes that addressed harm due to corporal punishment and/or abandonment, which could only apply to children. The Court considered whether "this demonstrates that the statute was clearly intended to apply only to children. However, section 16-3-85(B) [of the statute] also defines harm as inflicting or allowing to be inflicted on the child physical injury . . . and failing to supply the child with adequate health care . . . Either of these provisions may clearly be applied to an unborn child. Accordingly, given the language of the statute, and this Court's prior opinions defining a child to include a viable fetus, we find the plain language of the statute does not preclude its application to the present case."

An interesting twist on such prosecutions is *Lovill v. Texas*, in which Lovill, a pregnant probationer in treatment for cocaine addiction, experienced relapse, thereby violating her probation. The State decided to incarcerate her in order to protect her fetus, though such probation violations are typically treated with less restrictive actions. On appeal [37], this action was reversed. The Court of Appeals ruled that the prosecution represented a violation of Lovill's 14th Amendment protection against sex discrimination: "The evidence shows (1) that Lovill was treated differently than others who violated the terms of their probation but were not pregnant, and (2) that her pregnancy was a motivating factor in the decision to prosecute."

There are many criticisms of these decisions and similar prosecutions across the country. In most cases, there is a strong argument that science does not support the reputed harm attributed to drugs of abuse such as cocaine. As was argued in a similar case in Maryland [15] following *Robinson*, addiction is a disease, not subject to punishment and not cured by self-discipline or health warnings. Criminal penalties are likely to result in harm to newborns by virtue of separating them from their mother. Perhaps most importantly, it is likely that once it is known that mothers will be prosecuted under these conditions, they will avoid seeking medical care during pregnancy, including treatment for addictive illness or the many causes of fetal and maternal morbidity. Thus, mothers will be deterred from seeking care for themselves and their fetuses; their medical care and health will be undermined, and the very children intended to be protected by these legal actions will experience greater endangerment [67]. These recent decisions are important lessons in how, even in relatively well-informed contemporary times, the legal system can act on biased presuppositions and endanger individuals whom it is trying to protect. These cases also underscore the importance of the legal and medical/psychiatric communities communicating about such legal movements so that they can be addressed through the work of professional organizations serving as *amici*.

Addiction in Criminal Populations

A great majority, up to 95% in some studies, of those in prisoner populations suffer from addictive illness [34], and over half of state and federal prisoners reported being under the influence of drugs or alcohol at the time of their criminal offense [11]. These findings raise the important question of the relationship between substance use and criminality. Of course, this is a broad subject in which there are opposing views. One idea is that criminals become involved with drugs along with other criminal activities and that incarceration is the correct punishment [69]. Another analysis is that drug-abusing individuals commit crimes related to and caused by their addiction. A corollary of the latter analysis is that treatment is the only remedy for criminal behavior caused by addictive illness; punishment is less likely to remedy such behavior. Studies that show decreased criminal recidivism following addiction treatment support this point of view [25, 78]. These ideas also have given rise to the development of alternatives to incarceration such as drug courts (discussed below) and similar diversion programs. Court-ordered, coerced addiction treatment has been found to be effective [46].

Despite the fact that so many prisoners suffer from addictive disorders and that their crimes were committed while they under the influence, only about 40% of state and federal prisons provided on-site addiction treatment in 1997 [72]. Only about a third of state and a quarter of federal inmates reported receiving drug or alcohol treatment in that year [31].

Standards for correctional mental health care have been published by The National Commission on Correctional Health Care in 1999 and the American Psychiatric Association in 2000. The principle behind these recommendations is that the same level of mental health services should be provided to each individual in the criminal justice system as is available in the community [45]. The situation in correctional addiction treatment falls short of this target.

Among the many kinds of treatment programs offered in correctional settings, the most successful are residential programs [57], including therapeutic communities [82], which require 6–24 months to finish. The most successful groups in terms of success with criminal recidivism are those individuals who complete a therapeutic community treatment in prison and, upon release from incarceration, enter a community-based residential therapeutic community. Jails and prisons also utilize less intensive programs, especially for those who reside in the general population of prisoners (as opposed to higher security levels or protective custody), which may engage a prisoner up to 4 hours a day—short-term programs in which the goal is to motivate inmates to obtain addiction treatment in the community when released, i.e., group and individual therapies modeled after outpatient community treatment. Twelve-step programs are generally available, though in many jails and prisons not widely so—that is, there are few meetings, and they may not be available throughout the facility. Twelve-step programs are often problematic to utilize in correctional settings because of their emphasis on openness and honesty, while in most other prison venues the "convict code" ("don't rat on another inmate") and the need for protecting oneself physically and emotionally rule inmate behavior.

There also is a high rate of comorbid psychiatric illness among criminal offenders with addiction problems. However, there are few treatment programs in jails and prisons for this population. In correctional settings, there is a long history of bifurcation between the systems that address addiction problems and those that treat mental illness. The paucity of programming for comorbid conditions in part reflects this legacy. Another problem is that therapeutic communities and other residential programs in correctional settings are quite psychologically stressful because of their emphasis on one-to-one confrontational techniques. This makes it troublesome to tolerate if not contraindicated for inmates with moderate-to-severe mental illnesses. More intensive psychiatric services and

modified therapeutic community techniques are necessary for this population [21].

Drug Courts

Drug courts have taken hold in the popular imagination: one newspaper story reported that as an addicted woman graduated from a drug court program, "...Prosecutors and public defenders applauded when she was handed her certificate; a policewoman hugged her, and a child shouted triumphantly, 'Yeah, Mamma! [20]' " Although such optimism is encouraging, the drug court model deserves a rigorous evaluation. The diversion of non-violent drug offenders to drug courts is increasingly popular and, as defined by the United States Department of Justice, "...(integrates) substance abuse treatment, sanctions, and incentives with case processing to place nonviolent drug-involved defendants in judicially supervised rehabilitation programs" [18].

Engendered in the late 1980s as the crack cocaine epidemic overwhelmed United States jails and prisons, drug courts have evolved as collaborations between the justice system and addiction treaters—collaborations based on the ability of the two camps to speak and understand the other's professional language. Studies reveal that the high up-front cost of drug courts often—but not always—pay off in terms of improved outcomes for addicts and benefits to society, economic and otherwise. Challenges to the drug court model include the obvious bias to help addicts who commit crimes over other addicts who do not, objections to a government mandate for participation in quasi-religious programs such as Alcoholics Anonymous, inadequate data on the overall economic benefits of drug courts, and a philosophical concern about providing punishment for relapse.

Formal drug courts first arose in Judge Stanley Goldstein's 1989 Miami Circuit Court in response to the huge numbers of cocaine-linked offenders flooding the local jails. The prevailing ethos in the late 1980s was a simplistic response to addiction best exemplified by Nancy Reagan's 1982 recommendation that people should "just say no" [35] to drugs. It quickly became apparent to the court that addicted offenders responded well to the treatment services offered, and made quantifiable gains in terms of reduced criminal activity, educational strides, employment, and stabilized family interactions.

By establishing similar drug court dockets within their courts, judges around the country quickly followed Miami's lead, integrating to various degrees drug law enforcement with addiction treatment. By 2007, all 50 states had active drug courts, with 1,932 judges serving on a total of 1,662 drug courts nationwide, and with 386 more drug courts in the planning stages [10].

The concept of "therapeutic jurisprudence", which came to fruition in the late 1980s, was defined as "the study of the extent to which substantive rules, legal procedures, and the roles of lawyers and judges produce therapeutic or anti-therapeutic consequences for individuals involved in the legal process" [29]. This paradigm shift for the legal system was matched by a similar shift in the drug treatment system, an acceptance of the role of coercion in the treatment of addicted individuals: "...Addicts need not be internally motivated at the outset of treatment in order to benefit from it. Indeed, addicts who are legally pressured into treatment may outperform voluntary patients, because they are likely to stay in treatment longer and are more likely to graduate..." [65].

Unlike the judicial coercion inherent in civil commitment proceedings, entrance into a drug court system necessitates a choice by the addicted offender. He or she may choose to accept the legal consequences of the crime, a choice some make in order to avoid treatment. In many circumstances, the drug treatment entails a longer time under judicial supervision than the threatened jail sentence.

The United States Government Accountability Office conducted a 2005 meta- analysis of adult drug courts [76], in which they evaluated 23 programs and found demonstrable reductions in criminal recidivism, though less clear results for actual reductions in drug use.

The Government Accountability Office study was much clearer about the financial benefits of the drug courts assessed. Generally, the drug court model cost substantially more than the non-drug court model. However, the authors conclude that reductions in recidivism would more than compensate for this increased up-front cost. Another study reached similar conclusions [7].

Sentencing in drug courts will involve orders to maintain sobriety, attend treatment and support groups, and participate in tissue screening, as well as other requirements that are essentially clinical in their thrust. Addiction specialists are often asked to evaluate criminal offenders related to such sentencing issues. As in other areas of the law that make use of the concept of therapeutic jurisprudence—mental health courts and parental psychiatric evaluation in child-custody disputes—it behooves the addiction specialist to become familiar and comfortable with the actors and institutions of the legal system.

Regulatory Matters

Impairment and Fitness to Practice

The word "impairment" is used quite differently across the literature and verbiage about impaired professionals. It is sometimes used to refer to having an addictive illness, recovering from an addictive illness, or having an illness that can cause impairment. The authors define it as the inability to practice the profession with sufficient skill and safety to the clientele of that profession due to illness or injury [23]. The illness may be addictive, other psychiatric, or medical, including comorbidities of the three categories. Note that by this definition, having the illness, even if it impairs functioning outside of work, does not constitute impairment. Impairment should be distinguished from deficiencies of knowledge and skill to practice the profession, which have to do with competence. Impairment does not imply incompetence, and incompetence does not imply impairment. Psychiatrists and addiction specialists are often asked by professional licensing boards—regulatory boards that operate based on regulatory laws of the states in the United States—to evaluate practitioners to determine whether they are safe to practice. This raises the question of impairment and the practitioner's fitness for duty, concepts that are related [5]. Professions controlled by regulatory/licensing authorities include most medically related professions (medicine, nursing, dentistry, pharmacy, veterinary medicine, and podiatry) through their boards, attorneys through boards or the state supreme courts, and commercial and private pilots through the Federal Aviation Administration, among others. Each of these agencies has laws, regulations, and policies unique to them; physicians and others performing evaluations for such agencies must become familiar with them individually. For instance, the Federal Aviation Administration has specific ways of defining addictive illness as it applies to commercial pilots; working from the *Diagnostic and Statistical Manual of Mental Disorders* will not suffice.

Impairment, as defined here, usually occurs in the late stages of addictive illness, at least among professionals. Professionals tend to be strongly identified with their profession, and their self-esteem is quite tied to work performance. As a result, even when other areas of life—family, marriage, emotions, and health—are suffering as a result of an addiction, the professional will protect the sanctity of the workplace until the illness is completely out of control. A corollary of this analysis is that by the time impairment occurs, the professional's life—and not just his or her career—is in danger.

When addictive illness causes impairment, it is usually related to symptoms of cognitive dysfunction, emotional liability, impaired judgment, erratic behavior, or a combination thereof. Interference with these functions may be caused by the neurological consequences of substance intoxication, an acute or sustained withdrawal syndrome, or damage to other organs that secondarily affects brain function (e.g., severe liver disease in chronic alcoholism). Chronic

exposure to drugs of abuse also causes personality changes, especially irritability, reduced tolerance of frustration and ambiguity, and impulsivity—the psychotoxicity of extended substance exposure. Evaluating fitness for duty requires understanding the nature of the work that the professional is either fit or unfit to practice. In the report, the evaluator should connect the diagnosis to the symptoms, to the bearing of those symptoms on mental and physical functioning, to the relationship between any loss of function and its impact on the duties of the job in question. The report also should discuss treatment for the addiction (and/or the degree to which recovery and abstinence have been achieved), the prognosis, and the best strategies for monitoring the professional in the future. The interplay of the addictive illness with other psychiatric and medical conditions also should be addressed, along with how this might affect work function. Treatment and prognosis of all potentially impairing illness should be discussed because the regulatory authority will be concerned about both the present and future safety of the professional's clientele.

"Monitoring" is a technical term referring to how professionals are followed once their condition is known. Monitoring activities support but do not substitute for treatment. In fact, the success of physicians with addictive disorders, defined in terms of rates of recovery and rates of returning to or maintaining professional practice [17, 40], may be largely due to the systematic monitoring that they receive. Monitoring activities typically consist of periodic clinical assessment, random tissue testing for alcohol and drugs (and other laboratory testing for markers of addictive illness), and repeated contact with outside sources of information such as spouse, therapist, treatment program, and the professional's workplace. In the United States and Canada, those doctors with addictive disorders (and other illnesses) are monitored by physician health programs, a variation on the theme of peer assistance programs that are involved with many of the other professions. From profession to profession and from state to state, there is much variability in these programs in terms of the illnesses that they address, their structure, their relationship to the regulatory (licensing) authority, and the laws that govern that authority. Most peer assistance programs provide at least some degree of confidentiality from the licensing board, but only with the consent of the board. Addiction specialists involved in evaluating a professional's fitness for duty should be knowledgeable about the capabilities of the peer assistance program of that profession.

Every physician and other addiction specialist who treats or evaluates professionals should be familiar with the laws that govern the profession, especially as applied to any duties that they may have to report an addicted professional to the licensing authority and whether that report is immune for liability [64]. Taking the example of the Medical Practices Act, which governs physicians in Colorado [41], the condition of being addicted to alcohol or drugs is classified as unprofessional conduct. All physicians have a duty to report unprofessional conduct to the Board of Medical Examiners. Colorado law, however, provides a reporting exception for a physician involved in treating physicians with mental health problems, including addictions. However, there is an exception to the exception if the treating physician thinks that the physician-patient is not safe to practice. If a doctor makes a report about another physician to the medical board, the doctor is immune from liability, assuming that the action was taken in good faith.

Addiction psychiatrists and other addiction specialists may work in roles other than forensic evaluator in working with professionals, but all roles require knowledge and facility in the forensic world. For instance, working as a treating psychiatrist, especially if treating in the rubric of a professional's participation in a monitoring program or license stipulation, requires understanding the limitations upon the confidentiality of the treatment and the specific reporting responsibilities that come with that role. Other possible roles include that of medical directors of monitoring programs, which are embedded in specific legal and regulatory contexts and must be well understood for the program to be effective.

For all addiction specialists working with professionals, it is essential for them to understand the psychology, culture, mores, demands, and realities of that profession. That physicians do not function well as patients [23], that lawyers often reject the concept of illness as a factor affecting their behavior, that commercial pilots deny weaknesses, and that astronauts believe that they must be perfect in all dimensions, are extremely relevant to evaluating, assessing, and monitoring them.

Tissue Testing

Testing various body tissues for drugs of abuse is a standard practice in the regulation and monitoring of professionals and other workers when public safety is at risk. Commercial pilots, for instance, are randomly tested for drugs and alcohol; the Federal Aviation Administration prohibits pilots from using intoxicants, including legal ones such as alcohol, within 12 hours of flying. Other professionals are routinely required to undergo such testing if they are known to have an addictive illness. In 1988, the United States Department of Health and Human Services published guidelines [75] mandating a drug-free workplace for federal employees. These guidelines also have served as the model for employment policies and practices in private industry. Pre-employment screening, random testing, and testing for cause are the common types of testing. Working with government or private industry, an addiction specialist may serve in a clinical role, evaluating those found positive on testing, or in a medical review officer role, assuring that the process of drug testing and the interpretation of the results are appropriate. Medical review officer work requires knowledge of the techniques and procedures of tissue testing so that false positives and false negatives can be distinguished from accurate results. Urine is the tissue that is most commonly screened; all tissues have their advantages and disadvantages. The important variables include the ease of obtaining the sample, ease of tampering with, contaminating, or substituting the sample, length of the window of detection, and likelihood that brief drug exposure could be found in the tissue, among others. Besides urine, sweat (via a skin patch), blood, nails, and hair are the most commonly tested [77].

Sports

Although the absolute numbers of athletes troubled by addictive illness may seem too small to warrant discussion in this chapter, the types of drugs used and abused in athletic communities are sufficiently different, and how the relevant institutions are responding to these problems are sufficiently important, to merit discussion. Further, the precedents set in this domain may well presage how other arenas of society approach these problems.

Differentiating between addictive responses to substances and the voluntary use of substances for performance enhancement is an important role for the addiction specialist working for a sports organization. Although the categories of "addiction" and "cheating" may seem clear a priori, the two interact in multiple and subtle ways. For instance, the anabolic androgenic steroids are unlikely to engender classic withdrawal and tolerance unless they are taken in massive supraphysiologic doses; some athletes do take them in such doses. Although most sports organizations now classify stimulants as performance-enhancing substances, the stimulants can be used as part of an addictive diathesis, or, more commonly for the elite athlete, their use can evolve from performance enhancing to addictive.

Addiction specialists who understand the legal and procedural framework of modern sports programs can function in one of three separate roles. First, they can work as a medical review officer, whose essential role is overseeing drug testing and verifying the validity of the results. Second, they can work as a treating clinician with a well-defined and transparent reporting obligation. Third, they can develop and administer employee assistance programs for a

team or within a particular sport. In all these roles, the combination of addiction and forensic knowledge allows the physician or the professional to produce accurate and helpful case formulations and treatment recommendations.

As in other workplaces, the medical review officer must understand the complexities of drug and alcohol testing within the context of the particular industry and federal law, especially the Americans with Disability Act [71]. In a sports organization, however, the medical review officer must, in addition, understand the science of testing for the specific drugs used illicitly [28], the culture and demographics of the program participants, and some specifics about the sport itself. For instance, the medical review officer must schedule the timing of testing before or after competition in order to provide an accurate assessment of any drug use actually taking place, while considering the convenience and dignity of the athletes. Testing for stimulants before a competition is less useful than testing during or after the competition since illicit users take the substances just before the game. As a matter of fairness to athletes who suffer from legitimate medical or psychiatric conditions, there is a need for occasional therapeutic use exemptions [27]. The therapeutic use exemption allows an athlete to use a banned substance after an appropriate diagnostic assessment, legitimate prescription, and ongoing monitoring. Psychostimulants for the treatment of attention deficit disorder and attention deficit hyperactivity disorder are the most common class of medications for which athletes request a therapeutic use exemption. The addiction specialist working in the sports environment must fashion a plan that allows the attention deficit disorder and attention deficit hyperactivity disorder sufferer to use appropriately prescribed medication while denying an exemption to those who are merely using the medications to improve their athletic performance. In addition, the therapeutic use exemption program must contemplate other potentially therapeutic uses for banned substances, such as testosterone for testicular deficiency, diuretics for hypertension, and opioids for pain. Major sports organizations, including the Olympics [54], the National Collegiate Athletic Association [50], the National Football League [51], Major League Baseball [38], the Professional Golf Association [60], and the National Hockey League [52], have processes for evaluating therapeutic use exemption requests.

Addiction psychiatrists and other addiction specialists can serve as treating physicians for athletes; a good understanding of forensic issues is important even in this clinical context. Even without any reporting responsibility, the clinician should be aware of the high visibility of elite athletes in the public consciousness: individual courts [14], the United States Congress [36], and private investigative bodies [47] may request—or subpoena—information about the treatment of such individuals.

Treating an athlete for an addictive disorder, or any substance use, requires that the clinician understand the profound pressures and stresses that affect the athlete. In addition to the rewards of fame and sometimes money that elite athletic performance can bring, the family dynamics of these individuals can be quite disturbing and counterintuitive to the clinician. The desires of family members for material success and celebrity treatment can drive the athlete to behavior that he or she would not otherwise have considered, especially if the financial rewards of peak performance can put food on the table for an otherwise indigent family.

More significant than financial rewards, however, is the internal driving force that the athlete may feel. If one's core value from a very early age is to win at any cost, boundaries often become fluid. Athletes at the elite level are not paralyzed by worry about hurting themselves, or they would not be elite athletes. In 1995, a sports medicine specialist informally posed the following question to 198 Olympic-level athletes: "If I had a drug that was so fantastic that if you took it once, you would win every competition you would enter, from the Olympic decathlon to the Mr. Universe Contest, for the next five years. But it had one minor drawback: It would kill you five years after you took it. Would you still take it?" More than half of the athletes acknowledged that they would take the drug [13]. So, taking a chance on a performance-enhancing drug might

not be a great leap, given the single-minded determination that these athletes have in their emotional repertoire.

For athletes—elite or otherwise—the rationale for allowing a treating psychiatrist or other physician to report relapse to a regulatory authority may appear less convincing than for commercial airline pilots or physicians. For professional athletes, labor unions may necessitate that any monitoring protocol be negotiated under the rules of the National Labor Relations Board [53]. As with any other impaired professional who is part of a monitoring program, the burden falls on the treating physician to make sure that the patient is well aware of the reporting obligations, his or her options for having treatment elsewhere, and the right to withdraw permission for reporting.

The clinician who decides to manage an employee assistance program has different and more complicated obligations than the treating clinician or the medical review officer. The administrator must fashion a program that delivers good care to athletes, functions well from the perspective of management, and conforms to mandates from all applicable laws. An understanding of the sport's culture, and close liaison with coaches, medical staff, and athletic trainers, will ensure that the employee assistance program functions as well as possible in an inherently difficult environment. As is the case with employee assistance programs in other industries, the limits of confidentiality must be spelled out as clearly as possible.

As in all forensic work, the addiction specialist must be prepared to justify clinical and administrative decisions on the basis of evidence-based clinical care and respect for the applicable legal or procedural framework.

Conclusions

There is a broad array of forensic contexts and considerations that present themselves to physicians and other health care providers interested in addictive illness. The contexts range from civil to criminal to regulatory, and within each are complex conceptual problems that must be addressed by the practitioner. This requires mastery of the clinical and scientific elements unique to addictive disease and their intersection with the specific forensic environment. That intersection is approached through unifying principles: neutrality in examination and reporting, addressing multifaceted confidentiality issues, distinguishing clinical from forensic terms, understanding and respecting legal definitions and the institutions from which they flow, working with attorneys and courts to gain sufficient knowledge and comprehension of the forensic questions to be answered, and carefully attending to the policies, statutes, and regulations that define the parameters of the forensic work to be done. The legal realm is not a comfortable one for most medical and psychiatric practitioners; the authors suggest that becoming familiar with this territory and asking for expert consultation when needed will allow those interested in or specializing in addictive illness to enrich their professional experience.

Introduction

Substance use disorders affect the body and brain on multiple levels and may have long-term disabling effects on the ability to function independently and meet the demands of daily living [26, 30, 54]. Although extensive scientific and medical research describes the biological basis for addictive disorders [6, 31, 48, 91, 92], legal and policy practitioners and those in the social sciences still debate the origins and consequences of addiction. Some see addiction as a moral failing that must be dealt with as such, and others see addiction as a medical disease to be treated. There is disagreement about the degree of volition involved in substance use disorders, what activities related to substance use disorders are worthy of sanction and punishment, and what legal actions to take when illegal activities occur as an antecedent or consequence of substance use disorders [93]. The role of environmental context and the interaction between environmental context and neurobiological and genetic factors also figure into the debate [17, 93]. This debate is more than theoretical—arguments on both sides can have a direct effect on policies and practices that have a substantial impact on the daily lives of people with substance use disorders.

People with substance use disorders, both those in recovery and those who are currently using, often have difficulty finding access to resources, employment, health care, and education, and they are vulnerable to high rates of incarceration, morbidity, and mortality [51].

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_73,

However, although provisions are made for those in recovery, those with substance use disorders who are currently using illegal substances are specifically excluded from the protections of the Americans with Disabilities Act [4] and the disability entitlements provided by the Social Security Administration through Supplemental Security Income and Social Security Disability Insurance [24]. Those in recovery who are currently not using illegal substances are covered. However, the varying definitions of what qualifies as "in recovery" often render the process of obtaining benefits or protections difficult and cumbersome.

The public health burden of substance use disorders becomes magnified when individuals who are impaired cannot obtain needed treatment. Medicaid managed care provides health care to people with low income and few resources. Medicaid is a publicly purchased product funded by the federal government jointly with individual states and is administered by states. Most states do not require Medicaid to provide full coverage of substance abuse treatment. Without adequate coverage, people with substance use disorders are at increased risk of developing more severe substance use disorders, becoming homeless, contracting other serious medical illnesses, transmitting communicable diseases to others, and cycling in and out of the public health system with additional stigmatizing labels (e.g., "difficult", "repeater", "recidivist", "a train wreck", "trouble", "hopeless", "one of those").

The current policies governing entitlements, protections, and medical coverage raise fundamental concerns about civil rights, equality, and fairness for people affected by substance use disorders, both those in recovery and those currently using. These policies reflect varying understandings of what it means to have a disability. Given that disability is a legal and administrative term, rather than a medical one, this variation is not surprising.

The meaning of disability may vary according to jurisdiction and can change over time with respect to legislation, policy, regulations, and ideology. The term is specifically defined to determine those who are considered to have a disability under the Americans with Disabilities Act or who are eligible for state and federal disability and rehabilitation benefits. Individuals with addictions are protected under the Americans with Disabilities Act only if illegal drug use has ceased; those actively using illegal substances are not protected [24]. Those addicted to and currently using alcohol fall under the protection of the Americans with Disabilities Act. However, an employer may discipline, discharge, or deny employment to a person with alcohol problems whose alcohol use adversely affects job performance or conduct, and the Americans with Disabilities Act permits employers to keep the workplace free of alcohol use [89].

Under the Americans with Disabilities Act, a disability is defined as a condition that demonstrates at least one of three elements:

- A physical or mental impairment that substantially limits one or more major life activities
- A record of a substantially limiting impairment
- Being viewed as having a disabling impairment [4]

"Major life activities" include "caring for oneself, performing manual tasks, walking, seeing, hearing, speaking, breathing, learning, and working" [4]. "Substantially limiting" is defined as "unable to perform a major life activity that the average person in the general population can perform" [4]. Factors that influence this determination are the nature and severity of the impairment, its duration, and its impact over time. It is difficult to empirically establish when an individual's impairment "substantially limits" performance compared with the performance of an "average" person, so the interpretation of this provision is a matter of subjective judgment.

The Prevalence of Disability in People Who Abuse Substances

The prevalence of disability in people with substance use disorders has not been well

characterized [5]. Studies of the co-occurrence of disability and substance abuse give a partial picture of the landscape, and data from large national studies on drug and alcohol use add to that picture. This composite gives a general, if imperfect, overview.

The majority of the epidemiological data available on the prevalence of drug use in persons with disabilities measures the prevalence of co-occurring disabling mental disorders and substance use disorders. A 2002 report prepared by the U.S. Department of Health and Human Services, Substance Abuse and Mental Health Services Administration's Division of Population Surveys, Office of Applied Studies, described the co-occurrence of serious mental illness and substance use disorders [29]. In 2002, 33.2 million adults ages 18 and older had either a serious mental illness or a substance use disorder. Of these adults, 4.0 million (12.2%) had both a serious mental illness and a substance use disorder.

The National Association on Alcohol, Drugs and Disability published a report in 1999 that measured prevalence of co-occurring disability for brain and spinal cord injuries as well as mental disorders. This report found that 50% of individuals with traumatic brain injuries, spinal cord injuries, or mental disorders had problems with substance use [20].

The National Epidemiological Survey on Alcohol and Related Conditions is a nationally representative face-to-face survey of the civilian, noninstitutionalized population in the United States, aged 18 years and older. Hasin and colleagues [40] examined disability in association with substance use disorder diagnoses in the National Epidemiological Survey on Alcohol and Related Conditions as measured by the Short Form 12 Version 2 [30]. The Short Form 12 Version 2 mental impairment scales included the mental component summary, mental health, social functioning (limitations caused by emotional problems), and role emotional functioning (the impact on social roles). Each Short Form 12 Version 2 score has an expected value of 50 in the general population and a standardized range of 0–100 points. Scores lower than 50 indicated a higher-than-expected rate of disability.

Mean Short Form 12 Version 2 scores for those with current alcohol abuse ranged from 48.8 to 49.8, or just below normal. Scores for those with alcohol dependence were lower, from 47.3 to 48.2. After adjusting for sociodemographic characteristics and other disorders, alcohol abuse was associated with low social functioning and role emotional functioning scores, whereas alcohol dependence was highly and significantly associated with low mental component summary, mental health, social functioning, and role emotional functioning. Overall, this is interpreted to show that, as compared with those who do not abuse alcohol, people who do experience greater limitations in emotional functioning as well as impaired social role abilities caused by these limitations. Disability increased steadily and significantly with the severity of alcohol dependence.

Compton and colleagues performed the same type of analysis for people with histories of drug abuse and dependence. The authors found that the mental component summary and the mental health, social functioning, and role emotional functioning scores on the Short Form 12 Version 2 for those with drug use disorders were approximately two points below average. Scores for those with drug dependence were as much as ten points below average. After adjusting for sociodemographic characteristics and other disorders, drug abuse (like alcohol abuse) was associated with lower mental component summary, mental health, social functioning, and role emotional functioning scores. Drug dependence led to much lower scores across the board, leading to the conclusion that drug dependence was clearly more disabling than abuse [21].

The National Comorbidity Survey: Replication was a nationally representative sample of respondents aged 18 years and older that measured the prevalence and correlates of mental disorders. It was funded by and implemented through the National Institute of Mental Health. According to the National Comorbidity Survey: Replication, 51.4% of people with a lifetime substance use disorder showed evidence of a mental disorder, and 50.9% of those with a mental disorder had a history of at least one substance use disorder [15].

For details on the prevalence of substance use disorders in people with disabilities, please see the section titled "Substance Abuse and People with Disabilities."

Discrimination Protections for Persons with Disabilities

Rehabilitation Act of 1973, Title V, Section 504

Historically, the legal protections for people with disabilities that are now in place began in 1973 in Title V of the Rehabilitation Act of 1973, Section 504 [68]. Section 504 titled "Nondiscrimination Under Federal Grants and Programs," protected both persons with addictive disease and those in recovery from such diseases under federal law. Specifically, the act stipulated that any organization receiving federal funds could not discriminate against people who were currently addicted to drugs or alcohol or in recovery from either condition [68].

Americans with Disabilities Act

The Rehabilitation Act of 1973 was a significant milestone that recognized the need to protect the rights of those with disabilities. It was, however, not comprehensive, so lobbying continued on the part of people with disabilities and their advocates. Their efforts bore fruit, and the Americans with Disabilities Act was enacted on July 26, 1990 [4]. The primary objective of the Americans with Disabilities Act is to extend maximum opportunity for full community participation to persons with disabilities in both public and private sectors of the United States. The Americans with Disabilities Act prohibits employment discrimination on the basis of disability in both private and public sectors, extending the protections of the Rehabilitation Act of 1973 beyond federally funded and conducted activities. In particular, the Americans with Disabilities Act applies to private employment, all publicly funded services, and public accommodations and services managed by private organizations.

When the Americans with Disabilities Act was being developed, however, there were efforts in Congress to exclude certain groups, including those with drug and alcohol addictions [28]. When the Americans with Disabilities Act was passed, protections for people who use illicit drugs that were present in Section 504 of the Rehabilitation Act of 1973 were dropped. Anyone who is currently engaged in the illegal use of drugs is not considered a qualified person with a disability under the Americans with Disabilities Act. However, those who have completed or are participating in a supervised rehabilitation program and are no longer using illegal drugs are protected, as are those who are erroneously regarded as engaged in illegal drug use [4]. The implication is that an individual who is addicted to heroin, for example, must be abstinent from the use of heroin to qualify for the protections afforded by the Americans with Disabilities Act. However, by definition addiction involves uncontrollable use of legal or illegal substances or both.

Many individuals who are impaired because of their addiction are unable to perform one or more major life activities and are viewed as disabled. It follows logically that at least one of the three criteria for disability as defined by the Americans with Disabilities Act has been met. However, the exclusion of people actively using illegal substances is likely meant to send a punitive message to those who are breaking the law. The sequelae of addiction (whether to caffeine, alcohol, nicotine, prescribed medications, or illegal substances) are similar, and distinctions made by drug class, with respect to the three criteria associated with disability, are hard to defend. The statute is particularly important for many people with substance use disorders who have co-occurring mental disorders. This population often faces difficulties in finding and holding jobs, in part because of the stigma attached to both addiction and mental disorders [37]. However, disabling psychiatric illnesses that meet any of the three criteria for

disabilities are considered qualified disabilities under the ADA.

In addition to the Americans with Disabilities Act's exclusion of those currently using illegal drugs, the act has several barriers that are of concern to the substance use disorders services and treatment community and to those with these disorders who wish to claim protection under the Act. As noted above, people with substance use disorders who are not currently using illicit drugs can claim protection from employment discrimination under the Americans with Disabilities Act. However, the meaning of "current" use is vague. Some court decisions have been equivocal about when recovery begins, requiring a period of active stability of, for example, six months, to be considered "in recovery," and therefore eligible for the Americans with Disabilities Act protections [95]. Employees who have alcoholism or who use illegal drugs must meet the same standards other employees are held to, even if their unsatisfactory behavior is attributable to their use of substances [4]. Lastly, employees must not pose a "direct threat" to others because of their substance use—a term that, like "current" use, has been debated frequently in litigation [95].

Protections against discrimination for people who actively use drugs and alcohol are influenced by current law and can change depending on case law rulings. Several recent decisions narrowed the focus of the Americans with Disabilities Act's protections and increased the barriers that individuals who are disabled or impaired must overcome to obtain equal opportunities in the United States. The emerging body of restrictive case law necessitated passage of the Americans with Disabilities Act Amendments Act of 2008 to reaffirm Congress's original intent.

Key Case Law for the Americans with Disabilities Act, 1990

Interpretation of the Americans with Disabilities Act is established through trial law as individual cases are considered; therefore, the rights accorded to people that are in recovery and those who are actively using are often determined in an administrative law hearing or through precedents established by court cases. The Americans with Disabilities Act offers technical definitions of disability and delineates the applications of and exceptions to these definitions. Nevertheless, the U.S. judicial system has the authority to interpret the act and determine the extent to which a particular impairment qualifies as a disability.

Raytheon v. *Hernandez*

Raytheon v. *Hernandez* [67] was a case that explored the extent to which employers can classify substance use disorder-related behaviors as willful misconduct rather than behaviors related to the substance use disorder. This case eventually appeared before the Supreme Court, and the decisions from *Raytheon* v. *Hernandez* may have an impact on how the Americans with Disabilities Act protections are applied to people in recovery from substance use disorders. Joel Hernandez applied for a position at Raytheon in 1994. He had previously worked for Raytheon (at that time Hughes Missile Systems) from 1966 to 1991. During his employment, he had experienced on-the-job challenges related to substance use disorder, but treatment efforts supported by his company were unsuccessful. One day Mr. Hernandez came to work with alcohol and cocaine in his system, which his employers confirmed through a drug test. Mr. Hernandez was offered the option to resign or face termination. He resigned.

After two years in recovery from his substance use disorder, Mr. Hernandez applied for a position doing the same work he had been doing before his resignation, submitting letters from his church and his Alcoholics Anonymous sponsor with his application. The company had a no rehire policy for ex-employees who had been terminated because of "misconduct," and Mr. Hernandez did not get the job. Mr. Hernandez surmised that he was being discriminated against because of his substance use disorder history. The Equal Employment

Opportunity Commission supported his claim of discrimination and granted him permission to sue Raytheon for violating his rights under the Americans with Disabilities Act [27].

The case was heard by the U.S. District Court in Arizona, which ruled in favor of Raytheon. Mr. Hernandez then appealed to the Ninth District Court of Appeals, which reversed the lower court's ruling [27]. Raytheon appealed the Ninth Circuit Court's decision, and the case was eventually argued before the Supreme Court of the United States on October 8, 2003, and decided on December 2, 2003 [67]. The Supreme Court upheld the ruling of the Arizona District Court in favor of Raytheon, stating that Mr. Hernandez was not passed over because of his substance use disorder history and, therefore, was not the object of disparate treatment because of his disability, as he claimed in his arguments.

The opinion of the Supreme Court, as delivered by Justice Thomas, was that "Petitioner's [Raytheon's] proffer of its neutral no-rehire policy plainly satisfied its obligation under McDonnell Douglas [a previous decision] to provide a legitimate, nondiscriminatory reason for refusing to rehire respondent" [67]. The opinion of the Court found that there was insufficient evidence to prove that Raytheon did not rehire Mr. Hernandez because of his substance use disorder history. In effect, the ruling allowed Raytheon to characterize Mr. Hernandez's behavior on the day he came to work under the influence of alcohol and cocaine as willful misconduct, rather than as behavior consistent with a treatable substance use disorder [17, 27, 28, 93].

The "Sutton Trilogy"

The "Sutton trilogy" refers to three rulings issued by the U.S. Supreme Court in Spring 1999. These cases addressed how the possibility of devices, medication, or even unconscious neuropsychological phenomena that mitigate a disabling condition can affect a person's disability status [52]. The first case, *Sutton* v. *United Air Lines, Inc.*, found that twin sisters with severe myopia that could be corrected to 20/20 vision with glasses were not protected under the Americans with Disabilities Act because the glasses mitigated the disability by improving their vision [80]. The second case, *Albertson's Inc.* v. *Kirkingburg*, found that Mr. Kirkingburg, a truck driver who was blind in one eye, was not protected under the Americans with Disabilities Act because he had developed the ability to compensate automatically for his lack of depth perception [3]. His compensation mitigated his disability. The third case, *Murphy* v. *the United States Postal Service, Inc.*, found that Mr. Murphy, a mechanic also required to drive a truck who was dismissed because his blood pressure did not meet Department of Transportation's health guidelines, was not protected by the Americans with Disabilities Act because, when medicated, his high blood pressure was near normal; also, he could still work as a mechanic, so he was not considered disabled [56].

In these three examples, mitigating factors included such things as medications, corrective lenses, and even neuropsychological phenomenon, all of which reduced the severity of the impairment. Recovery may be viewed as "mitigation" for people with substance use disorders, but a history of drug addiction still carries a significant burden of social stigma. People with substance use disorder histories may still require the Americans with Disabilities Act's protections, even though their technical "impairment" has been mitigated [28].

Americans with Disabilities Act Amendments Act of 2008

The Americans with Disabilities Act Amendments Act of 2008, which was signed into law on September 25, 2008, and became effective on January 1, 2009, amended the Americans with Disabilities Act of 1990 to redefine the term "disability." This change marks a broader interpretation of, and coverage for, individuals with a disability. The Americans with Disabilities Act Amendments Act of 2008

overturned the mitigating-measures holding of *Sutton* v. *United Air Lines* (1999), which had been applied to deprive many individuals with disabilities of the Americans with Disabilities Act's protections as described previously in this chapter [22]. A key purpose of the Act was to reinstate the "broad scope of protection" Congress intended to be available [4]. The new law clarifies that the effects of "mitigating measures," such as hearing aids and prosthetics, could not be used in weighing how a person's disability affects life activities [23]. The 2008 legislation also overturned the restrictive interpretation of "substantially limits," often narrowly interpreted by court rulings [22]. These changes now create an easier path for establishing that a person has a disability within Americans with Disabilities Act guidelines, and for a disabled person to seek protection under this Act. Passage of the legislation also extends protections to people with disabilities not immediately evident in the workplace, such as those of the immune, digestive, and neurological systems. The clarification that a major life activity includes the "operation of a major bodily function" may benefit some persons who are not currently using but do have some of the long-term disabling effects of drug or alcohol use described in the section of this chapter on "The Role of Addictive Disorders in Developing Disability." None of the changes, however, specifically referred to illegal use of drugs or alcoholism.

History of Entitlements for People with Disabilities and the Place of People Who Abuse Substances

In the past, Supplemental Security Income and Social Security Disability Insurance programs provided monetary assistance as well as medical benefits to individuals with substance use disorders because substance abuse was considered a qualifying impairment. The level of oversight and scrutiny of Supplemental Security Income/Social Security Disability Insurance recipients with substance use disorders was much higher compared with that of other beneficiaries. In particular, a referral monitoring agency was enlisted by the Social Security Administration to ensure that Supplemental Security Income recipients with substance use disorders were compliant with treatment. People with substance use disorders did not receive their own entitlement checks. Instead, the checks were sent monthly to a representative payee, who disbursed the funds. The benefits were not to exceed three years.

There were problems associated with this method of organizing benefits for those with substance use disorders. At one point, the number of people with substance use disorders receiving disability benefits increased by more than 500% in a four-year period, and the Social Security Administration found it difficult to establish whether recipients were in treatment. One study found the rates of rehabilitation and returns to work were very low. There was also evidence that representative payees were allowing income to be used to purchase drugs [38].

Under the Clinton Administration, enactment of the Contract with America Advancement Act of 1996 (PL 104–121) made important changes that affected people with substance use disorders [38]. In particular, the Social Security Administration terminated payments for Social Security Disability Insurance and Supplemental Security Income on the basis of addiction alone. When someone has a co-occurring disabling condition and an active substance use disorder, the Social Security Administration must currently determine whether the disability being claimed is the result of a medical condition or the result of the effects of active drug use. The disability must be present even if consumption of alcohol and drugs has ceased. This determination is made by theoretically removing the limitations resulting from the substance use disorder and then deciding whether the remaining limitations from other impairments would still be disabling. Only after such an analysis can a determination of disability be made [71]. This situation points to the complexities in classifying

addiction as a disability in the current legislative climate.

Before PL 104–121, people with substance use disorders who received Supplemental Security Income and Social Security Disability Insurance for at least two years were eligible to receive Medicaid (for Supplemental Security Income) and Medicare (for Social Security Disability Insurance) [71]. A significant amount of federal funds for substance use disorder treatment flowed to the states through the two programs. With the new legislation, determination of benefits is now made by the states, and states vary to a considerable degree in how they fund substance abuse treatment [6]. Some states fully cover a course of treatment, whereas others only partially reimburse substance abuse treatment.

The clinical and social effects of the decision to eliminate Supplemental Security Income and Social Security Disability Insurance benefits for substance use disorders in 1996 are substantial for people with substance use disorders who are now ineligible for this resource. Although the problems inherent in the previous legislation were removed by eliminating the entitlement, other concerns have arisen that have an impact on public health and the individual costs of addiction to society. First, participation in substance abuse treatment has been reduced because the incentive to seek treatment has been removed. One primary barrier to treatment for people with substance use disorders is lack of financial resources to pay for services [70], and loss of Social Security Disability Insurance and Supplemental Security Income results in loss of Medicaid and Medicare coverage that would have paid for substance abuse treatment [38, 94]. Finally, the substantial prevalence of people with substance use disorders and co-occurring mental illnesses [20, 36, 38] creates an empirical and scientific challenge for the Social Security Administration. It is difficult to make materiality determinations if the agency cannot separate the functional limitations that each condition imposes.

There is no evidence in the scientific literature that indicates whether and how the limitations from substance use disorders can be completely separated from the limitations of a mental condition when both are present. This paradox underscores a lack of reliability and validity in the disability determination process when people with co-occurring disorders apply for disability benefits; many cases will remain undetermined or delayed in the decision-making process. In the meantime, a person who is truly disabled may not be able to gain access to the resources that he or she needs to make a recovery that would both improve quality of life and reduce costs to society.

Availability of Treatment and Medical Coverage

The definitions of disability have several implications for the treatment and medical coverage of people with substance use disorders. These implications have been described in the philosophical, legal, policy, legislative, and advocacy literature [12, 45, 65, 71, 93, 95]. The nature of addiction leaves a person with a substance use disorder at increased risk for multiple other medical conditions, chronic diseases, and disabling impairments [12]. Should society be obliged to pay for medical services for people with substance use disorders who have knowingly initiated an activity that was not sanctioned by society, was dangerous, and was in some instances illegal? This is a point of philosophical debate [45]. Given that society does not have unlimited resources for everyone in need of health care, is society required to pay for medical problems that result from a behavior the individual, theoretically, voluntarily undertook while fully aware of the potential consequences beforehand?

Those who object to caring for people with substance use disorders usually advocate a moral argument. Those who do not object to caring for people with substance use disorders may argue that it is unjust as well as naïve to assume that society has the capacity to determine the extent to which any behavior is voluntary in a given context. There is also empirical evidence from

the bio-behavioral underpinnings of addiction that it is a brain disease [6, 31, 51, 91, 92]. There is, therefore, a disparity between the language and underlying assumptions of the scientific research, which generally describe addiction as a chronic and relapsing treatable condition, and federal law, which deprives some people with substance use disorders of the resources and rights granted to those with non-substance use disorder conditions.

For example, the Americans with Disabilities Act protects qualified individuals with disabilities from discrimination in the workplace and addresses benefits with respect to employer-sponsored health plans under Title I of the act [4]. Title II of the Act provides protections from discrimination by public entities such as federal, state, and local governments through a contractual agreement [4]. Medicaid managed care, which is a publicly purchased product, falls under Title I of the Americans with Disabilities Act [71].

In applying the Americans with Disabilities Act to health insurance, including managed care, only certain practices can be challenged. Courts tend to distinguish between matters related to benefit design (e.g., what to cover, how much to cover, and other issues that go to the basic design of the benefits extended to employees) and cases that relate to the individual allocation of benefits. Benefit design decisions determine the structure of the benefit plan for all members and affect every member of the group regardless of individual health needs. However, other issues arise when the terms of the benefit plan are applied to individual cases [71].

Currently, Medicaid managed care is intended to benefit individuals and families with low incomes and few resources. It is jointly funded by the states and the federal government, and managed by the states. At this time, most states do not require health insurance policies to provide the same level of coverage for substance abuse treatment as is offered for medical or surgical treatment, and in some states substance abuse services are not even covered at the level of mental health treatment [57]. Although 44 States mandate parity between mental health and surgical or medical conditions, only 18 of these require parity for substance abuse or alcoholism [42]. Benefit design, or the amount of coverage associated with managed care models, has contributed to or reinforced discriminatory and disparate health care coverage for people with substance use disorders.

The Impact of Past Policy on Treatment

Understanding the sources of funding for treating substance use disorders is relevant to discussions about current policy and practice as they affect coverage for service costs. A recent analysis of national cost estimates for substance abuse treatment [57] found that 77% of substance abuse treatment spending nationwide in 2003 was funded primarily through public programs, including states, local governments, Medicaid, Medicare, and other federal funding. Private insurance represented only 10% of these treatment expenditures, although it covered 37% of all other health care expenditures [36]. The authors of this analysis speculate that the difference in spending by private insurance for substance use disorder treatment versus all health care may be related to fear of the consequences of disclosing "current" drug use in the work setting. The fact that there are no protections for discrimination against people who currently use drugs under the Americans with Disabilities Act or through other means may have discouraged employees from seeking treatment through private insurance [36]. Another interpretation is simply that employer-funded treatment does not usually support the level of care offered by other sources, so expenditures are less.

The disparate insurance coverage for substance use disorders, along with more stringent controls and monitoring for substance abuse treatment than for general health care, may also account for the lower percentage of substance abuse treatment spending covered by private insurance [36]. Either of these hypotheses is consistent with the systematic marginalization of

people with substance use disorders, although their health care needs are on a par with those suffering from any other medical condition.

The Impact of Legislation Requiring Mental Health and Addiction Parity

Until recently, Congressional actions to address the lack of insurance parity for health care to address substance use disorders were unsuccessful. In October 3, 2008, however, the Paul Wellstone and Pete Domenici Mental Health Parity and Addiction Equity Act of 2008 (usually referred to as the Parity Act) was signed into law. Ultimately, this Act will end discriminatory coverage in the vast majority of health plans in America [34].

The Parity Act requires covered health plans to provide the same financial terms, conditions, and requirements for mental health and addictions as they provide for medical and surgical conditions. Parity will be implemented by states, Medicaid agencies and Medicaid health plans, commercial health plans, health maintenance organizations, and managed behavioral health organizations, taking effect for most plans on January 1, 2010. Those *not* required to comply with its provisions include Medicare, employers with fewer than 50 employees, and plans that can show that because of the new requirements, their total premium costs increase more than 2% in the first year or 1% in a subsequent year [53]. The plan also will not result in greater access and coverage in states with Medicaid programs that do not cover substance abuse disorders.

Following is a brief summary of the Act:

- Mental health and addiction treatment cost-sharing, deductibles, co-pays and other forms of coinsurance as well as annual limits and lifetime limits must be equal to those covering medical and surgical conditions.
- Limitations on the scope of treatment and treatment frequency and duration cannot be more restrictive than those limiting medical conditions and care.
- Where allowed for other conditions, out-of-network benefits for mental health and addictions treatment must be provided and must be equal to those provided for medical and surgical benefits.
- Stronger state parity laws are not preempted by the Act.
- Plans can determine coverage on a case-by-case basis, but they must provide members, consumers, and providers with their criteria for determining medical necessity and with reasons for benefits/coverage or claims denial.

As a result of this legislation, people with substance use disorders who qualify for protection under the Americans with Disabilities Act and who are insured by a qualifying health plan will have coverage limitations on par with their medical and surgical coverage. The parity law will improve on the state-level parity and mandates of 32 states that currently offer no substance abuse parity and will enhance coverage in the 18 states that do provide some form of substance abuse parity.

The inclusion of substance abuse in this version of parity comes as no surprise. There is little argument with the overwhelming evidence that substance abuse and addictive conditions are serious medical conditions that take a great toll on the lives of individuals, their families, and their communities. Numerous studies have demonstrated the neurological, physiological, and genetic dimensions of addiction. The notion that addictions cannot be treated successfully has been disproven by outcome data, and scientifically valid evidence exists to support a wide range of best practices in treatment. Lawmakers who supported parity in 2008 understood and affirmed these facts.

The Role of Addictive Disorders in Developing Disability

Most drugs of abuse can cause adverse health conditions, but the conditions rarely rise to the level of a disability as defined by the

Americans with Disabilities Act or the Social Security Administration. If a person has discontinued drug use, the source of a disabling condition is immaterial to the protections provided by the Americans with Disabilities Act and eligibility for benefits from the Social Security Administration. Disabling conditions that are protected under the Americans with Disabilities Act can include infectious diseases and psychological illnesses as well as substantial physical impairment. The long-term physical effects of different substances vary widely; disabilities that arise from drug use include human immunodeficiency virus, difficulties with memory or cognition, clinical depression and drug-induced psychosis, brain damage from injuries sustained while under the influence of a drug, and musculoskeletal impairments arising from spinal chord injuries. People who abuse drugs are most likely to become disabled through impaired function while under the influence of the drug (e.g., falls and injuries from accidents or injuries from driving while intoxicated).

This section explains the long-term effects of the different classes of drugs of abuse, with details about neurological, physical, sensory, and functional impairment from each class. It examines the most common and debilitating effects of alcohol, illegal stimulants (e.g., cocaine, methamphetamine and methylenedioxymethamphetamine; prescription medications that are diverted to use as drugs of abuse, and substances that are used as drugs of abuse [e.g., androgenic anabolic steroids and solvent inhalants]). The risks to children born to mothers who abuse drugs and the complicated relationship between current disability and drug abuse and dependence are also discussed.

Table 1 provides a summary of many of the common medical consequences of alcohol and abuse of certain illegal substances (opioids and cocaine), as well as medical consequences that can result from injecting drugs. These consequences are classified according to the organ systems affected.

Alcohol

There is extensive literature on the many disabling conditions that can arise from alcohol abuse and dependence. Details of a few of the most common physical and neurological complications are provided below. Long-term alcohol abuse can harm most of the body's organ systems, including the liver, the immune system, the cardiovascular system, and the skeletal system [1, 39].

Injury

The most common disabling condition related to alcohol abuse is spinal cord injury from car crashes, falls, and other accidents [83]. Up to 50% of patients with spinal cord injuries were intoxicated at the time of injury, and those who were intoxicated at the time of injury are likely to have a history of alcohol abuse [41, 83]. Alcohol use is a major risk factor for both fatal and nonfatal injuries; the prevalence of nonfatal injuries is higher among people who abuse substances than in the general population [11, 41, 55].

In a literature review that examined the role of substance abuse in the cause of injury for patients using rehabilitation services, Hubbard and colleagues found that up to 79% of rehabilitation patients had alcohol-related traumatic injuries and that 35% of automobile injuries, 55% of motor vehicle deaths, 40% of drownings, and 30% of noncommercial airplane crashes were related to alcohol. Up to 72% of patients with head injuries from car crashes had positive blood alcohol levels. There was a 25–68% prevalence of preinjury alcohol addiction in head injury patients. Possible gender differences in these rates are worth noting; one study showed that, although 62% of males had positive blood alcohol levels at the time of head injury, only 27% of females had positive blood alcohol levels. Drinking or intoxication appeared to be involved in up to 79% of spinal cord injuries [41].

Table 1 Common medical consequences of alcohol and illegal substance abuse

	Drug of Abuse			
Organ system	Alcohol	Opioids	Cocaine	Injection effects
Cardiovascular	Cardiomyopathy Atrial fibrillation Hypertension Dysrhythmia Coronary artery spasm Myocardial ischemia Coronary artery disease Sudden death	N/A	Angina Aortic dissection Atrial Ventricular fibrillation Cardiomyopathy Supraventricular tachycardia Hypertension Moyamoya vasculopathy Left ventricular hypertrophy Ventricular dysrhythmias Myocarditis Sudden death	Endocarditis Thrombophlebitis
Endocrine	Hypoglycemia/ hyperglycemia Diabetes Ketoacidosis Hypertriglyceridemia Hyperuricemia and gout Gynecomastia Reversible hyperparathyroidism Osteopenia Infertility Amenorrhea	Osteopenia Gonadotropin alteration Decreased sperm motility Menstrual irregularities Amenorrhea	Diabetic ketoacidosis Amenorrhea	N/A
Gastrointestinal	Gastritis Esophagitis Pancreatitis Diarrhea Malabsorption Parotid enlargement Malignancy Colitis Barrett esophagus Gastroesophageal reflux Mallory-Weiss syndrome Gastrointestinal bleeding	Constipation Ileus Nausea	Ischemic bowel Colitis Nausea	N/A

This table is based on the sources [7, 35, 50, 58, 59, 66, 69]

Several studies have identified the high risk of injury in people with alcohol use disorders. In a case-control study at an emergency department in Mexico City, the prevalence of substance abuse or dependence in the last 12 months was 12.3% for alcohol compared with a prevalence of 1.8 % in a representative sample of residents of Mexico City of the same age group [11]. A retrospective cohort study of medical claims data on patients with alcohol- or drug-related primary or secondary diagnosis by Miller and colleagues estimated the excess risk of medically treated and hospitalized nonoccupational injury for people younger than age 65 with medically identified substance abuse. They found that people who were medically identified as abusing substances had a higher risk of injury in a three-year period. People who abused alcohol and drugs were almost four times as likely to be hospitalized for an injury during the three-year period as controls, and the risk of injury was substantially higher for female than male users of substances [55].

Organ Systems

Liver

Liver disease is a common debilitating result of alcohol abuse. Long-term, heavy alcohol use is the leading cause of illness and death from liver disease in the United States, with more than 2 million suffering from alcoholic liver disease ranging in severity from fatty liver to end-stage cirrhosis. Women develop alcoholic hepatitis and alcoholic cirrhosis after fewer years of drinking and smaller daily amounts of alcohol than men do [1, 55].

There are three forms of alcoholic liver disease: fatty liver, which is usually reversible with abstinence; alcoholic hepatitis, characterized by persistent liver inflammation; and cirrhosis, characterized by progressive scarring of liver tissue [77]. More than one type of liver disease can be present at the same time. Individuals with both cirrhosis and alcoholic hepatitis have a death rate of more than 60% over a four-year period, with most deaths occurring within the first 12 months of diagnosis [14, 55].

Alcohol initially causes liver injury by generating harmful metabolites, and continuing alcohol use exacerbates the initial injury. Chronic alcohol use leads to inflammation and weakens the ability of the liver to repair itself. It also leads to increased firbrogenesis, a major source of eventual cirrhosis [77].

Neurological and Social Functioning

Neurological complications from alcohol also lead to substantial long-term disabling conditions. Lasting cognitive impairment in people with alcoholism can be direct, through brain damage from long-term alcohol exposure, or indirect, as a result of head trauma, central nervous system infection, hepatic failure, or nutritional deficiency. Direct neurologic consequences of long-term alcohol use include Wernicke-Korsakoff syndrome, Marchiafava-Bignami syndrome, and central pontine myelinosis. Wernicke's syndrome, in which decreased attentiveness, alertness, and memory are usually accompanied by disordered eye movements and ataxia, is often followed by Korsakoff's dementia, a lasting amnestic disorder. Marchiafava-Bignami syndrome and central pontine myelinosis are related to damage to the myelin sheath of neurons in the corpus callosum and pons, respectively [14, 73]. Studies have shown that alcohol also directly damages the cerebrum sufficiently to cause dementia [14].

Alcohol dependence and abuse have profound effects on social and neuropsychiatric functioning. In a report on the results from the National Epidemiological Survey on Alcohol and Related Conditions, Hasin and colleagues measured the prevalence, correlates, disability, and comorbidities associated with alcohol abuse and dependence in the United States. Adjusting for sociodemographic characteristics and other disorders, alcohol abuse was associated with lower social and role function. Alcohol dependence was significantly associated with lower mental health and social and role function. The

level of disability was closely correlated with severity of alcohol dependence [39].

Immune System

Excessive alcohol consumption can lead to increased rates of illness and death from infectious diseases. People who abuse alcohol suffer from increased susceptibility to bacterial pneumonia, pulmonary tuberculosis, and hepatitis C virus. Individuals with alcoholic liver disease are at high risk of contracting hepatitis C virus. Individuals with alcoholic liver disease who are hepatitis C virus-positive have more severe liver disease and are younger than hepatitis C virus-negative individuals. This may reflect impaired immune function caused by alcohol abuse. Compared with people who do not abuse alcohol, those who do may also be at increased risk for infection with human immunodeficiency virus from risky sex practices while intoxicated. There is also research currently under way to investigate the possibility that alcohol consumption itself may increase susceptibility to human immunodeficiency virus infection or hasten the progression from human immunodeficiency virus infection to full-blown acquired immunodeficiency syndrome. Some alcohol-related organ damage may result in an autoimmune reaction [1, 73].

Cardiovascular System

Chronic heavy drinking is a leading cause of cardiovascular illnesses such as cardiomyopathy, coronary heart disease, high blood pressure, arrhythmias, and stroke. In alcoholic cardiomyopathy, long-term heavy drinking can enlarge the heart and impair its ability to contract. Symptoms of cardiomyopathy include shortness of breath and insufficient blood flow to the rest of the body. Women may have a greater risk than men of developing alcoholic cardiomyopathy. The condition may be at least partially reversible with abstinence [14].

An association between heavy alcohol consumption and increased blood pressure has been observed in more than 60 studies in diverse cultures and populations [1]. Heavy drinking can disrupt the heart rhythm both acutely (during an episode of drinking) and chronically (during long-term use). Intoxication can cause certain types of arrhythmia in both those with alcoholism and otherwise healthy individuals. The development of arrhythmias from binge drinking—a condition seen most frequently around the holidays—is known as "holiday heart syndrome." Sudden death attributable to arrhythmia is one of the causes of mortality in people with alcoholism with or without preexisting heart disease. Such deaths often occur during periods of abstinence, suggesting that arrhythmias are more likely to develop during alcohol withdrawal [1, 14, 73].

Skeletal System

Epidemiologic studies have found a significant association between alcohol consumption and bone fracture risk. In addition to the increased risk of accidental injury from impaired gait and balance, people with alcoholism may also suffer from a generalized decrease in bone mass. Heavy drinking may lead to osteoporosis, characterized by severe back pain, spinal deformity, and increased risk of wrist and hip fractures [1, 14, 73].

Special Populations

Older Adults

Older adults present a particular challenge. Alcohol abuse affects the elderly differently than it affects the young [32]. In people ages 55 and older, long-term and continuing alcohol abuse can have a wide range of physical, psychological, and social effects [25]. Although it causes fewer traumatic fatalities in this population, it is more likely to exacerbate

co-existing illnesses through alcohol–drug interactions, dietary or medication noncompliance, cognitive impairment, aggravated psychiatric illness, or co-morbidities [32]. As is true with younger adults, older adults consuming high amounts of alcohol have increased risks of coronary heart disease, hypertension, gastrointestinal bleed, and hemorrhagic and ischemic stroke, as well as increased rates of alcohol-related liver disease and increased risk of a range of cancers [25]. However, in older adults, these risks are heightened by the aging process and increase morbidity and mortality among older people in medical settings [46].

Alcohol consumption is one of the three main risk factors for falls. It can also contribute to the onset of dementia and other age-related cognitive deficits, Parkinson's disease, and a range of psychological problems, including depression and anxiety [25, 85]. Alcohol is a major contraindication for many medications prescribed for older people. Adverse interactions between alcohol and medication are common, and higher alcohol consumption in older age is associated with a range of social problems including self-neglect, poor nutrition, social isolation, and hypothermia [25].

Illegal Drugs of Abuse

Stimulants (e.g., cocaine, amphetamine, and methylenedioxymethamphetamine) and opioids (e.g., heroin) are illegal in the United States. People who use illegal drugs are at risk for injury and disease through a variety of social factors; in addition, long-term use of most of these substances can lead to documented changes in physical and neurological function.

In a study by Adrian and colleagues that compared the risk for morbid conditions of people who abuse legal drugs, illegal drugs, and alcohol in a large sample of patients in a Canadian hospital, the investigators observed that morbidity from illegal drugs affected fewer body systems, involved far fewer medical conditions, and was lower for most diagnoses when compared with alcohol. However, people who used illegal drugs were more likely to exhibit mental disorders as well as a higher likelihood of injury and poisonings than those who used alcohol, especially people who use legal medications, where poisoning was a result of misusing what are generally legal, therapeutic, prescription medications. People who use illegal drugs were much more likely to present with infectious and parasitic diseases than did people who abused other substances, suggesting more impaired immune function [2].

Toomey and colleagues identified the neurological deficits resulting from cocaine and/or amphetamine abuse by evaluating a group of twins. One twin of each pair was a heavy abuser of one or both drugs whose use had ended at least one year before evaluation. All subjects were tested on attention, executive functioning, motor skills, intelligence, and memory. Persons who had abused drugs demonstrated lower attention and motor skills than their nonabusing twins, showing that cognitive deficiencies persist even after one year of abstinence from drug use [86].

Cocaine

The most common long-term effects of cocaine include complications from stroke, depression, induced psychosis, cognitive deficits, and trauma-related injuries. Cocaine abuse can result in severe depression over the long term. Cocaine psychosis includes such symptoms as aggression and disturbing hallucinations, and people who use over the long term may experience permanent psychosis [60, 73].

People who abuse cocaine often exhibit lasting cognitive deficits even after cessation of use [13, 64]. In a study comparing 20 people in recovery who chronically abused with controls matched for age and education, O'Malley and colleagues used a series of standardized neuropsychological assessment procedures to assess cognitive impairment. They found that people who abused cocaine were 35% more likely than the control population to score in the impaired range of the Neuropsychological

Screening Exam. Those who abused cocaine also performed more poorly on tests for abstract thinking and reasoning and verbal memory. Neuropsychological performance was directly related to the severity of cocaine abuse, suggesting that cocaine played a direct role in affecting cognitive functioning [64].

Cognitive deficits from cocaine are often related to perfusion abnormalities or changes of blood flow in the brain [13, 30]. A study by Browndyke and colleagues showed the relationship between cognitive performance and the magnitude of perfusion abnormality. Their findings indicated significant regional perfusion abnormalities among people who abuse cocaine relative to normal controls and substantial deficits in neuropsychological functioning for people who abuse cocaine [13].

Although the incidence of cerebrovascular dysfunction from cocaine use was relatively low until the late 1990s, it began increasing toward the end of the decade. The vasoactive properties of cocaine and its metabolites can predispose people who use it to more severe cerebrovascular events at an earlier age than those who do not use it, with a poorer prognosis. In a study by Nanda and colleagues, the investigators found that people who abused cocaine were more likely to experience subarachnoid hemorrhage at an earlier age and had poorer outcome than did matched controls [51].

Heroin

The medical complications that arise from the use of heroin are related to the effect of the drug itself as well as the routes of administration, and several of the complications are relevant to all people who inject drugs [84]. Some of the most common and debilitating consequences of heroin use are human immunodeficiency virus/acquired immunodeficiency syndrome; hepatitis B, C, and delta; acute renal failure; abscesses and cellulites; and trauma-related injuries [60, 73].

In relation to the many infective complications of heroin use, recent research suggests that opioids significantly influence peripheral immunomodulatory functions. Endogenous opioids act as immune stimulators, but exogenous opioids such as heroin and related compounds tend to suppress various immune functions. Immune suppression, along with poor nutrition, intravenous routes of administration, polydrug use, and poor living conditions, may explain the prevalence of cutaneous and systemic infection often seen in individuals dependent on heroin.

Hyperalgesia is also a problem in many people in recovery from heroin. A recent study by Rosenblum and colleagues showed that chronic severe pain was prevalent among individuals in substance abuse treatment and that a large minority of those using a methadone maintenance program experienced significant chronic pain. The levels of pain measured in the study were high enough to cause functional impairment in the individuals observed [72].

Methamphetamine

Methamphetamine abuse is a fairly recent phenomenon, so studies on its long-term effects are just emerging. Research from the past decade suggests that methamphetamine dependence may cause long-term neural damage in humans, adversely affecting cognitive processes such as memory and attention. The neurotoxic effects of methamphetamine affect neurotransmitter systems, interfering with normal functioning of dopaminergic, serotonergic, noradrenergic, and glutamatergic systems [62, 63]. A review of the literature by Nordahl and colleagues found that neuroanatomical, neurochemical, and imaging data support the conclusion that methamphetamine abuse causes damage to multiple neurotransmitter systems that are distributed throughout the brain, noting that the permanence of the damage has not yet been determined [63]. The literature review also pointed to studies that showed that long-term methamphetamine use is associated with impaired performance on a number of cognitive tasks, including verbal memory and motor function, manipulation of information, abstract reasoning, and task-shifting strategies [63].

The cognitive impairment observed in people who abuse methamphetamine may also be related to abnormalities of frontal lobes of the brain [19]. Chung and colleagues reported that decreased gray-matter densities and glucose metabolism in the frontal region of the brain were correlated with impaired frontal executive functions (cognitive abilities that control and regulate other abilities and behaviors) in people who abuse methamphetamine. Executive functions are necessary for goal-directed behavior and come into play when adapting to change, in planning for the future, and in abstract thinking.

In a study comparing people who abuse methamphetamine with healthy subjects, Chung and colleagues used diffusion tensor imaging to describe the differences in frontal white-matter integrity and assessed differences in frontal executive functions with the Wisconsin Card Sorting Test. They found that frontal white matter was compromised in people who abuse methamphetamine and that these people showed more errors in the Wisconsin Card Sorting Test relative to healthy subjects. They also noted that the neurotoxic effect of methamphetamine on frontal white matter may be less prominent in women than in men, possibly because of estrogen's neuroprotective effect [19].

Methylenedioxymethamphetamine ("Ecstasy")

Methylenedioxymethamphetamine and related compounds have serious acute and chronic toxic effects that resemble those seen with other amphetamines. Neurotoxicity to the serotonergic system in the brain can also cause permanent physical and psychiatric problems, including confusion, depression, and impaired memory [43, 62]. The brains of people who used methylenedioxymethamphetamine over a long term, when examined while free of the drug, have abnormally low levels of serotonin and its metabolites in the cerebrospinal fluid and other significant alterations of neurotransmitter functioning. In these people there is upregulation of serotinin receptors during abstinence, in response to the decrease in serotonin release caused by the action of the drug. Electroencephalographic studies show changes similar to those seen in aging and dementia and a change in response to auditory stimuli. The prolactin and cortisol responses to stimulation of the serotonin system were reduced in the people who used methylenedioxymethamphetamine. These changes persisted for up to a year or more after the last use of the drug [43].

The demonstrated neurotoxic effects of methylenedioxymethamphetamine on the serotonin system may be the cause of a variety of mental and behavioral problems that outlast the actual drug experience by months or years. These problems are quite varied, but they all involve functions in which serotonin is known to play an important role. Some persistent problems include impaired verbal and visual memory (with the degree of impairment being roughly proportional to the intensity of the preceding use of the drug), decision-making, information processing, logical reasoning, and simple problem solving as well as greater impulsivity and lack of self-control, recurrent paranoia, hallucinations, depersonalization, flashbacks, and even psychotic episodes. Finally, people who use methylenedioxymethamphetamine can experience severe depression that is resistant to any treatment other than selective serotonin reuptake inhibitors [43].

Inhalants

Inhaled solvents are the most commonly abused substances classified as inhalants. Long-term abuse of solvents can cause damage to most organ systems, including the central and peripheral nervous systems and hepatic, renal, pulmonary, and cardiovascular systems. Solvent abuse can also affect bone marrow formation and lead to anemia. Cognitive effects include confusion, forgetfulness, and irritability [16]. The psychiatric and neurological sequelae of chronic solvent abuse are serious and potentially irreversible [16].

A study of the psychiatric and neurological effects of solvent inhalation in a group of 22 individuals with histories of chronic solvent abuse (primarily of toluene-based solvents) found that the chronic inhalation of toluene-based adhesives can produce a paranoid psychosis that may persist. The authors also found a high incidence of temporal lobe epilepsy and a decrease in IQ. They pointed to toluene as a major factor in the morbidity associated with people who chronically abuse solvents [16].

To measure the consequences of long-term exposure to inhaled solvents, Yücel and colleagues reviewed neuroimaging and neuropsychological studies, examining chronic toluene misuse in humans. They found that toluene preferentially affects white matter structures and periventricular/subcortical regions in the brain. They hypothesized that the lipid-dependent distribution and pharmacokinetic properties of toluene would likely explain the pattern of abnormalities, as well as the common symptoms and signs of toluene encephalopathy. The commonly observed neuropsychological deficits such as impairments in processing speed, sustained attention, memory retrieval, executive function, and language are also consistent with white matter pathology [96].

Anabolic Steroids

The abuse of androgenic anabolic steroids can cause high blood pressure, heart attacks, and liver cancer. [42]. Long-term use of anabolic steroids may cause a range of adverse cardiovascular effects, some of which may be irreversible, including cardiomyopathy, dyslipidemia and other artherosclerotic effects, hypertension, myocardial ischemia, and arrhythmias [42]. Anabolic steroids are capable of increasing vascular tone, arterial tension, and platelet aggregation and may give rise to atherothrombotic phenomena [74]. Although there are few reports of ischemic stroke related to anabolic steroid abuse, Santamarina and colleagues reported a case of a 26-year-old male amateur athlete who suffered a posterior territory ischemic stroke, whose only significant risk factor was nonmedical use of stanozolol, an anabolic steroid [74].

Neuroendocrine effects from anabolic steroid abuse can cause infertility and major depressive disorders [42]. In a study of the long-term side effects of high doses of self-administered anabolic steroids, Bonetti and colleagues observed 20 male bodybuilders who voluntarily self-administered anabolic steroids. The subjects were tested every six months over two years. Physical examination, hematological, metabolic and endocrine variables, semen analysis, hepatic and prostate ultrasound, and echocardiographic evaluations were performed. The most important long-term adverse effects observed were lower fertility and sperm counts and impaired lipid profiles associated with increased cardiovascular risk [10].

More rarely, the long-term use of orally active anabolic steroids can have adverse hepatic effects, ultimately resulting in hepatocellular adenomas or carcinomas, although these hepatic effects are often reversible. In vitro studies have shown that concentrations of anabolic steroids comparable with those likely present in many people who abuse steroids can cause apoptosis in human endothelial and neuronal cell lines as well as apoptotic death of myocardial cells in rat models, suggesting the possibility of irreversible neuropsychiatric toxicity as well as a mechanism for the cardiovascular effects already noted. Steroid abuse also appears to be associated with a range of potentially prolonged psychiatric effects, including dependence syndromes, mood syndromes, and progression to other forms of substance abuse, although the prevalence and severity of these various effects are not yet known [42].

Prescription Medications

Individuals who have a history of substance abuse are more likely to abuse other agents, including prescription medications. Drugs classified as prescription medications have become

a major category of abused substances, and there is evidence that the abuse of prescription medications may soon overtake that of illegal drugs. Abused prescription medications include sedative hypnotics, stimulants, and anabolic steroids (discussed above). Other abused prescription medications include anticholinergics and ketamine.

The increasing therapeutic use of opioids coincides with increasing abuse in individuals receiving opioids and nonmedical use of other psychotherapeutic agents, including pain relievers, tranquilizers, stimulants, and sedatives. Opioid use, abuse, and nonmedical use are prevalent in both adults and teenagers in the United States. The 2006 National Survey on Drug Use and Health found that more than 20% of people in the United States ages 12 and older had used prescription psychotherapeutic agents nonmedically during their lifetime. There are multiple adverse consequences to long-term use, including effects on the hormonal and immune system, abuse and addiction, tolerance, and hyperalgesia [49].

Sedative-hypnotic medications, which include benzodiazepines, barbiturates, and non-benzodiazepine anxiolytics are generally prescribed to treat insomnia or anxiety. In current practice, the term "sedative-hypnotic" often refers to benzodiazepines (e.g., diazepam and lorazepam). Neuropsychiatric effects of prolonged sedative-hypnotic addiction include deficits in memory, motor coordination, visuospatial learning, processing speed, and verbal learning. These phenomena have been difficult to study because some of the cognitive difficulties may result from sedation while others result from inattention or abnormally high plasma levels. However, recent meta-analyses have demonstrated that these effects can occur even after drug discontinuation. After drug discontinuation, cognition improves but may not return to the baseline level of function [18].

Prescription therapeutic psychostimulants available in oral formulations through non-refillable prescriptions include amphetamine and amphetamine-like stimulants, such as dextroamphetamine, methylphenidate, and diet pills, which are prescribed for the treatment of attention deficit/hyperactivity disorder, narcolepsy, and obesity. Prescription stimulants are classified as controlled substances with a high potential for dependence or abuse when used outside appropriate medical supervision [18]. With long-term use, stimulants may cause insomnia, irritability, aggressive behavior, and psychosis (e.g., paranoia). Medical complications of acute intoxication with stimulants include altered mental status, autonomic instability (e.g., hyperthermia), seizures, or development of serotonin syndrome [18]. Methylphenidate and dextroamphetamine have been associated with cerebral arteritis, renal necrotizing vasculitis, and systemic and pulmonary hypertension [18, 76, 81].

Risk of Addiction and Disability for Children Born to Mothers Who are Addicted

Drug use during pregnancy can lead to severe problems for the fetus, ranging from increased rates of miscarriage to withdrawal symptoms upon birth to congenital birth defects that persist throughout life. Different drugs of abuse affect the fetus differently, and the severity of the effect is generally related to the level of use during pregnancy. It is important to keep in mind that the effects of illegal drugs on intrauterine development are confounded by ethanol and tobacco use, malnutrition, inadequate prenatal care, and incompetent parenting.

Withdrawal symptoms are seen in the majority of newborns of mothers addicted to heroin or methadone [90]. Opioid use during pregnancy causes a neonatal withdrawal syndrome considerably more severe than that encountered in adults, with symptoms such as tremor, screaming, sneezing, lacrimation, fever, tachycardia, tachypnea, vomiting, and diarrhea. Neonatal withdrawal syndrome is often fatal if left untreated. Some studies have found that infants exposed in utero to heroin are born small for

their gestational age, at risk for respiratory distress, and cognitively impaired later in life, although other studies did not find long-term developmental or cognitive problems after correcting for other risk factors [14].

In a retrospective case controlled study of pregnant women who abused narcotics, Lam and colleagues found that the major antenatal complications were prematurity, small size for gestational age baby, antepartum hemorrhage, and high prevalence of venereal disease. The babies born to mothers with drug addictions had lower birth weight, smaller head circumference, and shorter body length. Neonatal withdrawal symptoms occurred in 83% of all drug-exposed neonates, and the perinatal mortality rate was 2.5 times higher than that of the control group [47].

Cocaine has been shown to affect birth weight and head size [78]. It also has mostly transient central and autonomic nervous system effects [8]. Amphetamine use during pregnancy increases the likelihood of perinatal mortality during premature births [90]. The recent Infant Development, Environment and Lifestyle study screened newborns for exposure in utero to a variety of legal and illegal drugs of abuse. The Neonatal Intensive Care Unit Network Neurobehavioral Scale was administered within the first five days of life for all neonatal subjects. Smith and colleagues analyzed Infant Development, Environment and Lifestyle data to measure methamphetamine effects on newborns, including exposure group effects, heavy methamphetamine use effects, and dose-response relationships with amphetamine metabolites. Exposure to methamphetamine was associated with increased physiological stress in newborns. Heavy methamphetamine use was related to lower arousal, more lethargy, and increased physiological stress. More specifically, first trimester methamphetamine use was related to elevated stress abstinence; and third trimester use was related to a poorer quality of movement. Higher level of amphetamine metabolites in meconium was associated with increased central nervous system stress [79].

Alcohol is an established teratogen. Also, fetal alcohol syndrome can result from drinking during pregnancy. Fetal alcohol syndrome consists of characteristic facial anomalies, impaired prenatal and postnatal growth, and microcephaly with mental retardation. The severity of the syndrome is dose related, with lower amounts of ethanol producing cognitive disturbance without the associated musculoskeletal anomalies [18].

Most studies on the effects of drugs on fetal development and drug abuse have focused on alcohol or illegal drugs of abuse. However, many solvents are strongly teratogenic and cause major birth deformities when used during pregnancy. A study in Manitoba of women who abused solvents during pregnancy found that 21.4% of them delivered infants preterm. Of the newborn infants, 16.1% had major anomalies, 12.5% had facial features similar to those in children with fetal alcohol syndrome, and 10.7% exhibited hearing loss [75].

Substance Abuse and People with Disabilities

People with mental and physical disabilities are at increased risk for substance abuse because of their use of substances (prescribed or used as self-medication) to control pain and the stress of physical handicaps, mood disturbances or other mental problems, vocational difficulties, and problems of self-image. As noted in the section titled "Alcohol," alcohol often contributes to or causes physically debilitating injuries, and other drugs of abuse are also involved in disabling accidental injury [41, 87]. Patients who are congenitally disabled and those with disabilities caused by traumatic injury are prescribed psychotherapeutic medications. The difficulties of life with a disability place many of these people at risk for prescription misuse and abuse [40].

Drug and alcohol abuse in individuals with disabilities from spinal cord injuries can be as high as 79%, both before and after the injury that caused the physical disability [40, 41]. In patients with brain injuries, drug and alcohol

use may decline after the injury, but prevalence of abuse can still be at least 27% [41]. Those with congenital conditions that lead to disability are also at risk for high rates of substance abuse. In a survey of people with multiple sclerosis, Bombardier and colleagues found that up to 19% of those questioned reported some form of substance abuse [9].

The characteristics and prevalence of substance abuse among those with intellectual disabilities are not well characterized, and the issue of substance abuse in those with mental disabilities is somewhat hidden [82]. A study by Taggart and colleagues of adults with co-occurring substance use disorders and intellectual disabilities found that alcohol abuse was most common, followed by abuse of a combination of illicit drugs and/or prescribed medication [82].

The co-occurrence of alcohol and drug abuse disorders and physical and intellectual disabilities creates a complex situation for those receiving Supplemental Security Income disability benefits [5]. At least 50% of people who self-reported as "disabled and unable to work" have co-occurring drug and alcohol use problems [5]. Although most of those with co-occurring substance use disorders and physical and intellectual disabilities are still able to receive Supplemental Security Income benefits despite the changes mandated by the Contract with America Advancement Act of 1996, the current Medicaid managed care environment creates challenges of access to and payment for substance abuse treatment [5].

People with disabilities who abuse substances tend to enter treatment for substance abuse at a much lower rate than those without disabilities [46]. Some barriers to care include lack of transportation, difficulty with physical access to the treatment center, and limited knowledge among treatment providers about the special needs of people with disabilities [5, 46]. A report on alcohol and drug treatment services in Ontario found that, although a substantial percentage of clients had physical disabilities and developmental handicaps, few of the centers had services tailored specifically for persons with disabilities or resources for clients who are physically disabled. Staff felt that clients with developmental handicaps would be better served by specialized programs with additional staff training, while those who were physically disabled could be adequately served by "mainstream" services. Several centers indicated that they would not want better resources for the physically disabled, even if funding was available [88].

Conclusion

The relationship between substance use disorders and disability is intricate. The legal and administrative concepts of disability and the reality of what is actually a disabling condition are often disparate. Although a person with an substance use disorder may effectively be limited in his or her actions and abilities, the moral and legal status of addiction leaves these disorders in a gray area. To complicate matters further, substance use disorders can have long-term effects that render a person, even someone in recovery, permanently compromised—cognitively and/or physically. These effects may often reach the level of disabilities, regardless of the severity of the substance use disorder. In turn, many people with disabilities are at greater risk for developing substance use disorders.

The political climate can substantially affect the help that people with substance use disorders can expect from federal, state, and local agencies. Many people with substance use disorders have faced substantial barriers, including physical limitations, job discrimination, and difficulty obtaining coverage for substance abuse treatment. However, there have been few protections for people with substance use disorders, and being in legal and administrative limbo because of their disorders has left many of those afflicted in a precarious position.

Access to care has also been difficult for many persons with these disorders, particularly those who live in poverty. However, the passage of the Paul Wellstone and Pete Domenici Mental Health and Addiction Equity Act will

end discriminatory coverage by group plans covered in the act and require that access to care be comparable to that provided for surgical and medical conditions. As Medicaid managed care and many employer-sponsored plans respond to these requirements, a slow shift in available treatment options is expected that will benefit many people who rely on publicly-funded addiction treatment and others who rely on employer-funded plans [34].

This chapter tells the story of a moral, legal, political, physical, and mental struggle over disability and addiction that ends with some promise and hope. "If there is no struggle there is no progress; this struggle may be a moral one, or it may be a physical one, and it may be both moral and physical, but it must be a struggle" (Frederick Douglass, August 3, 1857).

Acknowledgments The author would like to acknowledge the efforts of Clarinda Mac Low and Susan Hills, Ph.D., in the development of this chapter.

Introduction

Understanding the composition and needs of the homeless represents a major challenge for all researchers and providers, not least for a group endeavoring to present a chapter summarizing available knowledge about this complex population. Starting with seemingly simple questions, such as defining homelessness, and moving to much more complex questions, such as treatment and other interventions for this population with multiple needs and problems, numerous interrelated issues must be considered. Complicating this discussion, existing research studies share limited methodological commonalities, often making direct comparisons of the findings from the diverse endeavors speculative at best.

Despite these challenges, the purpose of this chapter is: to conceptualize the homeless as a population and discuss population prevalence; to detail rates of substance use and abuse, other mental illness and medical risk factors, and comorbidities; and to identify service models that have been demonstrated effective. Conceptually, this task begins with the complex issue of identifying just what is meant by a "homeless population" and understanding how different inclusion criteria lead to very different prevalence estimates and identified

B.A. Johnson (ed.), *Addiction Medicine*, DOI 10.1007/978-1-4419-0338-9_74,

characteristics of the population. Following the discussion of the definition of homeless population, given the disproportionate rates of substance use and abuse relative to housed populations, the next task is to understand the issues surrounding substance use and disorders, including general estimates of all substances combined and those specific to individual substances. Once substance use and abuse have been presented, it becomes important to understand rates of other psychiatric and other medical illnesses, especially the remarkably high rates of psychiatric comorbidities. This chapter will conclude by discussing treatment needs and reviewing the increasingly available evidence for the effectiveness of specific types of interventions.

Before beginning this examination of homelessness, it is important to note a few caveats. This chapter focuses almost exclusively on homeless adults, specifically single homeless adults. The length constraints of a single chapter preclude discussion of various subpopulations, such as homeless children, runaway and homeless adolescents, single women with children, or homeless families. Further, except where those issues have specific relevance for individual-level risk factors, this chapter does not investigate structural and economic causes for homelessness. A broader consideration of homelessness as an economic or social phenomenon would need to include discussions around housing availability and affordability, extreme poverty, social inequalities, and the impact of policy decisions on rates of homelessness.

Homelessness

Historical Context

Multiple historical events have been linked with current conceptualizations of homelessness, including such disparate populations as those created by sixteenth-century Elizabethan Poor Law, colonization of the North American continent, and itinerant workers in the late nineteenth century [104]. For example, Elizabethan Poor Laws were the first attempt to provide service for landless and homeless poverty populations. In the nineteenth century, discussions of homelessness often focused on itinerant workers, or "hobos". Historically, homelessness has not necessarily been identified as a "problem". Wright [104] points out that various descriptions of the homeless, some as recently as the 1950s and 1960s, have romanticized the lives of hobos and migrant workers. However, starting with changes in the population from the time of deinstitutionalization in the 1960s, there is a general consensus that homelessness has emerged as a serious and increasingly important social issue [3, 6, 35, 38, 104], and that this issue is closely interrelated with substance use and abuse and other psychiatric illness [2, 81].

It is also important to consider the conduct of research on this population from a historical perspective. Although there are no doubt exceptions, early research on homelessness (for the sake of the current discussion, operationalized as published prior to 1970) was generally ethnographic or even anecdotal in method. Seminal works, such as those by Whyte [102], Gans [33], and Liebow [47], focused on the complex interactions among small groups of urban dwellers. Although more recent re-examination of these works demonstrates the significance of illicit substances in the lives of these "streetcorner" groups [47], questions of "how many" or prevalence of these disorders were not addressed in these studies.

The 1970s and 1980s witnessed an explosion of research on homelessness, with over 500 published articles and books listed on the subject in those two decades [87]. Unfortunately, a vast majority of this research was also methodologically flawed, either presenting population descriptions incorporating a convenience sample or services-limited research consisting of program descriptions or non-randomized studies comparing different interventions [55, 87]. It was not until the late 1980s that leaders in the field called for research to "move beyond" demographic descriptions to conduct more complete and methodologically sophisticated research

[57, 97] addressing complex epidemiologic issues [93].

In the last two decades, numerous methodologically sound cross-sectional studies have concluded that addiction and other psychiatric disorders are disproportionately prevalent among the homeless population. Unfortunately, because of sampling-related issues emanating from varied definitions applied to the problem of homelessness, changes in the population over time, and the lack of an acceptable national sample, our subsequent discussions of homelessness and associated comorbidities represent at best an incomplete snapshot of the problem. Thus, answers to the specific questions of "how many" (e.g., "What is the prevalence of psychiatric illness in the homeless population?") vary with these methodological differences, even among studies deemed methodologically adequate for most purposes. Given this situation, we will present ranges of likely prevalence estimates rather than providing specific figures of undeterminable validity.

Operationalizing Homelessness

Historically, homeless samples in research studies have often been limited to service-using populations, especially individuals using services directed to homeless populations, such as overnight shelters. General consensus, however, is that this subset captures only a segment of the homeless population that may not be representative of the larger homeless population [28]. Perhaps the most commonly accepted definition of homelessness is that of the 1987 Stewart B. McKinney Homeless Assistance Act [54] which defines a homeless person as "(1) an individual who lacks a fixed, regular, and adequate nighttime residence and (2) an individual who has a primary nighttime residence that is (a) a supervised, publicly or privately operated shelter designed to provide temporary living accommodations, (b) an institution that provides a temporary residence for individuals intended to be institutionalized, or (c) a public or private place not designed for or ordinarily used as a regular sleeping accommodation for human beings."

Understanding differences among specific definitions of homelessness requires consideration of a number of factors. These factors include what personal circumstances are considered homeless (e.g., inclusion of individuals doubled up/marginally housed versus only counting individuals literally without housing), how long one must be homeless to be included (one night versus a longer spell), and whether one self-identifies or is identified by some external criteria as homeless. Currently, operational definitions of homelessness have focused either on individuals who are literally homelessness or those marginally housed. Definitions of literal homelessness include not just those found in shelter settings, following the definition in the McKinney Act [54], but also individuals sleeping "on the streets" and in other locations not considered appropriate housing (e.g., subways, abandoned properties). Definitions of literal homelessness vary both in duration and in the types of non-housing locations included [28, 66]. Inclusion of marginally housed individuals broadens the definition of homelessness to include individuals with precarious housing situations such as those living in single room occupancy buildings and staying with others without paying rent, and has been used to provide broader estimates of the lifetime prevalence of homelessness [49]. Most recently, researchers have identified an additional dimension to measuring homelessness with given definitions that may affect estimates of population prevalence. Eyrich-Garg and colleagues [28] have discussed differences between "subjective" (self-identified) and "objective" (identified by others) determinations of homelessness, and have demonstrated significant differences in risk patterns among samples of heavy-drinking women identified with different methods of determining homelessness.

As discussed above, the many definitions of homelessness emerging from variations on an array of elements comprising this concept are destined to yield inconsistent sample characteristics and prevalence estimates. Because there

is no unified definition of homelessness, there can be no single gold standard for determining the status of homelessness of individuals, and, therefore, it should be understood that in the remainder of this chapter, the relevant research to be reviewed necessarily consists of work derived from samples based on a variety of non-uniform definitions of homelessness from different perspectives. Although we will be careful to identify both definitions of homelessness and the resulting types of samples included in specific studies (and to present critiques of current estimates in part based on this limitation), readers are encouraged to pay attention to these issues and remain cognizant of how these choices can subtly or even dramatically influence estimates of homelessness prevalence and observed characteristics of the population being studied.

Population Size Estimates

A number of methodological and conceptual issues must be considered in answering the question: "How many homeless people are there?" Similar to the complexities described around defining homelessness discussed in the previous section, issues requiring explication in interpreting estimations of population size include considerations of the sampling source and measurement methods (e.g. agency-based versus epidemiologic samples, neighborhood versus urban area versus national samples, point versus recent or lifetime prevalence estimates versus incidence).

Early prevalence estimates of homeless populations consisted of cross-sectional point prevalence estimates projected from samples counted at one or more overnight shelters. In one of the more thorough studies of this type, Burt and Cohen [11] estimated that there were 194,000 adult users of homeless shelters and soup kitchens in cities of 100,000 or more in a given week in 1987. Although basing their estimate on national shelter numbers represented a methodological improvement on previous estimates, because their estimate excluded multiple other sources of homeless people (e.g., soup kitchens, unsheltered locations), it was generally considered a substantial underestimate. Other commonly discussed population estimates (e.g., census enumeration) attempted to determine the size of homeless populations on a given night using single enumeration methods. However, we agree with an assertion made by Burt and Cohen [11] and endorsed by many others that these single-night estimations are also likely to miss substantial proportions of the literally homeless population, and thus represent significant undercounts. Populations underrepresented include the literal homeless (particularly those sleeping in hidden locations, such as in abandoned buildings) and those housed for single nights or for short spells. For these reasons, we will not further consider single-night estimates here.

Perhaps the best of the prevalence estimates emerge from Burt et al.'s [12] seminal work on homelessness. Using data from the 1996 National Survey of Homeless Assistance Providers and Clients (a survey of a variety of providers for two one-month periods) and extrapolating from previous estimations, they were able to arrive at reasonable estimates of how many service-using individuals were homeless on a given day or week, and estimating the total number of homeless individuals (both accessing and not accessing services) for the same periods. Readers wishing to understand more about how these estimates were reached are invited to explore the details of the various methods and estimates provided in this work [12].

In examining the various estimates, the best defensible figures of homeless service users who were homeless at the time of receipt of services were approximately between 440,000 and 840,000 in a given week and between 260,000 and 460,000 on a given night (including adults and children) in the National Survey of Homeless Assistance Providers and Clients [12]. Using their methods for estimating the proportion of individuals not using services, Burt and colleagues argued that between 1.4 and 2.1 million adults were homeless in a given year. This number is not out of line with other estimates for

approximately the same time period [23]. More recently, using multiple enumeration strategies, the "Homelessness Counts" report gave a higher estimation of around 750,000 on a given night [60]. Importantly, in estimating lifetime prevalence, a telephone household survey found that 6.5% of adults had experienced a spell of literal homelessness at some time in their lives, and that 3% had been homeless within the past year [48, 49], numbers far greater than any of the previous estimates.

An ongoing debate in the homelessness arena is the accuracy of these population estimates over time and their applicability to current population size and generalizability across locations. In terms of current population estimates, a relative consensus holds that the size of the homeless population increased in the 1980s [74] and that the population size has remained stable or grown since. However, as the National Alliance to End Homelessness pointed out [60], consistent enumerations are lacking beyond the flawed census attempts in 1990 and 2000 [51], and, therefore, any discussions around changing size of the population are more speculative than factual. Thus, the estimates presented here, while representing best available evidence, cannot be considered precise or even necessarily accurate. In terms of generalizability of findings across locations, Culhane and colleagues [52] have used administrative records from homeless service providers to attempt to examine population size across multiple jurisdictions. Their results, although representing the state of the art, point out once again the difficulties in estimating population size, as they find rates ranging from 0.1 to 2.1% in different cities of the overall population on a yearly basis using similar approaches to those applied in administrative records data collection.

Although discussions of overall population size over time have been inconsistent at best and lacking at worst, some persuasive evidence points to recent changes in the composition of those who are homeless. North and colleagues [66], using three comparable representative samples each examined a decade apart within a single urban environment, noted significant increases in substance use and mood disorders among homeless cohorts over time. Their findings suggest that the homeless population may be changing, and that some of the differences found across studies are likely attributable to changing characteristics of the population rather than simply variation created by use of different sampling strategies and study of different environments. Further, they argued that observed changes in the population over time may represent unintended consequences of changes in national policy.

Chronic Versus Short-Term

Efforts to understand the composition of the homeless population require examination of linked issues of duration of homelessness and number of spells of homelessness that have long received considerable attention in the homelessness literature and have focused efforts to help this population toward specific subgroups with distinct characteristics. Currently, much of the Federal policy is aimed at addressing the "chronic" homeless population. Classifications of homelessness generally break the population into some variation of three not-always-distinct groups: crisis/first-episode, episodic, and chronic [1, 8, 12, 45, 69, 103]. Estimates of proportions for the chronic subgroups vary from almost half falling into the chronic category [11] to less than one-quarter [8, 12] and as low as ten percent [23]. Caton and colleagues [17] examined predictors of remaining homelessness over 18 months in a cohort of newly homeless individuals, finding that shorter duration of homeless spells was associated with employment, no history of substance treatment or incarceration, and younger age. These observed differences indicate that these subgroups are distinct, with the additional implication that they may have differing treatment needs.

A Critique

Careful readers will note that much of this discussion of the homelessness population has included repeated cautions about the role of

methodological issues in shaping the findings, including the definition of homelessness, sampling methods (e.g., service-using versus non-service-using samples), and evolution of the population over time, to name only a few. Although numerous articles, books, and governmental reports have debated each of these issues separately and together, a broad conclusion from this literature is that it collectively yields only a vague understanding of the size and composition of the homeless population. We echo numerous other writers in noting the frustrations and complexities of integrating a large, methodologically flawed body of information that has been unable to describe this multifaceted population coherently or precisely. Much more could be written, including similar discussions of proportions of the population falling into various demographic sub-groupings, but all would be marred by this same general critique. Given the focus of this chapter on substance use disorders and associated psychiatric and medical risk factors, we will now move away from this general discussion of the homeless population to the central task of examining substance use disorders and comorbidities.

Substance Use Disorders

Association Between Substance Use Disorders and Other Risk Factors and Homelessness

Before launching a discussion of rates of risk factors among the homeless population, it is important to address the relationships of substance use disorders and other risk factors with homelessness. Generally, an implicit assumption in the popular literature holds that the disproportionate findings of these risk factors in the homeless population indicate that substance use and abuse/dependence and other mental illness "cause" these individuals to become homeless. However, evidence on onset of homelessness and psychiatric disorders has called into question this assumption.

Research on the causal nature of psychiatric disorders on homelessness has, in fact, concluded that the association between these factors is not simply unidirectional. O'Toole and colleagues [67] found evidence for changes in alcohol and drug abuse patterns after first onset of homelessness, including escalating use for some individuals and diminished use among others. North and colleagues [65] compared the relative timing of onsets of substance use disorders and other psychiatric disorders with first episode of homelessness and found that the proportion of homeless individuals with onset of their illnesses prior to the onset of their first episode of homelessness was similar to the proportion of a national community sample with onset of illness before an age comparable to that of the homeless sample's age of first homelessness. Earlier assumptions of direct unidirectional causality from psychopathology to homelessness have largely been abandoned by the experts who now argue that there are also multiple indirect effects related to having a psychiatric disorder that may not only increase individual risk for entering homelessness but also create barriers to exiting homelessness [32, 39, 67, 100].

Prevalence Rates

When we use the term "substance use disorder", we are referring to substance abuse or substance dependence as defined in the *Diagnostic and Statistical Manual of Mental Disorders* (editions III, III-R, or IV depending on when the research was conducted). Meeting diagnostic criteria for either alcohol use disorder or for any specific drug use disorder (e.g., cocaine use disorder, cannabis use disorder, opioid use disorder) qualifies one for a diagnosis of substance use disorder.

There is a general scientific consensus that the prevalence of substance use disorder is disproportionately high in the homeless population. According to epidemiologic studies, the lifetime prevalence of substance use disorder is estimated

to be in excess of two-thirds of homeless people [43, 76]. Women range between 31 and 63%, and men between 71 and 75% [9, 76, 90, 91]. Systematic shelter-selected samples (e.g., 30) yield similar lifetime prevalence rates. The current (12-month) prevalence of substance use disorder is estimated to be somewhere between 38 and 52% [66, 76].

One study [66] found that substance use disorders accounted for the vast majority of all lifetime psychiatric disorders among a representative sample of homeless people. A lifetime psychiatric diagnosis was detected in 88% of men and 69% of women, and a lifetime substance use disorder was identified in 84% of men and 58% of women.

Alcohol and Drug Use Disorder Comorbidity

The overlap between alcohol use disorders and drug use disorders is considerable in the homeless population. Approximately 61% of homeless women with lifetime alcohol use disorder also report a history of lifetime drug use disorder [91], and approximately 40% of men and women who report a history of lifetime drug use disorder also report a history of lifetime alcohol use disorder [90, 91]. A substantial proportion of the homeless population meets criteria for both alcohol and other drug use disorders. Approximately 36–42% of homeless people meet lifetime criteria for both alcohol and other drug use disorders [66, 76]. Somewhere between 29 and 33% of women meet lifetime criteria for both alcohol and other drug use disorders [76, 91], and approximately 38% of men meet lifetime criteria for both types of disorders [76]. Approximately 18% of homeless people meet current (12-month) criteria for both alcohol and other drug use disorders [76].

Many homeless people with substance use disorders also have at least one other psychiatric disorder. Epidemiologic studies have shown that of homeless people with lifetime alcohol use disorder, 32–38% meet diagnostic criteria for a lifetime non-substance psychiatric disorder [9]. Of men with a lifetime non-substance psychiatric disorder, 60% meet diagnostic criteria for lifetime alcohol use disorder and 24% meet diagnostic criteria for lifetime drug use disorder [9]. Of women with a lifetime non-substance psychiatric disorder, 46% meet diagnostic criteria for lifetime alcohol use disorder and 20% meet criteria for lifetime drug use disorder [9].

Alcohol Use Disorder

Prevalence Rates

Alcohol use disorders are highly prevalent in the homeless population, ranging from approximately 53–63% according to epidemiologic studies of lifetime rates [43, 66, 76]. Lifetime prevalence ranges from 17 to 40% in women and 56–68% in men [9, 90, 91]. Most individuals who meet criteria for lifetime alcohol use disorder also meet criteria for current alcohol use disorder [76, 90, 91]. Current year prevalence rates for the disorder among homeless populations are estimated to be between 39 and 42% [66, 76], approximately 32% in women and 41–50% in men [76, 90, 91].

Studies comparing prevalence rates of lifetime and current (6-month) alcohol use disorder between homeless persons and housed groups have found significantly higher alcohol use disorder rates among the homeless [43]. However, this finding may not generalize to particular homeless subgroups. For example, lifetime rates of alcohol use disorder do not appear to differ between first-time, non-mentally ill, shelter-seekers and persons applying for government assistance [16]. Shelter-using, mentally ill women have be found to have higher current (6-month) rates of alcohol use disorder than their housed, mentally ill female counterparts [15]; however, no significant difference was detected in the current (6-month) rates of alcohol use disorder between shelter-using, mentally ill men and housed, mentally ill men [14].

The literature indicates that excessive alcohol use is a strong discriminator between homeless and housed families. For instance, single female parents who were homeless reported a history of using alcohol excessively 23 times more frequently than single female parents who were housed [5].

Other Drug Use Disorders

Overall Prevalence Rates

As with alcohol use disorder, drug use disorder is overrepresented in homeless populations. Lifetime prevalence of drug use disorder is estimated between 31 and 58% [43, 66, 76]. According to North and colleagues [66], drug use disorders in the homeless population have increased significantly in prevalence over the past two decades. Women's lifetime rates range between 23 and 51%, and men's lifetime rates range between 40 and 61% [66, 76, 90, 91]. Current (12-month) prevalence of drug use disorder is estimated to be between 31 and 38% [66, 76], approximately 32–35% for women and 18% to 38 for men [66, 76, 90, 91]. Current (12-month) prevalence among shelter-using mentally ill women appears to be in line with these estimates [15], but shelter-using mentally ill men appear to have a substantially higher prevalence of drug use disorder (77%) [14].

Drugs of Choice

The literature is clear that the drug associated with the highest rates of abuse and dependence among the homeless is cocaine. Cocaine use disorder has grown substantially in the homeless population through the 1990s and 2000s [66]. Lifetime cocaine use disorder prevalence rates ranges from 16 to 40% for women and from 37 to 46% for men [66, 76, 90, 91]. Current (12-month) cocaine use disorder rates are approximately 26–29% for women and 24–33% for men [66, 76].

The drug with the second highest abuse/dependence rate is cannabis. During the mid-1980s, cannabis appeared to be the most prevalent drug of abuse (8% for women and 7% for men) in the homeless population [9], but that has changed. Lifetime cannabis use disorder prevalence estimates range between 7 and 28% for women and 30 and 37% for men [66, 76, 90, 91]. Current (12-month) prevalence of cannabis use disorder is approximately 8–12% for women and 10–16% for men [66, 76].

Stimulant, opioid, and sedative use disorders have estimated lifetime prevalence rates between 3 and 10% [66, 76]. Current (12-month) prevalence is similar for stimulant, opioid, and sedative use disorders [66, 76].

Some differences emerge for subgroups of the homeless population. First-time shelter-seeking men appear to have lifetime prevalence rates of cocaine (33%), cannabis (32%), and heroin (11%) use disorders that are similar to those of their housed counterparts [16]. First-time shelter-seeking women, however, have elevated prevalence of cocaine (40%) and heroin (23%) but not cannabis (22%) use disorders, when compared with their housed counterparts [16].

Injection Drug Use

In this brief section, we present information on a particular type of drug ingestion—injection drug use. Note that we discuss use (as opposed to drug abuse/dependence) and that this use may or may not be part of a drug use disorder. Injection drug use is important to mention apart from diagnosis because sharing works is a risk factor for contracting and spreading HIV. Many cities view needle-sharing as such a problem that they fund needle-exchange programs in which people can exchange their used needles for sanitary ones free of charge.

Epidemiologic studies have found that 22% of the homeless population has a lifetime history of injection drug use, with 10% of men and 5% women injecting within the past year. The relative proportions of injection drugs of choice were

heroin (94%), cocaine (58%), stimulants (45%), other opiates (20%), sedatives (19%), and hallucinogens (7%). Sex and age appear to play a role in the likelihood of injection drug use. In one study of severely mentally ill homeless people, rates of injection drug use across study recruitment sites ranged from 16 to 26% for men and 6 to 8% for women [95]. Younger persons in this subpopulation (e.g., under the age of 45) were more likely than older persons to have injected drugs at some point in their lives [95].

Looking Forward

Substance use disorders among the homeless have been studied for many years now. Research needs to continue to identify shifts in the abuse/dependence of popular substances. It is not yet known whether the recently documented trends of increasing oxycodone abuse in the general substance abuse treatment-seeking population [13] and methamphetamine abuse observed in the general population [88] are also reflected in the homeless population.

Non-Substance Psychiatric Disorders

Besides substance abuse, other psychiatric illness is an important issue to examine in homeless populations because of its prevalence, its relationship to homelessness, and its implications for service use and outcomes (for both homelessness and psychiatric illness). It can compromise a person's economic situation (e.g., psychiatric care costs, medication costs, inability to work), medical status (reducing ability to care for oneself), and social status (in terms of family and friendships).

Mood Disorders

Major depression is the most prevalent non-substance Axis I disorder in the homeless population. The lifetime prevalence of major depression is estimated to be between 18 and 21% [43, 66], with greater prevalence found among women (around 25%) [91] compared with men (around 18%) [90].

Major depression can be challenging to assess and difficult to interpret in homeless populations. North and colleagues [65] studied the relationship between ambient weather and same-day assessments of major depression in homeless people using a structured diagnostic interview. They found that men were more likely to meet diagnostic criteria for major depression when the weather was cold and wet. Yet, this difference was not detected among women, who are often allowed to spend days in the shelters (probably because most of them have children) while men are thrust out into the day's weather each day. North and colleagues concluded that the symptoms of major depression can be difficult to separate from the "miseries of homelessness", including hardships of exposure to inclement weather, especially for men. It is possible that the methods used to measure major depression in many epidemiologic studies do not distinguish between the major depression that people typically present with in psychiatric treatment settings and emotional distress and disillusionment among homeless people coping with the extraordinary hardships of being homeless (physical and mental discomforts, hunger, fatigue, social isolation, demoralization, lack of privacy, and the presence of danger). If this is the case, then the standard treatments for major depression (e.g., medication, talk therapy) may not be appropriate for distressed homeless people as with clinically depressed treatment populations. Treatments for major depression are likely to be ineffective for ameliorating the situational distress and misery of homelessness that may be quite difficult to differentiate from major depression.

Instead of using a systematic diagnostic instrument to provide diagnosis of major depression according to *Diagnostic and Statistical Manual of Mental Disorders* criteria (e.g., the Diagnostic Interview Schedule, the Composite International Diagnostic Interview, or the Structured Clinical Interview for *Diagnostic and*

Statistical Manual of Mental Disorders), many studies use proxies such as symptom screens, measures of distress or depressed mood or distinctions of "clinical caseness". Studies based on such nondiagnostic measures have asserted that almost three-quarters (73%) of homeless samples can be defined as having clinically significant emotional distress or clinical caseness for some sort of depressive-like syndrome [75], and approximately one-third of epidemiologic and first-time shelter-user samples (ranging from 33 to 37%) have been reported to suffer from "extreme distress" [75, 93]. As we stated before, being homeless can make one extremely stressed and unhappy. Even diagnostic instruments may over-represent distress as major depression in this population, but they are far less likely to fall into this error than nondiagnostic screening tools. We suspect that high rates, such as 73%, for emotional distress/clinical caseness are a result of inadvertent capturing of the agonies of homelessness and their obfuscation with diagnostic syndromes.

The next mood disorder we will discuss is bipolar disorder. Breakey and colleagues [9] estimated the lifetime prevalence of bipolar disorder in homeless populations of the mid-80s to be around 7–8% for both women and men. Another epidemiologic study of homelessness estimated the lifetime prevalence of bipolar disorder to be around 11% [43]. A study conducted in the early 2000s [66] estimated lifetime rates of bipolar disorder to be around 9%.

Anxiety Disorders

Anxiety disorders, including panic disorder, generalized anxiety disorder, and post-traumatic stress disorder, are prevalent in the homeless population as well. One epidemiologic study estimated the lifetime prevalence of any anxiety disorder for shelter users to be around 39% and the 6-month prevalence to be around 22% [30]. However, prevalence estimates of these disorders have been lower in more recent epidemiologic studies. Similar to our discussion of the challenges of diagnosing major depression in the homeless population, it can be difficult to diagnose anxiety disorders correctly in this population. Real threats of violence, theft, lack of food, and a need to avoid the police in some cities (for fear of being arrested for vagrancy) understandably generate anxiety for many homeless people. This situational anxiety can be difficult to distinguish from symptoms of psychiatric disorders such as panic disorder and generalized anxiety disorder.

Post-traumatic stress disorder appears to be the most prevalent anxiety disorder among homeless people. Lifetime prevalence of post-traumatic stress disorder is estimated to be around 20% for all homeless people [66]—34% for homeless women [91] and 18% for homeless men [90]. Current (12-month) prevalence is estimated to be slightly less (15%) [66].

Panic disorder is typically the next most prevalent anxiety disorder in studies of homeless populations. The lifetime prevalence of panic disorder in the homeless population is estimated to be around 8–9% [43, 66]—3% in women [91] and 5% in men [90]. Current (both 6-month and 12-month) prevalence of panic disorder appears to be slightly less overall (5%) but very similar when reported separately by sex (women: 3%; men: 4%) [43, 90, 91].

Generalized anxiety disorder is the last anxiety disorder we will discuss. Lifetime rates of generalized anxiety disorders range from 7 to 14% [43, 66, 90, 91]. Current (both 6-month and 12-month) prevalence rates of the disorder appear to be slightly lower, ranging from 5 to 11% [43, 66, 90, 91].

Psychotic Disorders

When asked to conjure up an image of a homeless person, most people imagine someone who is severely mentally ill. They think of someone who is psychotic (hearing voices and seeing images that do not exist) and who talks to or yells at imaginary others, such as someone suffering from schizophrenia. Systematic research

shows, however, that a very small percentage of the homeless population fits this description. Contrary to anecdotal evidence, psychotic disorders, most often represented by schizophrenia, are not nearly as prevalent as the news media's sensationalistic presentation of them in the homeless population. Epidemiologic studies have estimated the lifetime prevalence of schizophrenia to be between 4 and 17% [9, 43, 63, 66]. First-time homeless shelter-using men have reported a prevalence estimate within this range—8% [93].

Personality Disorders

The most consistently measured Axis II diagnosis in the homeless literature is antisocial personality disorder. The prevalence of antisocial personality disorder appears to be remarkably, disproportionately high among homeless populations. Epidemiologic data show that between 16 and 20% of the homeless population meet criteria for the lifetime disorder [30, 66], with approximately 10% of women and 25% of men qualifying for the diagnosis [90, 91]. Some researchers [29] have argued that meeting criteria for antisocial personality disorder can be a functional and adaptive, survival pattern of behavior in the context of homelessness rather than a strictly pathological phenomenon. Therefore, they would argue that using the diagnosis in the homeless population is culturally insensitive. North et al. [64] refuted this argument, contending that onset of adult antisocial personality disorder almost always occurs prior to the onset of homelessness and correlates with childhood conduct symptoms, and, in their analysis, the rates of antisocial personality disorder did not decline significantly when they removed criterion symptoms related to homelessness from the algorithms. They concluded that although homelessness may exacerbate the manifestations of antisocial personality disorder, it is a valid diagnosis in this population.

Other personality disorders have received generally less attention in the scientific literature. A pioneering study in the 1980s by Bassuk and colleagues [4] examined rates of *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition—diagnosed personality disorders in sheltered homeless families. In this study, an astounding 71% of homeless mothers in their sample met diagnostic criteria for at least one personality disorder. Diagnoses provided by psychiatrists yielded the following prevalence rates of various personality disorders: dependent (24%), atypical (10%), borderline (6%), narcissistic (4%), antisocial (4%), passive-aggressive (4%), mixed (4%), schizoid (3%), and histrionic (1%). The authors of the study were quick to point out that Axis II diagnoses are less reliable than Axis I diagnoses and that many external environmental factors—e.g., poverty, racism, and sexism—may play a role in determining observable features masquerading as personality traits in this population barraged by extraordinary stressors.

Overall Prevalence Rates

According to a major epidemiologic study conducted in the early 2000s [66], 49% of homeless people have a lifetime history of at least one non-substance Axis I disorder, most of which is accounted for by major depression. This means that (1) half of the homeless population does not have any history of non-substance Axis I disorder and (2) of those with a lifetime history of non-substance Axis I disorder, very few have chronic and persistent severe mental illness (e.g., schizophrenia, bipolar disorder). We exclude major depression from chronic and persistent severe mental illness (see [82] for definitions).

The Roles of Sex and Race in Psychiatric Disorders Among the Homeless

A common theme among the psychiatric disorders in the homeless population is differences in findings by sex and race. Homeless Caucasian women have been found to have a greater prevalence of schizophrenia, major depression, and

bipolar, panic, generalized anxiety, and post-traumatic stress disorders than homeless women of color [63]. This indicates that the homeless women of color may have less major psychiatric illness than homeless Caucasian women. Although we cannot determine causality, these data lend support to ideas that racism, oppression, social inequities, and social injustices may play a proportionately greater role in the homelessness of women of color.

The prevalence of cocaine, opioid, and amphetamine use disorders is greater among homeless men than among homeless women, and more homeless women have alcohol and cannabis use disorders, major depression, and schizophrenia compared with homeless men [9, 76].

Medical Illness

Medical illness is also disproportionately over-represented in the homeless population. Life on the streets and in the shelter system can be dangerous, stressful, and hazardous to one's health. It can be difficult to locate a free place to shower and wash one's clothes to maintain proper hygiene; this makes it difficult to prevent as well as treat illness. Few homeless people have health insurance and can take preventive health care measures (perhaps, in part, because of competing immediate demands such as food and shelter). Many may wait for health conditions to become urgent or emergent before seeking medical attention and then use emergency rooms rather than regular outpatient services for treatment [37].

We cannot state that all medical problems in the homeless population are the direct result of homelessness. Housed low-income populations often have poor health as well. This poor health can be attributed to a variety of factors including poor diet, lack of preventive health care, and lack of exercise. Medical problems among those who are low-income and become homeless are generally problems well known to be associated with circumstances of extreme poverty and other associated social problems. It is, however, likely that being homeless exacerbates the health problems that are already endemic in these populations.

HIV/AIDS

HIV/AIDS has recently begun to receive increased attention in homeless populations. The prevalence of HIV/AIDS among the homeless and marginally housed populations has been estimated to be between 10 and 15% in San Francisco [10, 77], 6 and 19% among the mentally ill homeless in New York City [26, 94], and 16% among soup kitchen attendees in New York City [50]. One study [24] found that people with HIV/AIDS in Philadelphia were 3 times as likely to be homeless as people without the infection. Another study [89] found that homeless injection drug users had a greater prevalence of HIV than housed injection drug users (19% vs. 11%).

Risk for engaging in risky sexual behaviors, which increase one's chances of contracting HIV, is increased in association with intoxication with alcohol and other drugs in homeless populations as in other populations [31]. Because many homeless people, particularly women, trade sex for food, clothing, drugs, or a place to stay, they are at heightened risk for contracting the virus [101]. Homeless people, especially those who are most transient, may not have a reliable place to store their works; therefore, they are more likely than others to borrow injection equipment [22, 34] or visit a shooting gallery [34]. This places them at even greater risk for contracting the virus.

Infectious Diseases

People who experience homelessness may be exposed to or carry infectious diseases. One study of people using soup kitchen services in New York City [50] found high rates of

hepatitis B exposure (21%), hepatitis B carrier (6%), hepatitis C seropositive (19%), and syphilis exposure (15%) [18, 85]. The Centers for Disease Control and Prevention reported the rate of tuberculosis among the homeless to be 6.5% in 1997 [18].

Homeless Services

Following the considerations presented above, treatment of homeless individuals requires attention to a variety of interrelated treatment needs. A general consensus in the treatment literature is that information sought to identify specific treatment needs must address issues around housing, psychiatric and medical illness, employment and economic factors, family [70] and social supports [27], and contextual elements such as availability and accessibility of services [12]. It is equally clear from both the services literature and the review of risk factors presented in this chapter that individual treatment requires attention to these multiple needs.

Research has further identified a series of barriers that complicate delivery of services to homeless individuals. These include suspicions harbored by homeless individuals about the consequences of receiving treatment [46], "hang out" or "street" groups that discourage treatment engagement [71], and disjuncture between professionally assessed needs versus those perceived by the homeless individual [20, 62].

Despite the complex needs identified in this chapter and the multiple factors complicating service delivery, it is possible to make some general statements about what constitutes effective treatment for this population. Perhaps most simply, there is a positive association between amount of service use and the achievement of favorable outcomes [7, 42, 58, 72, 73, 83]. A second consistent finding is that achievement of a broad variety of outcomes requires effective matching of needs to services, as well as integration of care [19, 25, 36, 41, 44, 53, 80]. A third finding is that coordination of intensive services with transitions to housing increases the likelihood of positive outcomes [73, 79, 92, 96, 105].

Research on effective treatment for homeless individuals has generally focused on the development and testing of intervention models. Although an in-depth discussion of services research is beyond the scope of this chapter, examining existing intervention models provides insight into effective approaches and can help point to opportunities for individual treatment and broader service responses. The past decade has seen the development and testing of a variety of effective models of intervention for homeless populations. Perhaps the most promising of these models is the Housing First approach to permanent housing [68, 98, 99]. This model, which combines immediate noncontingent housing and supportive services, has been demonstrated to have relatively substantial effect sizes in increasing housing stability and other associated outcomes [61]. Importantly, Housing First services have also been shown to be equally effective as treatment-first approaches in outcomes around drug and alcohol use over time [68]. In a comparison of permanent housing with assertive community treatment and intensive case management, although all three service types did better than their various comparison conditions (generally treatment as usual, which in most instances was case management), permanent housing was shown to have greater effect sizes for housing outcomes than assertive community treatment or intensive case management [61].

A number of other models have demonstrated promise through either clinical trials or quasi-experimental designs for homeless populations with mental illness. The "critical time intervention" by Susser and colleagues [40, 96] demonstrated significant gains in housing stability relative to usual services; Assertive Community Treatment demonstrated superior housing and mental health outcomes to case management [21, 59]; a psychiatric rehabilitation model demonstrated a wide variety of housing and psychiatric outcomes relative to standard treatment [86]; and intensive case management demonstrated moderate effect sizes relative to case management

[19]. Examining costs associated with outcomes, [78] noted that innovative programs tend to be more expensive than usual services, but challenged his readers to examine his findings in light of the value that society places on these marginalized members.

In the literature on services for homeless populations, addiction treatment is often not the primary focus of the intervention. As we have already noted, housing first is eponymous—it aims to get individuals into housing first regardless of other behaviors (primarily addiction-related ones). Thus, the findings from these type of interventions generally focuses extensively on housing outcomes, often concluding that housing-first approaches do equally well as their comparison groups in addiction-related outcomes (cf. [99]). Generally, research on services for addiction in homeless populations focuses on either "dually diagnosed" populations [36] or on including substances in integrated models [25]. One effective model for homelessness that incorporates a contingency management intervention paired with abstinence-based housing demonstrated positive and housing-related outcomes [56, 84].

Conclusions

In summing up knowledge on homelessness, substance use and abuse, other psychiatric and medical illness, and available services, some very broad conclusions can be made. First, the homeless population is a substantial one in terms of size, particularly with consideration of longer assessment periods. Although spells of homelessness for a majority of the population identified are relatively short-term, the substantial minority of individual spells that are chronic present complex challenges in service provision.

In terms of substance use and abuse, all psychiatric disorders have a disproportionate prevalence in the homeless population, regardless of sampling or assessment methods. The primary drugs of abuse are cocaine (in various forms, but especially crack cocaine), alcohol, and marijuana; and the proportion of the homeless population with addictions appears to be increasing in recent decades. However, despite popular assumptions, addiction does not appear to have a simple direct causal relationship with homelessness, rather it appears to have indirect effects contributing to the likelihood of becoming homeless. Further, it appears that homelessness has a similar indirect effect on the likelihood of substance use and abuse.

There appears to be a disproportionate prevalence of psychiatric (especially substance use disorders) and other medical illness in this population. However, even including the disproportionate prevalence of psychiatric and medical illness among the homeless, the majority do not have a non-substance-related psychiatric diagnosis, and the most common category of psychiatric malady (outside of the highly prevalent substance abuse) is not severe and persistent mental illness such as schizophrenia, but rather major depression or some homelessness-related phenotypic variant of depression related to the miseries of homelessness. Further, these psychiatric and other medical disorders in homeless populations appear to occur almost exclusively as comorbidities with addictive disorders.

Generally effective services for homeless populations must be intensive in nature, matched closely with assessed and perceived needs, effectively addressing barriers to care (especially lack of coordination across providers), and providing intensive services at key transitional times. A number of effective models have been demonstrated to yield favorable housing outcomes relative to comparison conditions, including Housing First, Assertive Community Treatment, Intensive Case Management, Critical Time interventions, and psychiatric rehabilitation.

In concluding this review, we return to the ongoing methodological issues that have consistently plagued the field and, therefore, complicated this chapter. At best, the research applied to discuss this population has limited consistency, in large part due to difficulties in methodological designs of existing research studies. Important issues such as changes to the population over time, differences among locations such

as cities (particularly around transience), and the interrelationship of the individual-level risk factors with economic and policy factors all remain understudied and may significantly impact our understanding of homeless individuals. What is required to address these issues is methodologically sophisticated, longitudinal research that incorporates multiple sites, consistent sampling and multiple levels of data (individual, social, environmental), and complex modeling congruent with the data sophistication.

A Retrospective View on the Hallmarks of Neurobiological Alcohol and Drug Abuse Research

What were the major achievements in the past in neurobiologically oriented alcohol and drug abuse research? This can only be answered by a very personal view. I would like to illustrate this in terms of the hallmarks of alcohol research. In 1940, Curd Paul Richter [80] reported that laboratory rats voluntarily consume alcohol, though with high individual variability. This discovery marked the beginning of animal research in the study of alcohol. Furthermore, this observed variability in alcohol intake provided the basis for the generation of alcohol-preferring and non-preferring rat and mouse lines, 8 of which have been genetically selected since 1960 [26]. Thousands of studies on alcohol drinking in rodents have been conducted subsequently, permitting the deciphering of the genetic and neurochemical basis of alcohol reinforcement. Studies of alcohol self-administration in laboratory animals remain crucial to the development of medication in the field of alcohol research, and the predictive value of these models is demonstrated by the fact that all available pharmacotherapies, e.g., naltrexone and acamprosate [98], have been based on animal work of this nature. The same is true for any other drug of abuse—without appropriate animal models only little progress would have been made in the field of addiction research. In fact, most of the animal models, e.g., intravenous self-administration of heroin and cocaine, provide excellent face and construct validity [86].

In terms of construct validity the discovery of the brain reinforcement system by James Olds in 1954 [70]—one of the outstanding experimental psychologists of the last century—ultimately provided the key to understanding the neuroanatomical correlates underlying alcohol and drug reinforcement. Again, knowledge derived from animal work on the neuroanatomical and functional aspects of alcohol and drug reinforcement has been systematically translated to

humans by means of neuroimaging techniques [116].

The foundation for understanding the neurochemical substrates of alcohol and drug reward[1] was laid by the three research teams in 1973 responsible for identifying the first opioid receptors [74, 93, 104]. In the hunt for the endogenous ligands, John Hughes and Hans Kosterlitz [40] then identified the first opioids in the brain only two years later, and called them enkephalins. However, it took almost two decades until the molecular cloning of the first opioid receptors was achieved [27, 49]. These studies not only promoted opioid research in general, but also represented key discoveries for subsequent alcohol and drug abuse research. Similarly, the isolation of Δ^9tetrahydrocannabinol in 1964 by the group of Ralph Mechoulam [29] marked the beginning of cannabinoid research. The brain targets of tetrahydrocannabinol remained unidentified until 1988, when a seminal paper by the group of Allyn Howlet [16] identified a G-protein-coupled receptor as the target of natural cannabinoids. It was followed immediately by the molecular cloning of the cannabinoid receptor 1 [60] and by the identification of the first endogenous ligand of the cannabinoid receptor, an arachidonic acid derivative termed anandamide [17]. These key discoveries led to one of the most active fields of research in neurobiology. But the real surprise came from the discovery of the role of the endocannabinoid system in reward processes and in the neurobiology of addictive behavior. Both the endocannabinoids and the cannabinoid receptor appear to be crucial in opioid, alcohol, psychostimulant and nicotine addiction and it can be foreseen that within the next 10 years we will have effective treatments on the market targeting various components of the endocannabinoid system [82].

Besides endocannabinoids, endogenous opioid systems are thought to induce the pleasurable and rewarding effects of alcohol and other drugs of abuse, and thereby constitute ideal targets for treatment [96]. The first description of opioid receptor blockade by means of naltrexone, and the resultant reduction of voluntary alcohol consumption in rats [2] marked the starting point of the development of relapse medication in alcohol research. A decade later, the first reports on the clinical efficacy of naltrexone in alcohol-dependent individuals were published [71, 117] and a recent meta-analysis of 24 randomised controlled trials that included a total of 2,861 subjects demonstrates that naltrexone decreased the relative risk of relapse compared to placebo by a significant 36% [101]. A further milestone in medication development was the finding that a functional polymorphism of the μ-opioid receptor gene may predict response to naltrexone [72]. Although this finding has recently been replicated [3] no final judgement on this pharmacogenetic discovery will be possible for several years. Nevertheless given the fact that our century is dominated by the belief that personalised medicine will power further biomedical developments, the study of Oslin et al. has already marked this shift in paradigms. Despite the promise of pharmacogenetics to identify treatment responders, there have so far been very few success stories in all of medicine.

[1] It must be emphasized that primary drug reinforcement processes mediated by mesolimbic dopamine release do not necessarily reflect the emotional hedonic components of alcohol and drug reward; it seems more likely that an enhanced mesolimbic dopamine signal highlights important stimuli and functions as a neurochemical learning signal for reinforcing stimuli [100]. Whether mesolimbic dopamine plays also a role in mediating hedonic aspects of alcohol and drug self-administration is not known. However, the endocannabinoid and especially the endogenous opioid systems may well serve as neurochemical substrates involved in the mediation of these positive mood states [96].

New Vistas in Neurobiological Alcohol and Drug Abuse Research

Addictive behavior is the result of cumulative responses to drug exposure, the genetic make-up of an individual, and the environmental perturbations over time. This very complex

"drug × gene × environment" interaction, which has to be seen in a life-span perspective, cannot be studied by a reductionistic approach. Instead, a systems-oriented perspective in which the interactions and dynamics of all endogenous and environmental factors involved are centrally integrated, will lead to further progress in alcohol and drug abuse research [96]. My future perspective adheres to a systems biology approach such that the interaction of a drug with primary targets within the brain is fundamental for understanding the behavioral consequences. As a result of the interaction of a drug with these targets, alterations in gene expression and synaptic plasticity take place that either function as protective mechanisms or lead to long-lasting alteration in neuronal network activity. As a subsequent consequence, drug-seeking responses ensue that can finally lead via complex environmental interactions to an addictive behavior (Fig. 1). This systems biology approach, opens up new vistas in addiction research on the genetic (see Section "New Vistas on the Genetic Level"), molecular (see Section "New Vistas on the Molecular Level"), synaptic (see Section "New Vistas in Alcohol- and Drug-Induced Synaptic Plasticity"), neuronal network (see Section "New Vistas on Neuronal Network Activity"), and finally on the behavioral level (see Section "New Vistas on Studying Alcohol- and Drug-Related Behaviors").

New Vistas on the Genetic Level

Genetics of Addictive Behavior

A large body of genetic epidemiological data strongly implicates genetic factors in the etiology of addictive behavior. In the following I will mainly focus on smoking behavior as progress in genetics are most pronounced in the field of nicotine addiction. The data from family, adoption and twin studies strongly support a genetic influence on the initiation and maintenance of smoking [102, 103]. Two general scientific human approaches to identify candidate genes are genetic linkage analysis and genetic association studies including genome-wide association studies. Despite the success of linkage approaches in unravelling the genetic antecedents of disease, the findings with respect to smoking behavior have been disappointingly inconsistent. However, a variety of plausible candidate genes have been examined for associations with smoking behavior. The vast majority of these studies have focused on genetic variations in relevant neurotransmitter pathways and/or nicotine metabolizing enzymes or neuronal nicotinic receptors. Despite the large number of studies published on the association between specific candidate genes and smoking behavior, one has to conclude from the existing literature that the evidence for a contribution

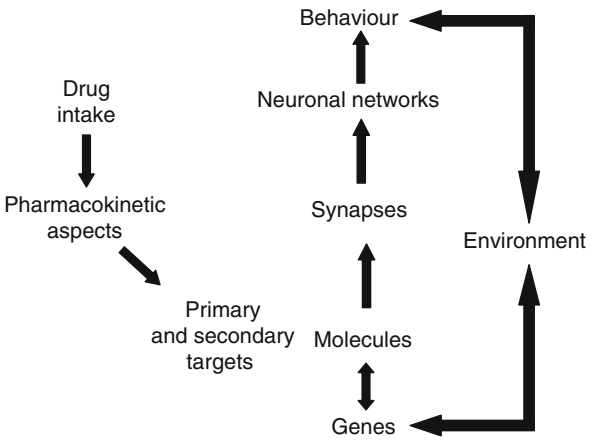

Fig. 1 This scheme shows a systems approach towards a better understanding of the acute and chronic effects of a drug. The here described future perspective follows exactly this approach. Thus, future advances on the genetic level, on drug/receptor interaction, on drug-induced synaptic plasticity, on neuronal network activity, and finally on the behavioral analysis are described

of a specific gene to smoking behavior is rather small.

Genome-Wide Association Studies in Addiction Research

Genome-wide association studies employing a high number (500,000+) of single nucleotide polymorphisms across the genome have now been conducted in a variety of complex disorders and have been shown to be a successful tool in identifying underlying susceptibility genes (for all published genome-wide association studies see: www.genome.gov/26525384). Several genome-wide association studies have recently also been conducted on smoking behavior phenotypes. These studies have used sample sizes up to 11,000 cases [106] and have implicated a number of novel genes in nicotine addiction[2] and smoking cessation, as well as known candidate genes [8, 10, 21, 106, 111]. Especially, in conjunction with several candidate gene studies [85, 87], evidence has been accumulated that genes encoding nicotinic acetylcholine receptor proteins are associated with multiple smoking phenotypes [1]. In particular, the nicotinic acetylcholine receptor subunit genes *CHRNA3*, *4* and *5,* as well as *CHRNB4* are associated with nicotine addiction. Although the robust association of the nicotinic acetylcholine receptor subunit genes investigated with smoking-related phenotypes is an apparent success story of genetic epidemiology, the respective variations seem to exert no relevant influence on smoking cessation probability in heavy smokers in the general population [11]. These data suggest that the corresponding nicotinic acetylcholine receptor single nucleotide polymorphisms are relevant to the development of chronic smoking behavior but might not influence abstinence and relapse behavior. Although this is somewhat discouraging regarding the usability of genetic determinants of susceptibility to nicotine addiction as predictors of smoking cessation, it highlights the importance of taking this highly interesting phenotype explicitly into account in future studies [11]. In conclusion, genome-wide association approaches as discussed here offer great promise for detecting candidate genes for the development of chronic smoking behavior and relapse, respectively. However, the demonstration of a causal relationship of a specific genotype with a pathological phenotype is difficult, if not impossible, to achieve in humans.

Forward Genetics in Preclinical Addiction Research

Animal Models Provide the Basis for Forward Genetic Approaches

Animal studies using intravenous self-administration in rodents represent a powerful method to functionally validate candidate genes deriving either from human genome-wide association study approaches or from gene expression profiling studies in animals. Intravenous self-administration is commonly used as an animal model for studying nicotine intake as it offers face validity from various perspectives, for example there is good concordance between the nicotine concentrations in plasma of human cigarette smokers and of rats in intravenous self-administration studies [92]. Furthermore, genetic differences have been reported since various strains of rats show different latencies to acquire nicotine self-administration behavior [91]. Thus, studies on the acquisition of intravenous self-administration will help to elucidate the genetic vulnerability of the development of chronic smoking behavior in humans.

[2] Note that the term "dependence" is avoided in this review. Addiction is a pathological behavioral syndrome that has to be strictly separated from physical dependence. Transient neuroadaptive processes underlie physical dependence to drugs of abuse whereas persistent changes within specific neuronal systems underlie addictive behavior. In order to avoid any confusion between clinicians, psychologists, and preclinicians, the term "dependence" should refer to a state of physical dependence—this terminology will most likely be also included in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders*.

Major progresses in animal models for addictive behavior also allow now to study compulsive nicotine-seeking behavior and relapse [97]. The most common procedure to study nicotine-seeking behavior—which can be considered as the motivational component of nicotine craving and relapse—is the reinstatement model [13]. In this model, intravenous self-administration of nicotine paired with conditioned cues has to be acquired at first. This is followed by a nicotine free period where the animals undergo extinction (i.e., allowing the animal to perform the operant response, without programmed consequences). Finally, in response to previously conditioned cues reinstatement can be tested. If instead of extinction training protracted abstinence is applied, responsiveness to conditioned cues progressively increases over the first weeks of abstinence (i.e., the animals remain in their home cage for at least one month without any further conditioning)—a phenomenon called incubation [35]. In summary, reinstatement of drug-seeking behavior as well as the incubation of this behavior following protracted abstinence has become the gold standard to measure craving and relapse in animals.

Alterations in Gene Expression in Drug-Exposed Animals

Microarray studies revealed that chronic exposure of nicotine increases expression of genes involved in regulation of food intake and energy expenditure as well as it co-regulates multiple neurotransmitter systems and pathways involved in protein modification/degradation in rat brain [45, 118]. Our knowledge on how these changes in gene expression contribute towards nicotine addiction is substantially limited because nicotine was administered passively in these studies which do not mimic the situation observed in smokers. No previous study has identified the effects of nicotine in active self-administering animals on brain regions and performed gene expression profiles of such regions. However, we know from a key publication by Jacobs et al. [42] that active drug consumption during intravenous self-administration is a crucial psychological factor directing long-term genomic responses in the brain, especially in the nucleus accumbens shell. Therefore, it will be crucial in the future to establish gene expression profiles in a triad design from animals that actively self-administer nicotine in direct comparison to yoked nicotine and saline control animals. This kind of studies usually result in a huge database on gene expression profiles in animals and it will be essential to combine this genomic information with datasets deriving from human genetic studies by a convergent translational genomics approach.

Convergent Translational Genomics Approach for Addictive Behavior

Convergent translational genomics approaches integrate genomic information (e.g., from microarrary analysis) from animal models with a candidate gene or genome-wide association study approach in humans. Especially, the explanatory power of genetic findings is enhanced by such a convergent approach [9] and as a result a priority gene list for functional validation is obtained. Very recently a convergent translational genomics approach was successfully applied to alcohol addiction [108]. In this study, genome-wide association study data from a huge case-control sample for alcoholism were combined with massive information from gene expression profiling in alcohol addicted rats. The genome-wide association studies produced approximately 100 single nucleotide polymorphisms with nominal $p < 10^{-4}$. These, together with 20 additional single nucleotide polymorphisms from genes showing differential expression in rats, were genotyped in a large replication sample. Fifteen single nucleotide polymorphisms showed significant association (two single nucleotide polymorphisms met genome-wide significance) with the same allele as in the genome-wide association studies. Eight out of the 15 genes derived from the animal data demonstrating that relevant genes would have been lost by a mere genome-wide

association study approach [108]. In response to this study, the Integrative Neuroscience Initiative on Alcoholism has now announced that one of their major aims is to integrate animal data into data obtained from studies in human alcoholics (www.scripps.edu/cnad/inia/structure.html). In summary, this novel translational tool results in a priority gene list that has to be functionally validated.

Reverse Genetic Approaches for the Functional Validation of Candidate Genes

Reverse genetics are used to assess the role of a candidate gene in a specific behavior, e.g., in nicotine self-administration. The most common reverse genetic approach is the generation of a conventional mouse knockout model and its subsequent behavioral analysis. However, the generation of a conventional knockout model is time consuming, cost-intensive, has no tissue specificity, and since the gene is ablated early in development numerous compensatory mechanisms may ensue. Through more advanced techniques such as Cre/loxP and tetracycline-inducible systems, a gene of interest can be expressed or inactivated in a tissue-specific and time-controlled manner [30]. Although those conditioned knockout models are of very high value for the neuroscience community they still do not provide a good rational for large scale functional validation of candidate genes because there is still an enormous effort to generate those model. As an alternative the use of viral vectors for gene delivery offer many advantages for rapid functional validation studies. In particular, the advent of adeno-associated virus vectors carrying cDNA for—or short hairpin RNA against—specific genes allows now for the first time the rapid bidirectional manipulation of gene function [51].

New Vistas on the Molecular Level

Hallmarks in drug abuse research were the discoveries of endogenous primary target systems. Thus, drugs of abuse act on specific receptors, channels, or transporters within the brain in order to produce their psychoactive and reinforcing effects; e.g., opiates act mainly on μ-opioid receptors [61], cannabis products such as Δ^9tetrahydrocannabinol act mainly on cannabinoid receptor 1 receptors [16], nicotine acts on the nicotinic acetylcholine receptor [1], psychostimulants such as cocaine act mainly via monoaminergic transporters [38], and hallucinogens such as lysergic acid diethylamide act via the serotonin-2A receptor [34]—to name the primary targets of the most important drug classes. However, how does alcohol affect the functions of the central nervous system—are there any primary sites of action?

What are the Primary Targets of Alcohol in the Central Nervous System?

It is only recently that a shift from the so-called lipid theory (i.e., the primary targets of ethanol are membrane lipids) to the protein theory (i.e., the primary targets of ethanol are membrane proteins, especially receptors) took place [73]. Into the 1990s, different lipid theories postulated that alcohol acts via some perturbation of the membrane lipids of central nervous system neurons. In particular, effects on membrane fluidity and disordering of the bulk lipid phase of membranes was originally an attractive hypothesis of alcohol action because it provided a possible mechanism by which alcohol could affect membrane proteins, such as ion channels, via an action on membrane lipids.

There are clear limitations to the lipid theory. First, effects of alcohol on membrane disorder are generally measurable only at alcohol levels well above the pharmacological range (>500 mg/dl blood alcohol levels); these levels are close to the LD_{50} of ethanol in humans.[3] Significant effects of membrane disordering on

[3] For historical reasons, blood alcohol concentrations are calculated as g/kg blood plasma given in %. Since the specific weight of plasma is 1.23, a blood alcohol level of 500 mg/dl corresponds to 4.06%.

protein function are even more difficult to envision at pharmacologically relevant alcohol concentrations. For example, at very high intoxicating blood alcohol levels associated with loss of consciousness (~ 300 mg/dl), there would be only one alcohol molecule per approximately 200 lipid molecules [73]. Second, membrane effects induced by alcohol concentrations exceeding the pharmacological range can be mimicked by an increase in temperature of just a few tenths of a degree Celsius [73], which clearly does not produce behavioral signs of alcohol intoxication or appreciably alter the function of membrane proteins such as neurotransmitter-gated ion channels. Therefore, the reported effects of alcohol on membrane fluidity and organisation seem to be a purely biophysical phenomenon without any relevance for the pharmacological central nervous system effects of alcohol. Taking even more refinements of the lipid theory into consideration [73] it remains very unlikely that membrane lipids are the primary targets of alcohol.

The protein theory predicts that alcohol acts specifically on membrane proteins such as receptors and ion channels. The main reason for a shift towards the protein theory comes from findings that alcohol—at concentrations in the 10–20 mM range—directly interferes with the function of several ion channels and receptors.[4] In a key publication, David Lovinger and colleagues [58] showed that *N*-methyl-*D*-aspartate function was inhibited by ethanol in a concentration-dependent manner over the range of 5–50 mM, a range that also produces intoxication. The amplitude of the *N*-methyl-*D*-aspartate-activated current was reduced 61 percent by 50 mM ethanol. What is more, the potency for inhibition of the *N*-methyl-*D*-aspartate-activated current by several alcohols is linearly related to their intoxicating potency. This suggests that ethanol-induced inhibition of responses to *N*-methyl-*D*-aspartate receptor activation may contribute to the neural and cognitive impairments associated with intoxication [58]. But how can ethanol directly interefere with *N*-methyl-*D*-aspartate receptor function?

The *N*-methyl-*D*-aspartate receptor is a ligand-gated ion channel with a heteromeric assembly of NR1, NR2 (A-D), and NR3 subunits. The NR1 subunit is crucial for channel function, the NR2 subunits contain the glutamate binding site, and the NR3 subunits have some modulatory function on channel activity, especially under pathological conditions. Electrophysiological studies show that ethanol interacts with domains that influence channel activity [120], suggesting that residues within transmembrane domains may be involved. In the search for a possible binding site of alcohol at the *N*-methyl-*D*-aspartate receptor, several site-directed mutagenesis studies were performed and putative binding sites in the transmembrane 3 and 4 of the NR1 and NR2A subunit, respectively, were identified [37, 78, 79, 83, 95].

It is not yet possible to directly measure the binding of an ethanol molecule to the *N*-methyl-*D*-aspartate receptor by means of physical methods. The reason for this is that ethanol is a small molecule with low binding energy being efficient only in the mid millimolar range. These pharmacological characteristics preclude a direct assessment of an ethanol protein binding site. However, with the discovery of the LUSH protein in the fruit fly *Drosophila melanogaster* it became possible to model how transmembrane residues can form a specific protein-binding pocket for ethanol. The high-resolution crystal structures of LUSH in complex with a series of short-chain alcohols were obtained by the team of David Jones in 2003 [53]. The structure of LUSH reveals a specific alcohol-binding site. LUSH exists in a partially molten globule state. The presence of ethanol at pharmacologically relevant concentrations less than 50 mM shifts the conformational equilibrium to a more compact state [12], demonstrating that ethanol induces a conformational change of the binding protein—an important requirement for a functional binding site. A group of amino acids form a network of concerted hydrogen bonds between

[4] For reference, a low intoxicating blood alcohol level of 50 mg/dl (0.4%) is equivalent to an ethanol concentration of 10.6 mM.

the protein and the ethanol molecules provide a structural motif to increase alcohol-binding affinity at this site. This motif seems to be conserved in a number of mammalian ligand-gated ion channels and it is therefore suggested that the alcohol-binding site in LUSH represents a general model for putative alcohol binding sites in proteins such as the *N*-methyl-*D*-aspartate receptors.

Taken together it has been demonstrated over the last 20 years that ethanol acts directly on the *N*-methyl-*D*-aspartate receptor. However, direct interactions have been also described with gamma-aminobutyric acid-A, serotonin-3, glycine and nicotinic acetylcholine receptors, as well as with several ion channels such as L-type Ca^{2+} channels, where concentrations as low as 1 mM produce alterations in the function of these receptors and ion channels [96, 115]. This modern view on selective primary targets of alcohol in the central nervous system has so far not well been implemented into the general knowledge of drug abuse researchers and neuroscientists. Actually, most researchers still consider alcohol as a "dirty drug" with an undefined mode of action. In the future it will therefore be important to better define the putative binding sites for ethanol in the central nervous system. In particular, the findings on LUSH have to be translated to the mammalian brain.

Agonist-Directed Trafficking of Receptor Stimulus—A Key for Understanding Drug Action

A gain of knowledge in structural biology will not only be essential to define the molecular mode of action of the ethanol molecule but also for other drugs of abuse. This is best exemplified by the mode of action of lysergic acid diethylamide on the serotonin-2A receptor. The demonstration that lysergic acid diethylamide and other hallucinogenic compounds elicit their psychoactive effects via serotonin-2A receptor activation has generated a fundamental paradox in a way that not all serotonin-2A receptor agonists exhibit hallucinogenic activity. Indeed, non-hallucinogenic compounds such as lisuride and ergotamine share significant structural similarities and comparable agonist activities at this receptor [24], but lack psychoactive properties. This pharmacological paradox has recently been resolved by demonstrating that hallucinogenic *vs.* non-hallucinogenic compounds, while acting at the same binding site, elicit different patterns of signalling that are responsible for their different behavioral activities [34]. But how can such a divergent effect been explained in view of the standard pharmacological model of G-protein-coupled receptor activation. The ternary complex model postulates a conformational change from an inactive to an active state following agonistic activation [48]. However, both theory and experimental evidence suggest that G-protein-coupled receptors adopt multiple conformations when activated by different agonists [6, 32]. Thus, an advanced model of "agonist-directed trafficking of receptor stimulus" has recently been proposed by Kenakin [48]. This expanded version of the ternary complex model posits that different receptor agonists stabilize distinct conformations that preferentially recruit and activate specific signalling pathways [48, 113]. The fact that serotonin-2A agonists can activate different signalling pathways is consistent with such an expanded version of the ternary complex model as it explains how distinct cellular responses could be produced by agonists acting at the same binding sites. Paradoxical effects on the receptor level have been also observed with other drugs of abuse (e.g., opioids); progress in structural biology and the application of the new concept of "agonist-directed trafficking of receptor stimulus" will not only be helpful for a better understanding of the molecular action of alcohol and drugs of abuse but will be also important for getting a better insight into the molecular processes underlying drug-induced synaptic plasticity.

New Vistas in Alcohol- and Drug-Induced Synaptic Plasticity

A ubiquitous property of all synapses is their ability to undergo activity-dependent changes

in synaptic plasticity that can be studied most effectively using electrophysiological methods in brain slices. Since these slices only remain viable for several hours, the cellular mechanisms underlying the first few hours of long-term potentiation and long-term depression are the best understood. It has been suggested that synaptic plasticity within the mesolimbic dopaminergic system and associated limbic structures, including the extended amygdala, becomes manifest following drug exposure [46]. Some key publications on drug-induced adaptations in the mesolimbic system have revealed that glutamatergic synapses on dopamine neurons in the ventral tegmental area in particular undergo plastic changes following administration of drugs of abuse including ethanol [84, 112].

By increasing synaptic strength [112], facilitating long-term potentiation [57], or blocking long-term depression [44], drugs of abuse augment the responsiveness of dopamine neurons to glutamate and ultimately promote enhanced dopamine release in brain areas such as the nucleus accumbens and the prefrontal cortex [33]. Drug-induced synaptic strengthening in dopamine neurons in the ventral tegmental area is associated with changes in alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor subunit composition [5]. Incorporation of the AMPA receptor subunit GluR1 promotes drug-induced synaptic strengthening, probably through the formation of highly conductive, Ca^{2+} permeable GluR1 homomeric AMPA receptors [20], while insertion of GluR2 containing receptors reverts it [59]. Synaptic recruitment of GluR1 subunits and the resultant synaptic potentiation requires the activation of *N*-methyl-*D*-aspartate receptors [20]. These synaptic changes in dopamine neurons are thought to be related to the development of drug-induced reinforcement processes ([46]; see also [25]).

In conclusion, drug-induced synaptic plasticity has been found in the ventral tegmental area—nucleus accumbens projection as well as in other brain areas of the extended amygdala. However, the generally held view that these cellular adaptations underlie drug reinforcement is based on purely associative findings. Direct experimental evidence for the behavioral significance of these drug-induced synaptic changes involving glutamate receptors is still lacking. Only in vivo electrophysiology in conditional mouse models that selectively lack, for example, *N*-methyl-*D*-aspartate receptors in dopaminergic neurons will provide a clear answer as to whether AMPA/*N*-methyl-*D*-aspartate receptor induced synaptic strengthening of dopamine neurons within the ventral tegmental area serves as a cellular model for the induction of drug reinforcement. It will be also important to know whether these drug-induced synaptic changes modulate neuronal network activity. For answering this question multielectrode recording and ultra high-field imaging in rodents will be useful.

New Vistas on Neuronal Network Activity

Multielectrode Recording to Reveal Neuronal Network Activity Underlying Alcohol- and Drug-Related Behavior

An increasing number of laboratories now have the capability to simultaneously monitor the extracellular activity of more than 100 single neurons in freely moving animals. This paradigm, known as multielectrode recording, is revolutionising systems neuroscience by enabling the visualization of the function of entire neural circuits [69].

So far, only a few studies have used this technique in freely moving animals in order to correlate drug-related behavior with neuronal activity. Janak et al. [43] used multielectrode recording within the shell of the nucleus accumbens during operant alcohol self-administration, and found that different, but overlapping, populations of neurons in the nucleus accumbens mediate each event occurring along the temporal dimension of a single trial performed to obtain ethanol reward. These data suggest that the nucleus accumbens

plays a crucial role in linking conditioned and unconditioned internal and external stimuli with motor plans in order to allow ethanol-seeking behavior to occur. In a recent study, multielectrode recording was used to determine the effects of ethanol on neuronal firing and network patterns of persistent activity in prefrontal cortex neurons [110]. The results of this study show that ethanol inhibits persistent activity and spike firing of prefrontal cortex neurons, and that the degree of ethanol inhibition may be influenced by dopamine D1 receptor tone. Ethanol-induced alterations in the activity of deep-layer cortical neurons may therefore underlie the disruptive effects of alcohol on cognitive functions supported by these neurons.

These few examples demonstrate that multielectrode recording in freely moving animals may prove a powerful future approach in understanding alterations of neural network activity during the course of long-term alcohol consumption. Application of this technique to investigate the transition from drug-seeking behavior to more compulsive behavior would be particularly valuable [86, 119]. Such studies would need to be performed over a long-time period; however, with repeated measures being taken over several weeks or even months, and data handling and analysis would be further limiting factors.

Animal Brain Imaging to Identify the Neuroanatomical and Neurochemical Substrates of Addictive Behavior

Brain imaging in small laboratory animals such as mice and rats is restricted, since the brain sites of interest are very small compared to those of the human brain and measurements can only be performed in anesthetized animals. Use of a comfortable head restraint device in well trained conscious monkeys; however, enables the performance of imaging and the assessment of conditioned drug responses [39]. Recent progress in ultra high-field imaging up to 17 T now allows brain imaging in rodents with a good resolution (<100 μm). Spectroscopy and pharmacological magnetic resonance imaging provide particularly powerful tools for the study of the progression of alcohol and drug consumption towards addictive behavior. The advantage of animal neuroimaging is that a subject can be studied repeatedly over a long period, allowing the investigation of neuronal network activity in the transition phase from controlled to compulsive behavior.

One important application for future studies in laboratory animals is glutamate spectroscopy. Pfeuffer and colleagues [75] demonstrated as long ago as 1999 that at least 18 metabolites, including glutamate and gamma-aminobutyric acid, can be quantified in the adult rat brain using [^{1}H] nuclear magnetic resonance spectroscopy at 9.4 T. In vivo detection and quantification of glutamate in the rat brain, as well as regional differences in signal intensities, have been also demonstrated by others [62]. High-field spectroscopy provides superior peak separation, allowing the direct measurement of glutamate in different brain areas of small laboratory animals, providing an ideal tool for non-invasive longitudinal tracking of neurometabolic plasticity within the glutamatergic systems accompanying alcohol and drug withdrawal, abstinence, and relapse.

The most promising approach however, is the in vivo mapping of functional connectivity in neurotransmitter systems using pharmacological magnetic resonance imaging. Schwarz and colleagues [88, 89] have pioneered the application of functional connectivity studies to pharmacological challenges. In their studies, analysis of the pharmacological magnetic resonance imaging responses to various drugs revealed specific structures for functionally connected brain regions that closely reflect known pathways in the neurotransmitter systems targeted by these drugs [88, 89]. These studies therefore demonstrate that the hemodynamic responses observed following a pharmacological challenge are closely related to drug-specific changes in neurotransmission. This novel approach can now be used to study the impact of pharmacological or genetic manipulation on functional connectivity. This application has already been used to study the disruption of drug-induced

functional connectivity by a dopamine D3 antagonist. The strongest modifications of functional connectivity by dopamine D3 blockade occurred in nigrostriatal connections [90]. This approach is also being applied to current alcohol research. The progression of alcohol drinking towards a habit-like behavior, as studied in terms of alteration in nigrostriatal connectivity of brain sites, is being studied in a long-term alcohol self-administration paradigm using a 9.4 T scanner. The working hypothesis is that the nigrostriatal pathway may be involved in the habit forming properties of alcohol and other drugs of abuse [18, 28, 31, 97]. More precisely, a neuroanatomical principle of striatal organization is that ventral domains, including the nucleus accumbens, exert control over dorsal striatal processes that are mediated by so-called "spiraling, striato-nigro-striatal" circuitry. Chronic administration of drugs of abuse may lead to alterations in this serial connectivity, and drug-seeking habits—a key characteristic of addictive behavior—are triggered as a result [4]. Functional connectivity studies with good resolution conducted in a high-field scanner provide a tool for proving this attractive hypothesis of alcohol/drug-induced alterations of striato-midbrain-striatal serial connectivity and will be very helpful to understand the neurobiology of drug-related behaviors such as drug-seeking and relapse.

New Vistas on Studying Alcohol- and Drug-Related Behaviors

Reconsolidation of Alcohol- and Drug-Related Memories

Relapses contribute considerably to the maintenance of addiction and are a major challenge in the treatment of addictive diseases. One fundamental problem in the treatment of drug addiction is the ability of drug-associated environmental cues to evoke drug-seeking behavior leading to relapse even after years of abstinence. Consistent with the long-lasting risk of relapse several recent studies indicate that long-term memory formation and development of drug addiction are sharing common neural circuitries and molecular mechanisms [41, 47]. Thus, understanding learning and memory processes in the addicted brain is an important key for understanding the persistence of addiction and it is reasonable to hypothesize that selective disruption of drug-related memories might help to prevent relapses.

Several earlier studies have shown that newly-acquired memories are initially labile but then are stabilized through a process called memory consolidation [22, 64]. Within the first minutes to hours this process is susceptible to interference. Following this stabilization period the consolidation theory proposes that memories, once stored, are resistant to interference [64]. In contrast to this idea Misanin and colleagues [66] proposed that reactivation of a consolidated memory trace returns it to an unstable state again. More than 30 years later, Nader et al. [67, 68] confirmed this assumption in a fear-conditioning paradigm with targeted infusions of the protein synthesis inhibitor anisomycin into the lateral and basal nuclei of the amygdala—sites known to play an important role in fear learning—after retrieving previously conditioned fear memories. This study demonstrated that infusion of anisomycin shortly after memory reactivation produced amnesia on later tests, while anisomycin application in the absence of re-exposure to the conditioned cue left the memory intact [68]. Thus, reactivation of a consolidated memory can return into a labile state in which the memory trace has to undergo reconsolidation for which, like consolidation, new protein synthesis is required. Subsequently, further evidence for the reconsolidation theory and its dependence on renewed protein synthesis has been provided [15, 23, 67]. In particular, antagonism of the *N*-methyl-*D*-aspartate subtype of glutamate receptor has been shown to be effective in disruption of memory reconsolidation [55, 77, 107, 109], likely because of the crucial role of these receptors in learning and memory. Furthermore, given the fact that adrenal stress hormones activate adrenergic receptors in the amygdala and that the basolateral amygdala is

essential for fear memory [64] it is suggested that the release of norepinephrine within the amygdala is of importance for reconsolidation processes. Indeed, infusion of the non-selective beta-adrenergic antagonist propranolol into the amygdala of rats shortly after the reactivation period of a previously acquired fear association impaired the fear expression on a long-term test [14]. Very recently, this finding was translated to humans in a randomized and double-blind placebo controlled design. In volunteers oral administration of propranolol before memory reactivation erased the behavioral expression of the fear memory 24 h later and prevented the return of fear [50]. This key finding has important implications for the treatment of persistent and self-perpetuating memories in individuals suffering not only from anxiety disorders but also from drug addiction.

The reconsolidation hypothesis was also tested in regard to drugs of abuse. In the laboratory of Barry Everitt, rats were examined in a cocaine self-administration paradigm in which a conditioned stimulus was presented during each self-administered cocaine infusion. The conditioned reinforcing properties of the conditioned stimulus were tested subsequently by measuring its ability to support the acquisition of a new instrumental drug-seeking response of lever pressing in the absence of the primary drug reinforcer. Thus, the rats were exposed to a brief test session in which a nose-poke resulted in presentation of the conditioned stimulus, but an infusion of saline instead of cocaine. This session was sufficient to reactivate the previously formed conditioned stimulus-drug association and render it sensitive to disruption since an infusion of anisomycin into the basolateral amygdala immediately after reactivation subsequently impaired the acquisition of the new response [56]. Furthermore, a single reactivation-dependent infusion of an antisense oligonucleotide targeting Zif268—an immediate-early gene (also known as EGR1, NGFI-A, and Krox24) that is significantly upregulated in the basolateral amygdala following self-administered cocaine [105]—into the amygdala, 24 h prior to testing resulted in a long-lasting disruption of the ability of a drug-associated stimulus to act as a conditioned reinforcer [54]. These results demonstrate that addictive drug memories undergo reconsolidation in a manner similar to fear memories. This key publication was followed by several other studies demonstrating disruption of the reconsolidation of cocaine-, heroin-, and morphine-related memories with various pharmacological manipulations and behavioral paradigms [7, 36, 56, 65, 81, 114]. Disruption of alcohol-associated memories was also very recently tested in animals trained to self-administer orally alcohol during which each self-administered alcohol drop a conditioned stimulus was presented. The protein synthesis inhibitor anisomycin and the non-competitive *N*-methyl-*D*-aspartate receptor antagonist MK-801 were given after retrieval of alcohol-related memories to test whether these memories undergo a protein synthesis- and *N*-methyl-*D*-aspartate receptor-dependent reconsolidation. Additionally, acamprosate as an abstinence-promoting agent that is widely used in the treatment of alcohol addiction was administered. Although the primary site of action is still not known it has been demonstrated that acamprosate dampens a hyper-glutamatergic state in the alcohol dependent brain and thereby reduces the risk of relapse [97, 98]. Due to this interference with the glutamatergic system it is hypothesized that acamprosate may also have an impact on the memory reconsolidation processes. With these experiments evidence was provided that alcohol-associated memories can also become unstable and liable to disruption after their reactivation. Thus, both the protein synthesis blocker anisomycin as well as the *N*-methyl-*D*-aspartate receptor antagonist MK-801 given immediately after re-exposure of animals to alcohol-paired conditioned stimuli impaired the ability of the conditioned stimuli to induce alcohol-seeking behavior in subsequent test-sessions whereas acamprosate had no impact on reconsolidation processes [von der Goltz et al., unpublished results]. These findings demonstrate that the administration of anisomycin and MK-801 specifically disrupted reconsolidation, as the administration of these agents without the reactivation of the

conditioned stimulus-alcohol-related memory had no effect on the responsiveness of the animals to the alcohol-paired conditioned stimulus during alcohol-seeking tests. Finally, reactivated alcohol-related memories as well as other reactivated reward-related memories are also susceptible to interference with beta-adrenergic blockade by propranolol [19].

In conclusion, it was shown that alcohol- and drug-associated memories can be disrupted pharmacologically after their reactivation by both protein synthesis inhibition and *N*-methyl-*D*-aspartate receptor antagonism. These findings have important clinical implications, because they show that it is possible to selectively reduce long-lasting drug-associated memories. Hence, the disruption of drug-related memory reconsolidation may be an effective treatment strategy for the reduction of relapse. These findings should be rapidly translated into alcoholics, smokers and illicit drug users as pharmacological manipulations before memory reactivation was shown to prevent the return of fear [50]. Either propranolol or ketamine treatment before memory reactivation in addicted individuals would be a promising starting point.

Summary

In this chapter I have given a personal retrospective view on the hallmarks of neurobiological alcohol and drug abuse research and have then discussed new approaches and challenges in the addiction field.

In terms of future genetic work I have highlighted the application of convergent translational genomics approaches. This novel bioinformatic tool has already been successfully applied to alcohol addiction [108]. It allows the integration of genetic information from animal and human studies thereby enhancing the explanatory power of genetic findings and will be essential to define candidate genes for alcohol- and drug-related phenotypes. Most importantly, candidate genes have to be functionally validated. Two reverse genetic strategies for the functional validation of candidate genes have been proposed here: the use of conditional mouse models and the application of virus-mediated gene transfer. Following this validation process genetic risk profiles can be defined for alcohol- and drug-taking behavior.

On the molecular level, the interaction of a drug with primary targets (e.g., receptors) within the brain has been discussed. In this context the concept of "agonist-directed trafficking of receptor stimulus" was highlighted for a future key to understand the consequences of drug/receptor interactions and subsequent signalling transduction.

On the synaptic level, new concepts were discussed in regard to drug-induced synaptic plasticity. Alterations on the synaptic level can modulate neuronal network activity which can be studied by means of multi-electrode recording or ultra high-field imaging in small rodents. A systems biology approach will then be helpful to integrate data sets obtained on the genetic, molecular, synaptic, and neuronal network level in order to understand addictive behavior.

Finally, the most burning question relates to new options for the treatment of addictive behavior? Instead of having discussed new potential anti-relapse compounds (for review see [52, 76, 94, 98]), I have highlighted the possibility of disrupting reconsolidation of alcohol- or drug-related memories as a new approach to treat our clients.

Opportunities, Challenges, and Successes in the Development of Medicines for the Treatment of Addiction

Contents

Animal Studies

Animal models have formed the foundation for understanding the neurobiology of abused substances and the mechanistic processes associated with the acquisition and maintenance of substance dependence. Our knowledge of the neuroscientific basis by which abused substances exert their reinforcing effects associated with their abuse liability is greater than our understanding of the biological determinants of disease in any other field of psychiatry. Predicated on this understanding, these pathways associated with the reinforcing effects of abused drugs have formed the molecular targets for the discovery of new medicines to treat substance dependence.

An important challenge in the discovery of new medicines is to find animal models that mimic accurately the human condition of alcohol or drug dependence. Prevailing in the demonstration of self-administration of abused substances has been the core element of the cortico-mesolimbic dopamine theory of addiction [49]. Basically, this theory proposed that most abused drugs—and, more recently, other addictive behaviors such as gambling (see Chapter "The Biology and Treatment of Pathological Gambling") and overeating [46] (see also Chapter "An Addiction Model of Binge Eating Disorder")—probably exert their reinforcing effects through activation of cortico-mesolimbic dopamine neurons and down-regulation of dopamine-2 receptors [47]. Plausibly, other more recently recognized addictive behaviors such as instant messaging also might be shown to activate the same circuit (see Chapter "Instant Messaging Addiction Among Teenagers: Abstracting from the Chinese Experience").

Furthering the cortico-mesolimbic dopamine theory, it has been demonstrated that substances with abuse liability have higher reinforcement value than natural reinforcers (e.g., food, water, and sex), and this primes and maintains the salience of substance-abusing behavior [6]. Clearly, this points to the teaching that medicines to treat dependence on abused substances are unlikely to be generally successful by simple ablation, destruction, or direct opposition of these cortico-mesolimbic pathways. Indeed, it is now accepted widely that direct dopaminergic antagonism, probably as a result of counter-regulatory neuroadaptive mechanisms, either has little effect or actually can

be a trigger for further substance use [15, 17]. Agonist theories, specific to dopamine enhancement, also have had little success, presumably because these also act as surrogate reinforcers. In gainsay, however, non-dopaminergic agonists have been useful treatment for some disorders (e.g., methadone for morphine or heroin dependence or the nicotine patch to treat nicotine dependence). Nevertheless, there is a continuing search even in these areas for treatments that have lower addictive potential. Contemporary avenues in medications development have, therefore, focused primarily on medicines that provide neuromodulation of these brain circuits.

Extension of the cortico-mesolimbic dopamine theory has necessitated greater understanding of not only how midbrain circuits modulate addictive behavior but also cortical processes. Some of these intriguing interactions have been amply demonstrated in studies that have examined dopamine function contemporaneously at various brain sites and in moving rather than yoked animals [12]. This should be linked with multiple electrode recordings to ensure higher concordance between neuronal activity and behavior. Emerging from these studies is that the cortico-mesolimbic system does not act in isolation to express reinforcing behavior but does so through its interaction with other neurotransmitter systems. Some of the complexity of these potential inter-neuronal interactions is shown in the conceptual model provided in Fig. 4 of Chapter "Pharmacotherapy for Alcoholism and Some Related Psychiatric and Addictive Disorders: Scientific Basis and Clinical Findings".

Addicted humans can retain strong memories and affect for the situations in which substances are abused. A useful elaboration of the cortico-mesolimbic dopamine theory has, therefore, been greater understanding of the role of the extended amygdala and associated stress hormones (e.g., corticotrophin-releasing factor), neurotransmitters (e.g., gamma-aminobutyric acid, glutamate, and the cannabinoid-1 receptor), orexins, and small molecules (e.g., neurokinins) in developing these enmeshed emotions that can trigger substance taking after a period of abstinence [31]. This has led to the development of reinstatement models of addiction, which are appealing as a relatively close cross-species estimate of relapse in animals and humans. Advances in this model are, however, needed to better segregate motoric response from actual drug-seeking behavior in animals so as to develop paradigms more analogous to alcohol or drug dependence in humans [7, 45]. Nevertheless, an important avenue for medications development using this paradigm might be to study agents that modulate activity in the extended amygdala. One notable example has been the demonstration of topiramate—a sulfamate-substituted fructopyranose derivative and gamma-aminobutyric acid-A/glutamate neuromodulator—as a treatment for alcohol dependence [22, 28] and possibly cocaine dependence [29]. Another includes the development of the neurokinin-1 antagonist, LY686017, for the treatment of alcohol dependence [11]. Other ideas for medications development in the alcoholism field include the targeting of neuropeptide Y.

Humans use substances with abuse liability repeatedly, not acutely, once the addiction is entrenched. Repeated dosing paradigms are, therefore, common in testing the efficacy of putative therapeutic medications in animals. The contrast between acute and repeated dosing models can lead to an incorrect estimate of the anti-reinforcing effects of putative therapeutic agents. For instance, compared with the acute dosing model, where a large pharmacological effect of naltrexone to diminish alcohol self-administration in nonhuman primates was seen, chronic naltrexone administration resulted in a modest anti-drinking effect [5]—a closer approximation to the magnitude of response seen in clinical studies [18, 41]. To extend this paradigm, repeated dosing schedules in animals have to be adjusted to examine behavioral effects over extended periods rather than just a few days. Often, this has necessitated the experimental use of nonhuman primates rather than rodents or smaller animals in such studies.

Arguably, the more striking examples of new medicines to treat addiction have been

seen in the alcohol field. Examples of these medicines include those that have been approved by the Food and Drug Administration (e.g., naltrexone and its analogs, and acamprosate) and experimental but promising medications such as baclofen, ondansetron, and topiramate [17]. Nevertheless, even with these promising medicines, the picture of their pharmacological effects in the array of animal models (i.e., craving, reinforcement, and reinstatement) is incomplete.

Continuing with the alcohol field as an example, no medication has been developed directly from animals to humans. Most of these medications—apart from topiramate, which was developed from basic conceptual theory and applied directly to the clinic [14]—have been found by secondary explorations, usually from clinical observations. Therefore, the general direction of development has been from humans with further testing to elucidate mechanisms in animals. As such, an important knowledge gap exists with respect to the pharmacobehavioral effects of these medicines on alcohol-seeking behavior.

An important realization of the process that has taken place in the alcoholism field is that medications development must be bi-directional—not only from animals to humans but from humans back to animals—to gain a greater understanding of how to identify other putative therapeutic compounds. For example, in a clinical trial testing a hypothesized conceptual framework [14], topiramate was found to be efficacious for treating alcohol dependence although there were almost no preclinical data available [22]. Implementing a bi-directional scientific approach to medications development means that it would now be necessary to test topiramate in an array of preclinical models to characterize fully and validate the mechanism of action that might underlie its therapeutic effect [22]. This strategy yields another scientific opportunity with important practical implications. Since preclinical testing of clinically promising medications for treating alcohol dependence is likely to exhibit a differential set of findings across the array of animal paradigms, especially if the medication's mechanism of action is relatively specific, it might be possible to construct a response pattern or "fingerprint" of such medication effects. Not only does this approach circumvent the thorny problem of defining the response to medication in a single animal model that translates best to efficacy in clinical testing, it suggests that animal models should be conducted in an array of paradigms, and that the response "fingerprint" from these studies should be used as the comparator to predict clinical efficacy between putative therapeutic medications. This reverse-engineering approach has been successful in bioengineering. In the substance abuse field, this approach has the attraction of enabling researchers to screen an array of agents efficiently in animals to yield a high likelihood of finding candidate medications with similar therapeutic profiles. A theoretical stumbling block also is bridged by this approach. These medications need not even be pharmacologically similar in structure in exact modes of action, but only to be capable of eliciting comparable therapeutic response. Indeed, these models to "fingerprint" response need not be confined to anthropomorphic approaches but should develop into those that provide the highest construct validity. Computational methods from systems biology can be applied usefully to increase the efficiency of this medication-finding process (see Chapter "In Silico Models of Alcohol Dependence Treatment: Stochastic Approach"). Furthermore, since each of the different animal models that exist have been pioneered or favored for study by particular laboratories, a practical and efficient method for conducting these experiments might be to develop and use a national network of preclinical laboratories. Apart from the obvious efficiency of this approach, a process also will be established to develop other additive and informative models and paradigms.

Animal studies examining molecular genetic paradigms on the pathophysiology of substance abuse and response to putative therapeutic agents should be expanded to consider a more diverse range of environmental and rearing conditions that also take into account gender differences across various species. Animal experiments that

vary the interaction between genetic and environmental factors would facilitate the development of preclinical models translating to special human populations, e.g., children and adolescents or individuals with comorbid disorders. Gene-by-environment approaches in animal studies might serve as models for understanding therapeutic response in special situations, conditions, or environments. These models might provide better characterization of the important determinants of individual response and the "elasticity" of the treatment effect across various subpopulations.

Integrating genomic studies in animals with humans appears to be a powerful approach for identifying a priority list of genes to understand the pathophysiology of addictive behavior. An example from the alcohol field is that this method allowed for the identification of 15 single nucleotide polymorphisms from gene-expression studies in rodents that could be associated with the same allele in the genome-wide association studies in humans [43]. A non-integrative approach, based solely on genome-wide association studies in humans, would have failed to identify 8 of these 15 genes. Thus, this integrative approach is essential to capture the spectrum of genetic influences on addictive behavior (see also Chapter "To Open Up New Vistas in Basic and Preclinical Addiction Research").

Advances in our understanding of synaptic plasticity due to abused drugs, especially alcohol [40, 44], have brought into prominence the role of the glutamate system and its interactions with calcium channels as modulators of cortico-mesolimbic dopamine-induced reinforcement. With respect to alcohol, the important role of the alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor, perhaps through the formation of Ca^{2+}-permeable glutamate receptor type 1 homomeric AMPA receptors [8] and other signaling pathways, has been elaborated into a hypothesis for the therapeutic mode of action of topiramate [14]. These ideas can be developed further into identifying other therapeutic compounds that might be efficacious in treating not only alcohol dependence but also a wider range of addictive disorders and behaviors.

As a bridge to the future in this field, animal models need to be developed that inform the possibility to define stages in the development and progression of substance-seeking behavior. Disease staging in humans is not well understood from a neurobiological perspective, presumably because it is difficult to segregate the manifest phenotype from endophenotypes of the disease process. Animal studies that combine molecular genetic techniques with variable exposures to the abused substance, under different conditions and stages of development (e.g., adolescence or adulthood), should provide important clues as to the pathophysiological steps in disease development. Clearly, these stages might define varying susceptibility to disease at specific points in development, as well as the direction and magnitude of response to putative therapeutic agents. These experiments should have useful parallels and insights with which to inform the human condition.

Greater emphasis on cross-species experiments in humans is needed to better validate pharmacobehavioral models. Experimentation with nonhuman primates should facilitate the development of models closer to mimicking the variety of responses to situation, set, and characteristics that form the variation in response to pharmacotherapy in the clinical treatment of substance dependence. Nonhuman primates might also be especially useful in the development of vaccines. Finally, nonhuman primates afford the possibility of studying the impact of disease states that have parallels with those that can occur in humans (e.g., hepatitis or HIV) on the pathophysiology of substance dependence.

Bridging the Gap: Human Laboratory Studies

In the development of medicines to treat addictive behaviors, human laboratory studies offer an important method to bridge the scientific

gap between animal studies and clinical trials. Human laboratory studies are typically conducted in either an inpatient or outpatient setting in a highly monitored (for medical safety) and controlled (i.e., for both set and setting, and the administration of experimental manipulations and measures) environment. Human laboratory studies are essential because, as yet, there are no animal paradigms that are directly predictive of therapeutic response to candidate medicines in humans. Also, human laboratory studies can include the examination of actual or surrogate experimental drug taking and the measurement of response to putative therapeutic agents, and can enable the characterization of adverse events, toxicology, and dose profiling [24] and, sometimes, the initial determination of efficacy [26, 36, 42] for candidate therapeutic medications.

Human laboratory procedures usually are split into those that measure conditioned craving, and others that ascertain self-administration of alcohol or other drugs. An important problem with studying one or the other of these procedures is that human drug-taking behavior incorporates both of these components.

In the human laboratory, there are three important challenges that can limit the utility of direct self-administration procedures to quantify alcohol or drug reinforcement, and any interactive effects with a candidate therapeutic medication. First, self-administration of alcohol or drugs in the human laboratory can have limited parametric validity in humans since the number of administrations is restricted by the need to avoid intoxication or toxicity in combination with candidate medications. Although there have been attempts to overcome such issues by providing small amounts of alcohol or drugs under scheduled responding paradigms, the lack of context within these settings (i.e., humans do not in natural settings self-administer alcohol or drugs on completion of fixed operant tasks such as lever-pressing) makes extrapolation to the clinical condition difficult. Second, with respect to alcohol self-administration, the scaling of pharmacobehavioral response to small amounts of alcohol is not entirely linear as a break point is reached between its stimulant and sedative effects, which can vary considerably among individuals. Thus, because of this biphasic pharmacological effect of alcohol, the timing of experimental procedures needs to be relatively precise, and the trend has been to concentrate efficacy testing of candidate therapeutic medications within the narrow time band of the ascending part of the alcohol effects dose curve. Third, experiments using stimulant drugs that are administered intravenously or intranasally can only be done with small, pharmacologically relevant doses, and repeated dosing in the same day, or even over several days, is constrained by safety concerns to limit exposure. Thus, human laboratory studies are not designed to be "real world" studies or truncated clinical trials but a mechanism for establishing safety and determining initial efficacy.

A relatively under-utilized but stronger strategy in the design of human laboratory studies is to combine conditioned craving response with behavioral measurement of reinforcement through choice procedures over monetary reward and delayed discounting (e.g., see [26]). The use of delayed discounting measures also enables avoidance of the restriction posed by self-administrating alcohol or drugs during the experiment, which can itself be a confounder of contemporaneous measurement of other parameters such as mood and cognition, but postpones this to afterwards. Recently, our group developed a further enhancement of this technique by providing serial exposures to this combined paradigm over several days rather than at a single time point. This allows the acute effects to be measured on the first day, which can then be compared with the serial measurements of repeated exposures over several days. The repeated-exposure component of this paradigm tests the ability of the candidate therapeutic medication to decrease alcohol or drug taking over time, and is hypothesized to be more predictive of results that would be expected from a clinical trial.

Human laboratory studies can couple the measurement of pharmacobehavioral aspects with other methods of segregating individual

response, such as molecular genetics [1] (including genome-wide association studies) and functional neuroimaging. Indeed, there are now well-established human laboratory paradigms for conducting pharmacobehavioral studies whilst performing simultaneous neuroimaging [35]. These additional techniques bolster the information from human laboratory studies by providing a greater understanding of the relationship between behavior and the site-specific effects of candidate medications.

As proposed in animals, a national network of human laboratory researchers should be established to "fingerprint" the pharmacobehavioral response of the interaction between the abused substance and the candidate therapeutic medication.

In recent years, there has been a decline in neuro-hormonal studies examining the impact of stress on pharmacobehavioral response to abused substances and their interaction with candidate medications. Neuro-hormonal probes for examining the monoamine system are used infrequently, and the delineation of effects by menstrual cycle and other hormonal changes across the life span needs greater study.

Future human laboratory studies and designs will have to address the issue of testing medication combinations for the treatment of substance dependence. The unique capabilities of human laboratory studies to examine contemporaneously both pharmacodynamic and pharmacokinetic effects [19] of abused drugs and their potential interactions with candidate medications will need to be harnessed further.

Clinical Trials

Randomized, double-blind, placebo-controlled clinical trials are the "gold standard" for determining the efficacy of candidate medications for the treatment of substance dependence. Nonetheless, this is not a perfect technology in the substance dependence field, and certain challenges and controversies remain. Some of these challenges are unique as to whether the field of study relates to treatment for alcohol or drug dependence. The alcohol field will be used as the illustrative example to highlight these challenges, with some additional references provided in the area of drug dependence.

It has become increasingly obvious that alcohol dependence is a heterogeneous disorder [20]; yet, this is not captured by diagnostic criteria including the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition [2] or the International Statistical Classification of Diseases and Related Health Problems, 10th Revision [50]. There is, therefore, a wide variation in pathophysiology and response to candidate therapeutic medications among individuals who meet the diagnostic criteria for alcohol dependence. For instance, it has been shown that medications with different actions on the serotonergic system are not efficacious within the same subtype of alcoholic. Serotonin reuptake inhibitors appear to be efficacious among alcohol-dependent individuals with a late-onset or Type A-like disease characterized by an onset of problem drinking after the age of 25 years, low familial loading for disease, and a range of anxiety- and mood-related symptoms [38]. In contrast, Johnson and colleagues have shown that the serotonin-3 receptor antagonist, ondansetron, is efficacious in treating early-onset or Type B-like alcoholism characterized by an onset of problem drinking before the age of 25, high familial loading for disease, and a range of impulse-dyscontrol behaviors [21]. These observations have now been developed into a conceptual understanding by which alcoholic subtypes can be segregated by allelic variation at the serotonin transporter that is differentially responsive to serotonergic medications [13]. Indeed, the results of the first large prospective pharmacogenetic study in the alcoholism field based on this serotonin transporter hypothesis are awaited eagerly. Conceptually, another approach would be to determine whether alcohol-dependent individuals can be additionally characterized through intermediate behavioral or pharmacological phenotypes, or both [9]; then, it might be possible to understand more accurately the basis of individual response to

drinking, and to increase the likelihood that we can tailor treatment to the subpopulation most likely to respond to that strategy.

Retrospective pharmacogenetic analyses have been done in the alcoholism field, particularly with respect to whether allelic variation in the OPRM1 gene predicts treatment response to naltrexone. Whilst some have found an association between allelic variation at the OPRM1 gene and therapeutic response to naltrexone [4], others have not [10]. Further studies are, therefore, needed to determine whether there is a relationship between polymorphisms of the OPRM1 gene and therapeutic response to naltrexone.

Other promising compounds are being studied in the treatment of alcohol dependence. Notably, these include baclofen, the neurokinin-1 receptor antagonist LY686017, and corticotrophin-releasing factor antagonists—all of which can be envisioned as modulators of stress response to alcohol dependence and its cessation (for a review, see Chapter "Pharmacotherapy for Alcoholism and Some Related Psychiatric and Addictive Disorders: Scientific Basis and Clinical Findings"). These medications expand the concept that the extended amygdala has an important role in the modulation of alcohol reinforcement in the cortico-mesolimbic dopamine system [30]. The results of phase II clinical trials with these medicines are awaited eagerly.

An important conundrum in the alcoholism field that appears to be resolving is the place of adjunctive psychotherapy in medication trials. Primarily in the United States, but also in other countries, there has been great effort in standardizing psychosocial treatment with respect to both its content and its delivery. While there is growing acceptance that psychosocial treatment should be viewed in terms of dose response, in much the same way as pharmacotherapy [18], it is curious that this concept is often considered as a unipolar paradigm—more psychosocial treatment being associated with greater or more prolonged therapeutic effect, or both. An important and seemingly forgotten lesson of Project MATCH is that there might be a "ceiling" of psychosocial treatment response [39]. For instance, it has not been proven in pharmacotherapy studies involving different intensities of psychosocial treatment that the maximum therapeutic response is always seen when the maximum level of the medication is combined with the most intensive psychosocial treatment. Additionally, if both the psychosocial and pharmacological treatments have a dose-response function that can interact, is it not reasonable to predict that some combinations might be not only ineffective but, actually, counter-therapeutic? What is emerging is that the "dose" of psychosocial treatment needed as an adjunct to a candidate therapeutic medication appears to be modest. This was demonstrated clearly in the COMBINE study, where the briefer medication management, compared with the high-intensity cognitive behavioral intervention, was more efficacious in combination with naltrexone [3]. Strikingly, in the COMBINE study, those assigned to no medication but just the high-intensity cognitive behavioral intervention had a worse outcome than those who received placebo plus medication management [48]. Furthermore, the pivotal studies that demonstrated the efficacy of topiramate for the treatment of alcohol dependence were all done using an even briefer intervention that maximizes participation and pill-taking compliance—brief behavioral compliance enhancement treatment [22, 28]. An important advantage of brief interventions like brief behavioral compliance enhancement treatment is that they can be delivered in about 10–15 min, which might make the findings from controlled trials more generalizable to clinical practice [23] (see also Chapter "Brief Interventions for the Treatment of Alcohol or Other Drug Addiction"). Hence, there is no current support for using intensive psychotherapy rather than a brief intervention as an adjunct in a pharmacotherapy trial.

Other conundrums remain in the development of medications for the treatment of alcohol dependence, some of which also are nearing a resolution. For example, there is growing acceptance that abstinence is an important, but not the only, valid endpoint in the treatment of alcoholism. Advocating the harm reduction model,

the present author has demonstrated the utility of entering individuals into clinical trials not after a brief period of abstinence, which was the traditional model, but whilst drinking actively [25]. Naturally, the most appropriate endpoint from such a paradigm would be a reduction in heavy drinking. This endpoint is now accepted as valid by the Food and Drug Administration, which is at present working collaboratively with academia and industry to refine exactly how this should be quantified. Hence, this approach promises to expand the array of potential medicines that can be used in the treatment of alcoholism beyond those that are simply designed to prevent relapse following a period of abstinence.

Pressure to deliver more efficacious medications for treating alcohol dependence has rekindled debate about whether there are proxies for large and time-intensive clinical trials. Such suggestions have included conducting smaller studies, often of inadequate sample size, to determine a "signal" that would encourage more elaborate clinical testing. Such approaches have more generally been used in testing candidate medications to treat drug rather than alcohol dependence and, to date, have proved fruitless and perhaps even more time-consuming. This is because positive "signals" from smaller studies frequently fail to be confirmed by larger clinical trials. Perhaps a more powerful strategy for the alcoholism field would be to develop a national network of clinical trials investigators such that the individual obligation to each site for testing a medication is lessened by dividing the workload across multiple sites, thereby increasing the scientific and practical efficiency of the medications development process. The National Institute on Alcohol Abuse and Alcoholism is, at present, using such a network to develop new medicines for the treatment of alcoholism.

Challenges remain in understanding the role of the placebo response in developing medicines to treat alcohol dependence. For instance, it is evident from most clinical trials that there is a high placebo response. Although this high placebo response is usually considered the "nuisance" that can mask the differential effect of active medication over placebo treatment against a platform of psychosocial intervention, the real problem associated with the failure to find clinical efficacy with most existing medications has been their small therapeutic effect size. Hence, even with current clinical trial paradigms, a "floor" effect in terms of the reduction in heavy drinking or abstinence rates is typically not reached, and there is ample room for moderately to highly efficacious medication treatments in adequately powered trials to demonstrate clinical efficacy. Nevertheless, two prevailing ideas that are currently being studied to reduce the placebo effect in clinical trials are to recruit individuals with much higher levels of alcohol consumption or to decrease the high degree of "reactivity" in clinical trials due to the many non-specific factors such as the high amount of personal attention and intensive questioning through experimental measures incorporated into their design. Future contemporary clinical trials in the alcoholism field will need to use more focused and economical clinical trial designs. Further study of the factors that determine the magnitude of the placebo response in clinical trials for alcohol dependence is needed to determine how these benefits can be harnessed to improve the effectiveness of candidate medicines in clinical practice [37].

Perhaps the most difficult challenges in the development of new medicines for the treatment of alcoholism are not entirely academic. An important roadblock occurs with the transfer of basic science discoveries into human testing. Conducting the studies required for an Investigational New Drug Application for promising preclinical compounds can be problematic for academic researchers and small companies because of the high cost that is involved and the level of expertise needed. Another important challenge lies in establishing public–private partnerships that will allow for a more comprehensive effort to discover and develop safe, effective medications. If successful, these partnerships will create more opportunities and choices for medications development. Networking among academia, industry, and governmental bodies (including the Food and Drug

Administration) needs to be coordinated more efficiently and focused to streamline the development process. Indeed, the Food and Drug Administration should be encouraged to play a more active role in not only the development of endpoints but also laying out clearly the essential benchmarks for registration trials. Important strides need to be made in the development of biomarkers, and surrogate endpoints that objectively indicate clinical success for candidate compounds would make the medications development process more predictable. Although progress has been made in identifying biomarkers of alcohol consumption, there are no ideal biomarkers (or surrogate endpoints) currently available [32]. Recently, advances in high-throughput technologies in genomics, proteomics, and metabolomics have created new, exciting opportunities for discovering and developing novel biomarkers. Exploring multiple genes, RNAs, proteins, and metabolites as well as a combination of markers might provide a characteristic pattern that indicates alcohol consumption, alcohol-induced organ damage, or both, and can be used subsequently to predict the efficacy of candidate compounds during clinical trials. Finally, an important hurdle has been the difficulty in broadly disseminating and implementing medications proved to be effective in clinical trials. Currently, only a small percentage of individuals receiving alcoholism treatment are prescribed medications for the disorder [33]. This is a serious problem that needs a concerted effort to educate health providers and the general public to increase the demand and utilization of efficacious medicines to treat alcoholism.

In the field of drug dependence, progress in identifying efficacious medicines has met with mixed success. In recent years, perhaps the most successful program has been the development of smoking cessation agents. Building upon the success of the nicotine patch and analogous compounds, there has been the development of bupropion and, more recently, varenicline as efficacious anti-smoking agents. Indeed, a recent editorial concluded that the medication-based treatments for smoking cessation had become so well established that there was no longer an excuse not to seek treatment [16]. A potentially important advance is the development of vaccines that will sequester nicotine in the bloodstream and prevent it from reaching the brain; however, these compounds are still a few years from reaching the market, and important technical problems remain to be solved (see Chapters "Nicotine" and "Nicotine").

Despite decades of scientific effort, no medications have been approved by the Food and Drug Administration for the treatment of either cocaine or methamphetamine dependence. The search for medicines to treat cocaine dependence has been particularly frustrating, especially as it appeared somewhat tantalizing that the solution would be to develop anti-dopaminergic agents. As detailed earlier, this approach of using direct anti-dopaminergic agents has failed, as have programs that have attempted the opposite—developing agonists of catecholamine function to provide a less stimulating or reinforcing "substitute" [15]. One avenue that appears promising in the cocaine dependence field has been the success of topiramate in an early clinical trial [29]. Results of large-scale phase II-type studies are, however, awaited to determine whether topiramate's efficacy in treating cocaine dependence can be established. Also, there is an intriguing signal for ondansetron as a possible therapeutic agent for treating cocaine dependence [27], and this lead is currently being followed up in an ongoing National Institutes of Health–funded study. Unfortunately, the initial promise of modafinil and disulfiram is unlikely to be realized on account of their failure due to a lack of efficacy and concerns related to toxicity, respectively, for this indication. There is some promise that a vaccine approach might yield some success; however, much needs to be done to improve its efficacy (for a review, see Chapter "Pharmacotherapy of Cocaine Addiction").

Many challenges remain in the development of medications to treat cocaine or methamphetamine dependence. Promising findings regarding the ability of candidate medications to decrease cocaine or methamphetamine intake or related behaviors in animals have not led to successful efficacy studies in clinical trials. Indeed, over 50 different candidate medications have been tested without a clear "signal"

predictive of efficacy for these indications (for a review, see Chapters "Pharmacotherapy of Cocaine Addiction" and "Methamphetamine").

The lack of concordance between animal studies and human trials is rather puzzling since preclinical studies have formed the backbone for understanding the neuropharmacological basis of addiction to stimulants and the basis for the selection of candidate medications. Most authorities have interpreted this lack of concordance as evidence that animal studies need to mimic the human condition more closely to have greater predictive value. Included in this argument is the proposal to validate studies done in lower animals (e.g., rodents) with experiments conducted in nonhuman primates. In gainsay, others have proposed that despite its face validity, the greater anthropomorphization of animal behaviors is the reason for the lack of concordance, and more useful models would be those that encompass greater construct validity. New animal models that enhance both the face and construct validity of cocaine- or methamphetamine-taking behavior as compared with the human condition continue to be developed.

One idea toward model building in the development of medications to treat cocaine or methamphetamine dependence would be to perform contemporaneous pharmacobehavioral studies in a variety of animal models and humans, once the toxicity profile of the candidate medication is known. Computational mathematical methods can then be used to determine the salient factors predictive of different "fingerprints" of response to the candidate medications.

Another approach toward finding an efficacious medicine to treat cocaine or methamphetamine dependence has been to embark on a search for candidate medications in the hope of finding an agent with a strong therapeutic effect. Critics of this approach have argued that this has led to an interminable search for a "magic bullet", which has failed to yield any tangible results. Also, such a process does not allow for the systematic accumulation of new knowledge upon which to obtain better clues as to why an agent might have failed in the clinic. Remarkably, this strategy has not enabled model building that could be achieved by testing medication combinations. Medication combinations have the potential advantage of at least a summation of therapeutic effects, and a more sustained duration of action, especially for compounds that act through ion channels [15].

Plausibly, individuals dependent on cocaine or methamphetamine, like alcohol, also might constitute a heterogeneous group. Few clinical studies have explored the possibility of phenomenological subtypes of the disease or an examination of response by molecular genetic or other biological differences. Future studies that explore the possibility of differential response to different subtypes of cocaine or methamphetamine taking are needed urgently.

An intriguing possibility for the treatment of cocaine dependence is the development of a potential vaccine. This vaccine is designed to tag succinylnorcocaine covalently with cholera toxin-B-subunit protein, to which the individual develops an antigenic response and the formation of antibodies. These antibodies bind to the antigenic complex in the bloodstream, thereby causing their sequestration and blockade from entering the brain. In a recent study, a clinical trial with the cocaine vaccine showed promising results in those with high antibody titres [34]. More work is, however, needed to develop a more robustly effective vaccine and to overcome the complexity by which it needs to be administered, especially to a population of poorly motivated, cocaine-dependent individuals (for a review, see Chapter "Pharmacotherapy of Cocaine Addiction"). Nevertheless, this is an approach that appears to be worth pursuing.

In the field of opiate dependence (including those opiates initially prescribed to treat a painful disorder), the agonist replacement or "substitution" approach has had much success with developing efficacious medicines. Notable examples include the use of methadone, levacetylmethadol, and suboxone (a combination of buprenorphine and naloxone). Since these medications are weak opiates, they do have to be used with care under strictly regulated schedules for their administration as they also have the potential to be habit forming or addictive. Hence, there is presently a search for non-opiate-based medications that can act as

pharmacological modulators of the neurotransmitters involved with the expression of opiate reinforcement. Furthermore, there is a need to widen access to treatment for opiate dependence, especially in semi-urban or rural communities in the United States.

Summary

The field of medications development for addictions has had many successes, and there are both important opportunities and challenges that lie ahead. Undoubtedly, these scientific advances have occurred against a background of exploding knowledge in cellular and structural biology, the neurosciences, neuroimaging, molecular genetics, and the behavioral sciences. Integrating these fields of knowledge to develop viable targets for medications development has been successful in several areas, including those that improve drinking outcomes and aid smoking cessation. Although no medication has been approved for the treatment of cocaine dependence, there are promising leads with newer agents, and a potentially useful vaccine remains in development. Developing better predictive models in animals, and in the human laboratory, that can predict therapeutic response in the clinic remains the vista that we all seek.

Acknowledgments I thank the National Institute on Alcohol Abuse and Alcoholism for its support through grants 5 R01 AA010522-14, 5 R01 AA012964-06, 5 R01 AA014628-04, and 5 R01 AA013964-05; the National Institutes of Health for its support through University of Virginia General Clinical Research Center Grant M01 RR00847, and Robert H. Cormier, Jr. and Ann Richards for their assistance with manuscript preparation.
